Subcortical MRI Volumes in Neuroleptic-Naive and Treated Patients With Schizophrenia

Raquel E. Gur, M.D., Ph.D., Veda Maany, B.A., P. David Mozley, M.D., Charlie Swanson, M.D., Warren Bilker, Ph.D., and Ruben C. Gur, Ph.D.

Objective: This study examined whether subcortical volumes of the basal ganglia and thalamus in schizophrenic patients are related to neuroleptic exposure and symptom severity. Method: Basal ganglia substructures and thalamic volumes were measured with magnetic resonance imaging in 96 patients with schizophrenia (50 men and 46 women) and 128 healthy comparison subjects (60 men and 68 women). Twenty-one of the patients were neuroleptic-naive; of the 75 previously treated patients, 48 had received typical neuroleptics only, and 27 had received typical and atypical neuroleptics. The relation of volume measures to treatment status, exposure to neuroleptics, and symptoms was examined. Results: The neuroleptic-naive patients did not differ from the healthy comparison subjects in subcortical volumes except for lower thalamic volume. In the neuroleptic-naive group, volumes did not correlate with severity of negative symptoms, but higher volumes in the thalamus and the putamen were associated with more severe positive symptoms. The previously treated group showed higher volumes in the putamen and globus pallidus than the healthy comparison subjects and the neuroleptic-naive patients. In the treated group, a higher dose of a typical neuroleptic was associated with higher caudate, putamen, and thalamus volumes, whereas a higher dose of an atypical neuroleptic was associated only with higher thalamic volume. Higher subcortical volumes were mildly associated with greater severity of both negative and positive symptoms. Conclusions: Increased subcortical volumes in treated schizophrenic patients seem to be medication-induced hypertrophy. This hypertrophy could reflect structural adaptation to receptor blockade and may moderate the effects of neuroleptic treatment.

(Neurological and neuroimaging studies have examined cortical and subcortical aberrations in schizophrenia (1–6). The role of the basal ganglia-thalamocortical loop in modulating multiple functional domains has been substantiated in research on animals and humans (7–10). Interest in the potential role of basal ganglia pathology in schizophrenia has been spurred by the recognition that the basal ganglia regulate not only motor behavior but also aspects of cognitive and limbic behavior (11–13). Extensive connections of thalamic nuclei with cortical and subcortical regions buttress their role in gating the cerebral cortex (14), but few neuroanatomic studies in schizophrenia have examined the thalamus (1–4).

Magnetic resonance imaging (MRI) complements neuropathological investigations of brain structure. While most MRI studies of cortical structures have reported decreased volume in schizophrenic patients, some studies of the basal ganglia noted increased volume in the putamen, globus pallidus (6, 15, 16), and caudate (17). These studies included chronic patients treated with neuroleptics, which may be associated with striatal activation, neuronal hypertrophy, and synaptic adaptation (18, 19). However, the association of early onset and lenticular hypertrophy has also been interpreted as supporting a neurodevelopmental model of schizophrenia (15), which attributes enlarged subcortical structures to decreased pruning (20). A longitudinal study of 29 first-episode patients and 10 comparison subjects, followed for 18 months, reported an increase in caudate volume in the patients relative to the healthy comparison group.)
the comparison subjects (21). This was associated with younger age and higher exposure to neuroleptics before the study. In a study that used an image averaging technique (4), thalamic abnormalities were reported in 39 male patients—most of whom were treated with neuroleptics for several years—compared with 47 healthy men; consistent with other findings (22, 23), the thalamus was smaller in the patients. An assessment of first-episode neuroleptic-naive patients would help clarify treatment effects.

To permit a comprehensive assessment of interconnected subcortical structures implicated in the pathophysiology of schizophrenia, we evaluated both basal ganglia regions and the thalamus. We compared a group of neuroleptic-naive patients with patients treated with typical and atypical neuroleptics, enabling an initial investigation of relations between volume, symptoms, and type of medication.

**METHOD**

The study participants were 96 patients (54 inpatients and 42 outpatients) and 128 healthy comparison subjects from the schizophrenia Mental Health Clinical Research Center at the University of Pennsylvania. The patients had a DSM-IV diagnosis of schizophrenia (24) established by procedures detailed previously (25). Those with schizoaffective disorder at study entry met the criteria for schizophrenia at follow-up. The healthy comparison subjects also underwent standard evaluations (26, 27). There were 21 neuroleptic-naive patients (13 men and eight women) and 75 previously treated patients (37 men and 38 women). The groups did not differ in age or parental education, but as expected, the patients had a lower level of education (table 1). The mean age at onset of illness for the neuroleptic-naive and previously treated patients were not significantly different. There were five, 11, and five left-handers in the neuroleptic-naive, previously treated, and healthy comparison groups, respectively. After complete description of the study, written informed consent was obtained from each subject.

**Clinical Measures**

*Rating scales.* Evaluations were conducted by trained investigators with established procedures (intraclass correlation coefficient [ICC] >0.85) (25). The patients’ symptoms were rated on the Scale for the Assessment of Negative Symptoms (SANS) (28) and the Scale for the Assessment of Positive Symptoms (SAPS) (29). The groups did not differ on the averaged global ratings of the SANS or the SAPS (table 1) and manifested mild symptoms.

*Medications.* A medication record documented for each subject the duration and doses of psychotropics before he or she entered research center protocols (30, 31). Information from records, caregivers, and patients was updated at 6-month intervals. Therapeutic interventions were clinically based, starting with typical neuroleptics and introducing atypical neuroleptics as indicated. Compliance was assessed by monitoring ingestion, supply, and visits but not blood levels. Total lifetime dose was quantified in chlorpromazine-equivalent units in milligrams per kilogram of body weight (32).

Forty-eight patients had been treated with typical neuroleptics only (haloperidol, N=28; haloperidol decanoate, N=8; loxapine, N=6; thioridazine, N=8; molindone, N=3; thiothixene, N=12; fluphenazine, N=4; fluphenazine decanoate, N=4; trifluoperazine, N=5; perphenazine, N=7; chlorpromazine, N=8). The number of patients taking various medications exceeds 48 because patients had taken several medications over the course of their illness. The mean duration of treatment was 1307.2 days (SD=1375.9, range=2-5954), and the mean drug dose was 407.1 chlorpromazine-equivalent units per day (SD=25.3, range=65.9-1095.1). Twenty-two patients had been treated with typical and then atypical neuroleptics. The typical neuroleptics were haloperidol (N=20), haloperidol decanoate (N=1), loxapine (N=7), thioridazine (N=6), molindone (N=3), thiothixene (N=5), fluphenazine (N=7), fluphenazine decanoate (N=4), trifluoperazine (N=13), perphenazine (N=8), and chlorpromazine (N=7).

The mean duration of treatment with typical neuroleptics was 1259.6 days (SD=1371.7, range=1-4238), and the mean dose was 720.4 chlorpromazine-equivalent units per day (SD=96.0, range=58.2-3723.5). The atypical neuroleptics included clozapine (N=15) and risperidone (N=14). The mean duration of treatment with the atypical neuroleptics was 383.4 days (SD=492.8, range=5-1601), and the mean dose was 334.1 chlorpromazine-equivalent units (SD=286.3, range=919.9). Five patients were treated only with an atypical neuroleptic, risperidone. The mean treatment duration was 70.4 days (SD=66.6, range=1-153), and the mean dose was 272.5 chlorpromazine-equivalent units (SD=96.6, range=150.0-400.0).

**MRI Measurements**

*Acquisition.* Scans were acquired on a GE Signa 1.5-T scanner (Milwaukee, Wis.) with uniform protocol and software. MRIs (spoiled GRASS pulse sequence, flip angle=35°, TR=35 msec, TE=6 msec, field of view=24 cm, number of excitations=1) of 1-mm slice thickness were realigned into a standardized transaxial plane along the anterior commissure-posterior commissure axis. Three-dimensional display and cutting options derive sagittal and coronal images perpendicular to these transaxial slices without affecting image quality for purposes of region drawing.

*Volumetric measures.* A segmentation algorithm (33, 34) used values of pixels within operator-defined regions of interest, and volumetric calculations in milliliters for the caudate, putamen, globus pallidus, and thalamus were performed. The borders of the structures were drawn by two investigators (F.D.M. and V.M.) on the basis of a neuroanatomy atlas and input from a neuroradiologist according to procedures standardized in our laboratory. The reliability (ICC) for 10 random cases (five patients and five comparison subjects) analyzed independently, without previous exposure to these scans, was as follows: for the caudate, 0.98; putamen, 0.99; globus pallidus, 0.94; thalamus, 0.99. The scans were blinded and mixed, and all analysis was completed by one researcher (V.M.).

FIGURE 1. Regions Defined in an MRI Study of Subcortical Volumes in Patients With Schizophrenia°

The procedure of placing the regions of interest began by displaying the transaxial images at a magnification factor of 0.89 of actual size. Operators could enlarge scans 16 or more times to view pixels distinctly around small structures such as the thalamostriate vein, kept outside the caudate. The delineation between the putamen and the globus pallidus and the boundaries for the thalamus were clearer on axial than on coronal images. Boundaries were drawn around the head and body of the caudate nucleus, the putamen, the globus pallidus, and the thalamus on full gray scale images. After the segmentation algorithm was allowed to find the true edge of each nucleus, the lines were drawn at least two pixels from the gray matter edges of the nuclei in the white matter tracts surrounding them (figure 1). The head of the caudate was defined in the transaxial plane as the mass of gray matter comprising the lateral walls of the lateral ventricles bounded inferolaterally by the anterior limb of the internal capsule and superolaterally by the external capsule. Region placement began inferiorly when the operator could see the most inferior aspect of the third ventricle and when the chiasmatic cistern was no longer visible, just above the amygdala. The boundary for the head of the caudate continued superiorly until the thalamus could no longer be visualized, and the anterior horn of the lateral ventricles became confluent with the posterior horn. The body of the caudate was defined as the portion above the thalamus after the confluence of the anterior and posterior horns of the lateral ventricles. The nucleus accumbens was included as caudate. The lenticular nucleus was defined as the gray matter bounded by the internal and external capsules. The boundary between the putamen and the globus pallidus was determined by two methods. First, when possible, a strip of white matter was identified between the crisscrossing by fingers of gray matter between the two regions; second, the boundary was noted by the difference in color between the two structures, since the putamen always appeared darker with this acquisition protocol. Boundaries for the globus pallidus began inferiorly at the level of the third ventricle. They extended superiorly until no more gray matter pixels medial to the boundary for the putamen could be detected. Region tracing for the putamen extended superiorly until the thalamus disappeared and the body of the caudate became continuous with the tail. The thalamus was defined as the portion of gray matter bounded medially and posteriorly by the walls of the third ventricle, laterally by the internal capsule, and anteriorly by the fornix and genu of the internal capsule. Region placement began inferiorly above the inferior colliculi when the posterior commissure was no longer visible and ended when the third ventricle merged with the posterior horns and the caudate body appeared. A switch from the full gray scale display to a segmentation map was used to verify that no more gray matter pixels were present when a specific region was no longer identified on the nonsegmented MRI.

Data Analysis

The volumes of the caudate, putamen, globus pallidus, and thalamus were the dependent measures in a group (neuroleptic-naïve patients, previously treated patients, healthy comparison subjects)-by-region multivariate analysis of covariance (MANCOVA), with cranial volume as a covariate. Use of this covariate is necessitated by the differences in cranial volume between the sexes and between diagnostic groups. Significant interactions between group and region were decomposed by contrasting each patient subgroup with the healthy comparison group by means of univariate ANCOVAs for each region. The association of volume with medication dose and with treatment duration was examined by correlating volumes with total lifetime dose in chlorpromazine-equivalent units and days of treatment. There were seven patients for whom dose was unavailable for some epochs; they were excluded from the correlational analysis. Because of the sample size, the group of previously treated patients was subdivided for the correlational analysis into 1) the patients treated with typical neuroleptics only (N=44) and 2) the patients treated with typical followed by atypical neuroleptics (N=19) combined with the patients treated with atypical neuroleptics only (N=5). Of the seven patients with missing data, four took typical neuroleptics only, and three were from the combined group. We repeated the analysis including the subjects with missing data by using...

FIGURE 2. Mean Volumes and Percent Laterality of Volumes in the Caudate, Putamen, Thalamus, and Globus Pallidus in Healthy Comparison Subjects and Neuroleptic-Naive and Previously Treated Schizophrenic Patients

The MANCOVAs comparing patient subgroups (neuroleptic-naive and previously treated patients) with healthy comparison subjects on the four subcortical regions showed a main effect of group (Hotelling-Lawley trace $T=0.17$, $F=2.26$, $df=16$, 424, $p=0.003$), a main effect of region ($T=0.17$, $F=12.15$, $df=3$, 218, $p<0.0001$), and a group-by-region interaction ($T=0.09$, $F=3.19$, $df=6$, 434, $p=0.004$). There was a hemisphere-by-region interaction ($T=0.04$, $F=2.83$, $df=3$, 218, $p=0.04$) and a group-by-hemisphere-by-region interaction ($T=0.06$, $F=2.11$, $df=6$, 434, $p=0.05$). The follow-up MANCOVAs comparing the neuroleptic-naive patients with the healthy subjects on the significant interactions showed only a marginal group-by-region interaction ($T=0.05$, $F=2.50$, $df=3$, 144, $p=0.06$). The group-by-hemisphere-by-region interaction was not significant. On the other hand, the MANCOVA contrasting the previously treated patients with the healthy comparison subjects showed both a group-by-region interaction ($T=0.07$, $F=4.52$, $df=3$, 198, $p=0.004$) and a group-by-hemisphere-by-region interaction ($T=0.06$, $F=4.00$, $df=3$, 198, $p=0.008$). These effects are illustrated in figure 2. As can be seen, the neuroleptic-naive group did not differ from the healthy comparison group except for a trend for lower thalamic volume ($F=3.08$, $df=1$, 148, $p=0.08$). On the other hand, the previously treated group showed higher volumes for the putamen ($F=4.86$, $df=1$, 202, $p=0.03$) and globus pallidus ($F=12.58$, $df=1$, 202, $p=0.0005$) (upper graphs of figure 2). The interaction with hemisphere reflects the increased left hemispheric globus pallidus volume in treated patients (lower right-most graph).

Correlations With Medication Dose

The correlations of subcortical volumes with total lifetime medication dose in chlorpromazine-equivalent units are shown in table 3. For patients treated with typical neuroleptics only, higher dose was associated with bilaterally higher caudate and thalamic volumes and higher left putamen volume. For the patients

RESULTS

The volumes of brain compartments and subcortical regions are presented in table 2. Cranial volume was lower in the male patients than in the healthy comparison men; among the women it was lower relative to the men in both the patients and the healthy comparison subjects.

The MANCOVAs comparing patient subgroups (neuroleptic-naive and previously treated patients)
treated with typical and atypical neuroleptics, a higher dose of a typical neuroleptic was associated with bilaterally higher volume of the thalamus and higher volume of the left putamen and globus pallidus. Only thalamic volume was correlated with dose of atypical neuroleptics. The correlations with duration of treatment were similar but lower. Partial correlations, when age, age at onset, and duration of illness were removed, remained significant.

Correlations With Severity of Symptoms

The correlations of subcortical volumes with severity of global positive and negative symptoms were generally positive: higher volumes were associated with greater severity. For the neuroleptic-naive group, subcortical volumes were not correlated with severity of negative symptoms, but higher volumes of the thalamus and putamen were associated with more severe positive symptoms ($r=0.50$, $df=19$, $p=0.02$, and $r=0.53$, $df=19$, $p=0.01$, respectively). This association was evident for hallucinations (caudate $r=0.44$, $df=19$, $p=0.04$; putamen $r=0.58$, $df=19$, $p=0.01$; thalamus $r=0.45$, $df=19$, $p=0.04$) and bizarre behavior (putamen $r=0.51$, $df=19$, $p=0.01$). For previously treated patients, higher subcortical volumes were associated with greater severity of both negative and positive symptoms. These correlations were small but significant for negative symptoms with volumes of the caudate ($r=0.29$, $df=73$, $p=0.01$) and putamen ($r=0.20$, $df=73$, $p=0.05$) and for positive symptoms with the putamen ($r=0.23$, $df=73$, $p=0.02$) and globus pallidus ($r=0.22$, $df=73$, $p=0.05$). Examination of subcategories of symptoms did not point to more specific links. These correlations were not attenuated by removing medication dose, duration of treatment, current age, age at onset, or duration of illness in partial correlations.

DISCUSSION

This study may help address the origins of subcortical hypertrophy reported in patients with schizophrenia by comparing patients never exposed to neuroleptics with treated patients. Differences between groups and correlations between subcortical volumes and dose of medication indicate that exposure to neuroleptics is associated with hypertrophy. The only region that differed between healthy comparison subjects and neuroleptic-naive patients was the thalamus, which was smaller in the patients. While this effect was only marginal in the present study according to a two-tailed test, it does replicate earlier findings of reduced thalamic volume in schizophrenia (4, 22, 23). Thus, there is some convergence of evidence from neuropathological and neuroimaging studies that suggests thalamic abnormalities in schizophrenia (1–4). This could provide neurobiological substrates for a range of behavioral deficits related to gating that are associated with thalamic and thalamocortical circuitry (35, 36).

Across subcortical regions, with the exception of the caudate, it appears that patients treated with neuroleptics show hypertrophy relative to their neuroleptic-naive counterparts and to healthy comparison subjects. The suggestion that increased subcortical volume is related to exposure to neuroleptics is further strengthened by the positive correlations between medication dose and volumes. Note that for patients treated with typical neuroleptics only, correlations were evident also in the caudate. Little is known from neuroimaging research about the effects of neuroleptics on brain volume. There are preliminary data suggesting that antipsychotics may be related to volume changes in both subcortical regions (21, 37, 38) and cortical regions (31). DeLisi et al. (38) observed larger caudate and lentiform nuclei volumes in chronic patients than in first-episode patients. In a longitudinal study, Chakos et al. (21) reported a 5.7% increase in caudate nuclei in first-episode patients taking typical neuroleptics. Reversal of caudate volume increase was seen in patients who were switched to clozapine in comparison with those who continued to take typical neuroleptics (37). In a longitudinal design, we found that in first-episode patients, a greater rate of reduction in frontal and temporal lobe volumes was associated with improvement of delusions and thought disorder and a higher dose of typical neuroleptics (31). It is noteworthy that in the present study, the dose of atypical neuroleptics is associated with bilaterally higher volumes only in the thalamus. This perhaps is related to differences in mode of action.

Morphometric MRI studies that examined cortical regions of interest have generally reported an association between decreased parenchymal volume and greater symptom severity (39, 40). We found small but
consistently positive correlations between subcortical volumes and severity of both positive and negative symptoms. This further supports the possibility that the hypertrophy associated with neuroleptic exposure reflects adaptive up-regulation of the occupancy of dopamine receptors (18, 19, 21), with concomitant persistence of symptoms. Indeed, as we see in the neuroleptic-naive group, before intervention with neuroleptics, higher subcortical volumes are quite specifically related to more severe positive symptoms, such as hallucinations and bizarre behavior. In patients treated with neuroleptics, this association, while attenuated, is generalized to both positive and negative symptoms. Thus, larger subcortical volumes portend more severe symptoms regardless of whether these volumes reflect endogenous processes or the effects of treatment.

Our results also suggest that the increase in volume is more pronounced in the left globus pallidus, and the correlations are consistently higher for left hemispheric subcortical regions. Lateralized abnormalities have been implicated in schizophrenia in some structural and functional neuroimaging studies as well as in post-mortem studies (1, 31, 41). This supports hypotheses of lateralized brain dysfunction in schizophrenia (42).

While we have observed substantial effects of neuroleptic exposure and dose, we should caution against interpreting all of the differences between the neuroleptic-naive and treated groups as demonstrating medication effects. Although we attempted to control for variables that could conceivably influence volume measures, the attribution of volume differences to medication must await longitudinal study. Such studies could also address more powerfully the relation between volume changes and response to treatment (21, 31). However, our results can rule out an explanation of subcortical hypertrophy as reflecting purely a lack of neuronal pruning as part of a neurodevelopmental aberration (15, 20). Medication type and dose also need scrutiny (37). Similarly, further parceling of brain regions will permit assessment of the reciprocity between cortical and subcortical anomalies.

Neuroanatomic studies have implicated multiple brain regions and their connecting circuitry; this may underlie the pervasive deficits evident in schizophrenia. While there are some inconsistencies in MRI structural studies of subcortical regions, most report either increased volume of basal ganglia structures in schizophrenic subjects or no difference from the structures of healthy people. There are few studies of the thalamus, and they suggest decreased volume in schizophrenic subjects. The critical role of neuroleptic intervention by modulating neurotransmitters needs to be addressed in neuroanatomic studies that use large study groups with controlled intervention. This study was limited by the lack of prospective therapeutic intervention with specific medications. However, the results encourage further integration of anatomic and clinical data with neurocognitive and functional neuroimaging.

glomeruli with recovery of histological changes; almost all were normocellular with open capillary lumina, with occasional glomeruli having mild tuft collapse and mild periglomerular fibrosis. The interstitium showed only mild tubular dilatation (fig. B). Electron microscopy showed near normal podocytes and disappearance of pseudocrescents; endothelial cytoplasmic inclusions were absent. 14 weeks after stopping dialysis his serum urea was 8 mmol/L and creatinine 132 μmol/L, urinary protein 0.8 g/L, serum albumin 39 g/L, total cholesterol 5.9 mmol/L, and CD4 count 0.12×10^9/L. Serum HIV-RNA by branched chain DNA assay was less than 500 copies/mL.

A report by UNAIDS indicates that approximately 7000 young people contract HIV-1 infection every day worldwide; 5-10% will develop nephropathy and end-stage renal disease, with a prevalence of HIV-1-associated end-stage renal disease as high as 38% in some inner city hospitals in the USA. Our patient had typical clinical features of HIV-1 nephropathy with heavy proteinuria and absent peripheral oedema, rapid progression to dialysis-dependent renal failure without hypertension, normal-sized kidneys on ultrasound examination, and pathological features of collapsing glomerulonephropathy with cystic dilation of the tubules and endothelial cells containing tubuloreticular cytoplasmic inclusions. This case supports the hypothesis that viral proteins and/or the host of cytokines released during active viral replication can have cytopathic effects on the kidneys: however, it is also possible that nephropathy may occur as a result of direct infection of the glomerular and tubular epithelial cells by HIV-1 in susceptible patients since HIV-1 has been shown to be in the kidneys of seropositive individuals both with and without nephropathy.

Antiretroviral treatment can improve glomerular and tubular histopathological changes of HIV-1-associated nephropathy in dialysis-dependent patients. Other reports have indicated some transient improvement in renal function and proteinuria in patients with nephropathy after treatment with steroids, angiotensin-converting enzyme blockers, or zidovudine, though most of these patients ultimately required long-term dialysis. Whether early initiation of anti-retroviral therapy, before substantial fibrosis occurs, results in optimum benefit is unknown. The initiation of anti-retroviral therapy, before substantial renal failure without hypertension, normal-sized kidneys on ultrasound examination, and pathological features of collapsing glomerulonephropathy with cystic dilation of the tubules and endothelial cells containing tubuloreticular cytoplasmic inclusions. This case supports the hypothesis that viral proteins and/or the host of cytokines released during active viral replication can have cytopathic effects on the kidneys: however, it is also possible that nephropathy may occur as a result of direct infection of the glomerular and tubular epithelial cells by HIV-1 in susceptible patients since HIV-1 has been shown to be in the kidneys of seropositive individuals both with and without nephropathy.

Neuroleptics in progressive structural brain abnormalities in psychiatric illness

**AL Madsen, N Kolding, A Korte, S Estbjerg, R Hemmingsen**

Progressive abnormalities have been reported in schizophrenic patients. We did a prospective, longitudinal study of brain structure. 31 drug-naive psychotic patients underwent computed tomography (CT) at first admission to hospital and after 5 years of illness. We obtained written informed consent from all patients. A radiologist masked to the patients’ identities and diagnoses, date of scans, and the nature of the study compared the first and second CT scans. Brain atrophy was assessed on a visual scale, on which 0-1 meant no changes or dubious atrophy and 2-3 meant moderate or severe atrophic changes. After 5 years of illness, we found significant progression of frontal atrophy in 21 schizophrenic patients, compared with nine consecutively included healthy volunteers. We saw progressive frontal atrophy in ten non-schizophrenic patients, but to a lesser degree.

During follow-up, schizophrenic patients received a median of 172,040 mg (range 19,540-928,450) neuroleptic medication (chlorpromazine equivalents). Seven non-schizophrenic patients received a median of 20,780 mg (range 6,784-141150). The only atypical neuroleptic used was clozapine, administered to three patients, always in high doses and in combination with traditional neuroleptics.

Patients were thought to have a chronic, non-remittent course of illness if all psychiatric records described a state of permanent psychosis, and if they were psychotic at the time of the reinvestigation. Some patients were described as remitted, but if in long interviews they showed firm delusional systems that seemed to be integrated but not necessarily overt parts of their lives, and if they were judged to be permanently deluded, despite their records, they were classified as non-remittent. This classification was made without knowledge of the results of the CT scans. Nine schizophrenic patients (eight men and one woman) had been continuously psychotic during follow-up. At reinvestigation, non-remittent patients had significantly higher ratings for psychopathology (SANS and SAPS) than remittent patients.

Because of the small sample, we did exact tests in a logistic regression analysis with LogXact, adjusted for sex, course of illness, (remission/non-remission), diagnosis, and neuroleptic load. Course of illness and diagnosis had no significant impact on the development of frontal atrophy. Sex was significant (p=0.036) if course of illness was not included into the model, but sex became non-significant (p=0.138) if course of illness was included. Neuroleptic load was significant whether sex was included or not (p=0.013 and 0.003, respectively). The estimated risk of atrophy increases by 6.4% for each additional 10 g neuroleptic drug. Non-remittent patients received a higher neuroleptic dose than remittent patients, but the model was corrected for this interaction.

Association has been shown between frontal atrophy or apasia and non-response to antipsychotic drugs, and neuroleptic side-effects as tardive dyskinesia and akathisia have been associated with wider sulci. These studies do not include neuroleptic load as a possible explanatory factor for the abnormalities found. Traditional neuroleptics have been shown to affect brain structure because they enhance the volume of basal ganglia, but the potential impact of neuroleptics, on frontal cortex, for example, is not known.

Factors causing progression of brain atrophy have not yet been identified. Our study showed an unexpected effect of...
neuroleptic medication on cerebral cortex, but our analysis suggests that the results cannot be taken as accidental. Future longitudinal studies of brain structure in schizophrenia are needed to show whether atypical antipsychotic drugs may be more beneficial.

Alcohol, drinking, illicit drug use, and stress in junior house officers in north-east England

D Birch, H Ashton, F Kamali

Doctors, due to the demanding nature of their jobs, are stressed. In July, 1997, we assessed the lifestyles of junior house officers (residents) in 18 National Health Service (NHS) Trust hospitals in the north east of England, UK, who had been surveyed during the second year of their medical course.

We contacted 114 house officers 1 year after graduation from Newcastle University; 80 (51%) agreed to participate. Anonymous information was obtained by a self-completed questionnaire, administered on site by one investigator (DB). The questionnaire was similar to that used in our previous surveys of students, with the addition of the 30-item general health questionnaire (GHQ) and job satisfaction component of the occupational stress indicator. The results are shown in the table. Among the 93% who drank alcohol, over 60% of both sexes exceeded recommended safe limits. The main reason given for drinking was “pleasure” (91–7% men and 87–9% women). More than 35% of men and 19% of women were currently using cannabis, with over 11% taking it regularly (weekly or monthly). Use of hallucinogenic mushrooms, lysergic acid diethylamide (LSD), ecstasy, amyl nitrite, cocaine, and amphetamine was also reported; 13% (M) and 10% (F) reported current use of one or more of these drugs. “Pleasure” was also the main reason for taking illicit drugs (76–0% in both sexes).

On the hospital anxiety and depression scale, 21% of men and 45% of women had anxiety scores of 8 or more, indicating possible pathological anxiety. On the GHQ, 35% scored over the threshold score of 4. Scores for the OSI component suggested some were dissatisfied with their job. 58% of men and 51% of women reported sleeping on average 7–8 hours per night whilst 42% and 49% slept 5–6 hours per night. 8% of men and 18% of women complained of difficulty getting to sleep and 23% and 58% were slow to become fully awake. Significant negative correlations were found between OSI and anxiety scores (r = 0.363; p < 0.001) and between OSI and depression (r = 0.346; p < 0.02) and none between alcohol or drug use and anxiety or occupational stress.

This study shows that most of the house officers surveyed drink excessive amounts of alcohol; many use cannabis and take other illicit drugs. Alcohol drinking had increased in both men and women, compared with when they were second-year medical students; mean (SD) 19.6 (13.1) units/week; range 2–67, median 18 for men; 11.8 (9.0) units/week, range 1–43, median 10 for women. High scores for anxiety and mental ill-health were related to work pressures, but unrelated to the use of alcohol or illicit drugs. These results are comparable with our previous studies of 765 UK university students from all faculties and of 785 second-year medical students from seven UK medical schools. Both these student populations showed high levels of alcohol consumption and drug use and high anxiety scores unrelated to alcohol or drug use.

It is unlikely that these lifestyles apply only to house officers in the north east of England. The current drinking habits, illicit drug use and stress in some junior doctors is of concern, not only for their own well being, but also how they may affect patient care. Is it possible to reduce the stress of house officers? Should routine or random drug and alcohol screening programmes be considered? There is no evidence that such schemes would be workable or appropriate in the UK National Health Service, but mandatory urine screening is undertaken in the UK army and some UK industries, and for doctors in the USA.

This study was supported by a grant from the Catherine Cookson Foundation.
