Attorney for Law Project for Psychiatric Rights

IN THE UNITED STATES DISTRICT COURT
DISTRICT OF ALASKA

UNITED STATES OF AMERICA *Ex rel.* Law Project for Psychiatric Rights, an Alaskan non-profit corporation, Plaintiff, vs. OSAMU H. MATSUTANI, MD, *et al*., Defendants.	)	Case No. 3:09-CV-00080-TMB

MOTION FOR PRELIMINARY INJUNCTION AGAINST DEFENDANTS HOGAN AND STREUR

Qui tam relator Law Project for Psychiatric Rights (PsychRights®) moves for a preliminary injunction prohibiting defendants William Hogan and William Streur, their agents, servants, employees and attorneys, and any persons who are in active concert or participation with them, from presenting claims or causing claims to be presented to Medicaid for reimbursement or payment of the United States Government's federal

financial participation (FFP) share[1] of outpatient prescriptions for psychotropic drugs to recipients under the age of 18 (children and youth) that are not for a medically accepted indication.

I. BACKGROUND

This is a case under the federal False Claims Act, 31 U.S.C. §3729, *et seq*., to:

(a) recover for false claims presented to and paid by Medicaid for outpatient psychiatric drugs prescribed to children and youth that were not for a "medically accepted indication;" and

(b) order the defendants to cease and desist from presenting or causing the presentment of such false claims.

This motion seeks to enjoin Defendants William Hogan and William Streur, their agents, servants, employees and attorneys, and any persons who are in active concert or participation with them from presenting claims or causing claims to be presented to Medicaid for outpatient prescriptions for psychotropic drugs to children and youth that are not covered under that program. Defendant Hogan is the Commissioner of the Alaska Department of Health and Social Services (DHSS), and Defendant William Streur is the Director of the Division of Health Care Services (HCS) within DHSS. Defendant Streur is in charge of the administration of the Medicaid program by the State of Alaska under the direction and supervision of Defendant Hogan. In other words, Defendants Hogan and Streur are in charge of the administration of the Medicaid program by the State of Alaska.

Congress restricted reimbursement for outpatient drugs by the federal government under Medicaid to those that are "medically accepted indications," defined as indications approved by the Food and Drug Administration (FDA), or the use of which is supported by one or more citations included or approved for inclusion in (i) American Hospital

[1] "FFP" stands for "Federal Financial Participation," which means "the Federal Government's share of a State's expenditures under the Medicaid program." 42 CFR §400.203.

Formulary Service Drug Information, (ii) United States Pharmacopeia-Drug Information (or its successor publications), or (iii) DRUGDEX Information System (Covered Outpatient Drugs). 42 USC § 1396r-8(k)(3); 42 USC § 1396r-8(k)(6); 42 USC § 1396r-8(g)(1)(B)(i).

The parties sought to be enjoined continue to present claims or cause claims to be presented to Medicaid for payment of prescriptions to children and youth for psychiatric drugs that are not for a medically accepted indication. This motion thus seeks to preliminarily enjoin such continuing violation of federal law.

II. STANDARDS FOR PRELIMINARY INJUNCTIONS

In *California Pharmacists Ass'n v. Maxwell-Jolly*, 563 F.3d 847, 849 (9th Cir. 2009), citing to *Winter v. Natural Res. Def. Council, Inc*., --- U.S. ----, 129 S.Ct. 365, 376, 172 L.Ed.2d 249 (2008), the 9th Circuit, recently had occasion to state the standard for obtaining a preliminary injunction:

> Plaintiffs seeking a preliminary injunction in a case in which the public interest is involved must establish that they are likely to succeed on the merits, that they are likely to suffer irreparable harm in the absence of preliminary relief, that the balance of equities tips in their favor, and that an injunction is in the public interest. .

These factors will be discussed in turn.

III. THE STANDARDS FOR ISSUANCE OF A PRELIMINARY INJUNCTION ARE MET HERE

A. PsychRights is Likely to Succeed on the Merits

(1) Medicaid Coverage for Outpatient Drugs is Limited to "Medically Accepted Indications

42 USC 1396R-8(k)(3) provides in pertinent part, "The term 'covered outpatient drug' does not include any . . . drug . . . used for a medical indication which is not a medically accepted indication." 42 USC 1396R-8(k)(6) provides:

> The term "medically accepted indication" means any use for a covered outpatient drug which is approved under the Federal Food, Drug, and Cosmetic Act [21 U.S.C.A. § 301 et seq.], or the use of which is supported by one or more citations included or approved for inclusion in any of the compendia described in subsection (g)(1)(B)(i) of this section.

42 USC § 1396R-8(g)(1)(B)(i), in turn, designates the compendia as

> (I) American Hospital Formulary Service Drug Information;
> (II) United States Pharmacopeia-Drug Information (or its successor publications); and
> (III) the DRUGDEX Information System.

(Compendia).

In sum, Medicaid is only permitted by Congress to reimburse the states for expenditures on outpatient drugs for "medically accepted indications," defined as indications approved by the FDA or "supported" by a citation in any of the three Compendia. This was recognized in *US ex rel Rost v. Pfizer*, 253 F.R.D. 11, 13-14 (D.Mass 2008) where the Court held:

> Medicaid can only pay for drugs that are used for a "medically accepted indication," meaning one that is either approved by the FDA or "supported by citations" in one of three drug compendia, including DRUGDEX. See 42 U.S.C. § 1396r8 (k)(3), (6); 42 U.S.C. § 1396r-8 (g)(1)(B)(I).

Similarly, in *U.S. ex rel. Franklin v. Parke-Davis*, 147 F.Supp. 2d 39, 44,45 (D.Mass 2001), the Court held:

> Whether a drug is FDA-approved for a particular use will largely determine whether a prescription for that use of the drug will be reimbursed under the federal Medicaid program. Reimbursement under Medicaid is, in most circumstances, available only for "covered outpatient drugs." 42 U.S.C. § 1396b(i)(10). Covered outpatient drugs do not include drugs that are "used for a medical indication which is not a medically accepted indication." Id. §1396r-8(k)(3). A medically accepted indication, in turn, includes a use "which is approved under the Federal Food Drug and Cosmetic Act" or which is included in specified drug compendia. Id. § 1396r-8(k)(6). See also id. § 1396r-8(g)(1)(B)(i) (identifying compendia to be consulted). Thus, unless a particular off-label use for a drug is included in one of the

> identified drug compendia, a prescription for the off-label use of that drug is not eligible for reimbursement under Medicaid.

(footnote omitted)

The Department of Justice concurs as shown by its news release announcing the $2.3 Billion settlement with Pfizer, in which it stated, "[Pfizer] caused false claims to be submitted to government health care programs for uses that were not medically accepted indications and therefore not covered by those programs." Exhibit A.

(2) Defendants Hogan and Streur Are Personally Liable for Presenting or Causing False Claims to be Presented to Medicaid.

Under *Stoner v. Santa Clara County Office of Education*, 502 F.3d 1116, 1124-5 (9th Cir. 2007), Defendants Hogan and Steur are personally liable for presenting or causing the presentment of false claims to Medicaid:

> The district court also held that Stoner failed to state an FCA [False Claims Act] claim against the individual defendants in their personal capacities because Stoner could not allege that the defendants' actions exceeded the scope of their official responsibilities. As explained below, this was an error. The plain language of the FCA subjects to liability "any person" who, among other things, knowingly submits a false claim or causes such a claim to be submitted to the United States. 31 U.S.C. § 3729. Although the FCA does not define the term "person," the Supreme Court has made clear that the term includes "natural persons." . . . Therefore, state employees sued in their personal capacities are "persons" who may be subject to liability for submitting a false claim to the United States. . . .
>
> To state a claim against Wilcox, Fimiani, and Wong in their personal capacities, Stoner need show only that the individual employees "knowingly present[ed], or cause[d] to be presented, to an officer or employee of the United States Government ... a false or fraudulent claim for payment or approval."

(citations omitted).

(3) Defendants Hogan and Streur Are Flouting Medicaid Requirements By Presenting or Causing the Presentment of Claims for Prescriptions of Psychotropic Drugs to Children and Youth That Are Not For A Medically Accepted Indication

In *ex rel Rost*, 253 F.R.D. at 14 the district court noted, "Each prospective Medicaid provider must agree that he will comply with all Medicaid requirements." States must similarly agree to abide by Medicaid requirements as a condition of participation. Attached hereto as Exhibit B is a copy of the State of Alaska's agreement to comply with all Medicaid requirements.

Among these requirements, under 42 USC §1396r-8 (g)(1)(A), the State of Alaska is required to have a drug use review program (DUR) "designed to educate physicians and pharmacists to identify and reduce the frequency of patterns of fraud."

Under 42 CFR §456.703, the DUR is required to include "prospective drug review." 42 CFR §456.705 in turn provides in pertinent part:

> **42 CFR §456.705 Prospective drug review.**
>
> (a) General. Except as provided in Sec. Sec. 456.703 (b) and (c), the State plan must provide for a review of drug therapy before each prescription is filled or delivered to a recipient . . . . The State must provide pharmacies with detailed information as to what they must do to comply with prospective DUR requirements . . . . The pharmacies, in turn, must provide this information to their pharmacists.

In other words, through this prospective drug review, before each prescription is filled, the state Medicaid agency is required to review it to determine if it is eligible for reimbursement by Medicaid.

42 CFR §456.722 allows for this prospective review of prescriptions to occur through a computerized system:

> **42 CFR §456.722 Electronic claims management system.**
>
> (a) Point-of-sale system. Each Medicaid agency, at its option, may establish, as its principal (but not necessarily exclusive) means of processing claims for covered outpatient drugs, a point-of-sale electronic claims management (ECM) system to perform on-line, real-time (that is,

immediate) eligibility verifications, claims data capture, adjudication of claims, and to assist pharmacists and other authorized persons (including dispensing physicians) in applying for and receiving payment. . . . If the State exercises this option and wishes to receive FFP for its ECM system, the system must meet the functional and additional procurement and system requirements in paragraphs (b) and (c) of this section.

(b) Functional requirements. The ECM system developed by the State must include at least the on-line, real-time capabilities specified in paragraphs (b)(1) through (3) of this section. . . .

(2) Claims data capture, including the following: . . .

(iii) Minimum data set (as defined in Part 11 of the State Medicaid Manual).

(3) Claims adjudication, including the following:

(i) Performing all edits and audits contained in the State's Medicaid Management Information System (MMIS) applicable to prescription drugs.

(ii) Notifying the pharmacist (or other authorized person, such as the dispensing physician) about the claim status.

(iii) Taking steps up to, but not including, payment of the claim.

Included in the data set of Part 11 of the State Medicaid Manual[2] are:

*6. Recipient's Date of Birth:

The date of birth of the recipient. . .

*61. Principal Diagnosis Code:

a. The diagnosis code for the principal condition requiring medical attention. . . .

62. Other Diagnosis Code:

a. The diagnosis code of any condition other than the principal condition which requires supplementary medical treatment. . . .

88. Drug Code:

Codes identifying particular drugs; e.g., National Drug Code, drug tables.

89. Diagnosis Code:

A table of codes identifying medical conditions; i.e., ICD-9-CM.

[2] Exhibit C, downloaded from http://www.cms.hhs.gov/manuals/downloads/P45_11.zip on March 17, 2010.

90. Drug Name:
The generally accepted nomenclature for a particular drug.
91. Drug Classification:
The therapeutic group in to which a drug is categorized.
92. Minimum Days Supply of Drugs:
The minimum units of a drug prescription eligible for payment.
93. Maximum Days Supply of Drug:
The maximum units of a drug prescription eligible for a particular drug. . . .
95. Diagnosis Name:
The generally accepted nomenclature for a diagnosis. Name is required only if not encoded by provider. (See Data Element No. 61.)

These statutory and regulatory provisions require the State of Alaska to screen prescriptions for compliance with the requirement that it not seek federal Medicaid payment for outpatient prescriptions to children and youth for psychotropic drugs that are not for a medically accepted indication.

To summarize: 42 USC §1396r-8 (g)(1)(A) requires a DUR program, 42 CFR §456.703 requires the DUR program to include prospective drug review, and 42 CFR §456.705 requires such prospective review to verify eligibility before the prescription is filled. Under 42 CFR §456.722, the State's electronic claims management system is required to collect the minimum data specified in Part 11 of the State Medicaid Manual, relevant elements of which are set forth above. These elements can determine whether psychotropic drugs prescribed to children and youth are or are not for a medically accepted indication.

Under Defendants Hogan's and Steur's administration of Alaska's Medicaid program, these requirements are being flouted.

(4) Injunctive Relief is Available Against Defendants Hogan and Streur

Injunctive relief to enjoin a state official from violating a federal statute is proper and not barred by the 11th Amendment to the United States Constitution. *Armstrong v. Wilson*, 124 F.3d 1019 (9th Cir. 1997); *Independent Living Center of Southern*

California, Inc., v Maxwell-Jolly, 572 F.3d 644 (9th Cir. 2009). Where a district court has the power to issue a permanent injunction, it also has authority to issue preliminary injunctions. *F.T.C. v. H. N. Singer, Inc.*, 668 F.2d 1107, 1111 (9th Cir. 1982).

B. The Plaintiff Will Suffer Irreparable Harm Without the Preliminary Injunction

(1) To the Extent the 11th Amendment Prohibits a Monetary Judgment Against the State of Alaska for its Medicaid Fraud, Irreparable Harm is Established as a Matter of Law.

In *California Pharmacists, supra*., 563 at 852, the 9th Circuit held that to the extent the 11th Amendment prevents a federal court from awarding a damages remedy against a state, irreparable harm is established as a matter of law:

> Because the economic injury doctrine rests only on ordinary equity principles precluding injunctive relief where a remedy at law is adequate, it does not apply where, as here, the Hospital Plaintiffs can obtain no remedy in damages against the state because of the Eleventh Amendment.

(citation and footnote omitted).

In *Stoner*, as set forth above, the Ninth Circuit held that state employees are personally liable under the False Claims Act for Medicaid violations while acting within the scope of their official duties. However, it specifically held open the question of whether the 11th Amendment prevented the district court from awarding money damages against a state under the False Claims Act through its employees:

> With respect to the official capacity claims, the district court held that the individually named defendants could not be sued for damages in their official capacities because such a suit would, in effect, be against the state. . . . The parties do not challenge this ruling and we express no opinion on the merits of the district court's conclusion.

572 F.3d at 1123 (citation omitted).

California Pharmacists does not mention *Stoner*, and the two cases are certainly distinguishable, especially in that *California Pharmacists* is not a False Claims Act case

while *Stoner* is, but it can be read to suggest that even under the False Claims Act, the 11th Amendment bars a federal court from awarding monetary damages against a state.

If Defendants Hogan and Streur, who are being represented by the Alaska Department of Law as to both their individual and official capacities,[3] concede that the State of Alaska is subject to monetary damages by virtue of Defendants Hogan and Streur having been sued in their official capacities as well as individually, then irreparable harm will not have been established on the grounds that the 11th Amendment bars this Court from awarding monetary damages against the State of Alaska through Defendants Hogan and Streur. However, if the State of Alaska, through Defendants Hogan and Streur, does not concede the State is subject to monetary damages, and this Court concludes the State of Alaska is immune, under *California Pharmacists*, irreparable harm has been established as a matter of law.

As will be discussed in the next section, however, even if the Court concludes the State of Alaska through Defendants Hogan and Streur is subject to monetary damages in this case and therefore irreparable harm has not been established for that reason, irreparable harm is established as a matter of law because the continuing violation of a federal statute constitutes irreparable harm as a matter of law.

(2) The Continuing Violation of a Federal Statute is Irreparable Harm as a Matter of Law.

In *New Motor Vehicle Bd. v. Orrin W. Fox Co.*, 434 U.S. 1345, 1351, 98 S.Ct. 359, 363, 54 L.Ed.2d 439 (1977) (Rehnquist, J., in chambers), the U.S. Supreme Court held, "any time a State is enjoined by a court from effectuating statutes enacted by representatives of its people, it suffers a form of irreparable injury." In *Coalition for Economic Equity v. Wilson*, 122 F.3d 718, 719 (9th Cir. 1997), citing *New Vehicle*, the Ninth Circuit held, "it is clear that a state suffers irreparable injury whenever an enactment of its people or their representatives is enjoined." In *Independent Living*

[3] *See*, Docket Nos. 52 & 55.

Center, *supra*., 572 F.3d at 658, the Ninth Circuit clarified, that while that may be true, enforcing federal law pre-empts such irreparable harm suffered by a state, stating:

> As the cited authority suggests, a state may suffer an abstract form of harm whenever one of its acts is enjoined. To the extent that is true, however, it is not dispositive of the balance of harms analysis. If it were, then the rule requiring "balance" of "competing claims of injury," *Winter*, 129 S.Ct. at 376, would be eviscerated. Federal courts instead have the power to enjoin state actions, in part, because those actions sometimes offend federal law provisions, which, like state statutes, are themselves "enactment [s] of its people or their representatives,"

PsychRights respectfully suggests the Ninth Circuit has thus implicitly held that allowing continuing violation of federal law constitutes irreparable harm as a matter of law.

C. The Balance of Equities Tips in Favor of the Plaintiff and the Injunction is in the Public Interest as a Matter of Law

Under California Pharmacists, *supra*., 563 at 852-853, as a matter of law, the balance of equities tips in favor of the plaintiff and a prospective preliminary injunction is in the public interest if the requested preliminary injunction is to enjoin continuing violation of federal law ("it is clear that it would not be equitable or in the public's interest to allow the state to continue to violate the requirements of federal law"). Thus, these two factors are satisfied as a matter of law. Where, as here, the violation of law is clear, the court must not allow it to continue.

IV. SCOPE OF THE REQUESTED PRELIMINARY INJUNCTION

Whether a prescription for a psychotropic drug to a child or youth that is not for an FDA approved indication is nonetheless covered under Medicaid because it is a medically accepted indication, the American Hospital Formulary Service and DRUGDEX compendia citations must be consulted to be if such use is "supported."[4]

[4] It is PsychRights' understanding, after inquiry, that United States Pharmacopeia-Drug Information (or its successor publications), the other compendium specified in 42 U.S.C. 1396r-8(g)(1)(B)(i), is no longer being published.

Attached hereto as Exhibit D are the most recent citations in the American Hospital Formulary Service compendium, and Exhibit E the most recent citations in DRUGDEX[5] available to PsychRights,[6] for specific prescription psychotropic drugs often prescribed to children and youth. These establish the following with respect to medically accepted indications prescribed to children and youth for the specific psychotropic drugs:

1. The following psychotropic drugs have no medically accepted indication for anyone under 18 years of age and should be prohibited entirely:

   a. Clorazil (clozapine)
   b. Cymbalta (duloxetine)
   c. Desyrel (trazadone)
   d. Effexor (venlafaxine)
   e. Geodon (ziprasidone)
   f. Invega (paliperidone)
   g. Paxil (paroxetine)
   h. Symbyax (fluoxetine hydrochloride/olanzapine)

2. The only medically accepted indications for anyone under 18 years of age are as set forth below for the following psychotropic drugs and all other indications should be prohibited:

Drug	**Medically Accepted Indication**	**Notes**
Abilify (Aripiprazole)		
	Bipolar I Disorder - Adjunctive therapy with lithium or valproate for Acute Manic or Mixed Episodes	10 yrs old and up
	Bipolar I Disorder, monotherapy, Manic	10-17 years old for acute therapy

[5] Exhibit F is a copy of the DRUGDEX Recommendation, Evidence and Efficacy Ratings.

[6] PsychRights has requested Defendant Thomson Reuters (Healthcare), the publisher of DRUGDEX, for the most recent citations in DRUGDEX and to keep them current so that any additions to medically accepted indications may be reflected in the requested preliminary injunction. *See*, Exhibit G.

Drug	Medically Accepted Indication	Notes
	or Mixed Episodes	
	Schizophrenia	13-17 years old
Adderall (amphetamine/dextroamphetamine)		
	Attention Deficit Hyperactivity Disorder (ADHD)	3 years old and up for immediate-release and 6 years old and up for extended-release
	Narcolepsy	6 years old and up for immediate release
Anafranil (clomipramine)		
	Obsessive-Compulsive Disorder	10 years and up
Concerta (methylphenidate)		
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years old to 12 years old
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years old and up for ConcertaR
Depakote (valproic acid)		
	Absence Seizure, Simple and Complex and/or Complex Partial Epileptic Seizure	10 years and older
Dexedrine (dextroamphetamine)		
	Attention Deficit Hyperactivity Disorder (ADHD)	3 years to 16 years old (immediate-release) and age 6 years to 16 years old (sustained-release))
	Narcolepsy	6 years old and up
Focalin (dexmethylphenidate)		
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years and older
Haldol (haloperidol)		
	Hyperactive Behavior, (Short-term treatment) after failure to respond to non-antipsychotic medication and psychotherapy	3 years old and up
	Problematic Behavior in Children (Severe), With failure to respond to non-antipsychotic medication or psychotherapy	3 years old and up
	Psychotic Disorder	3 years old and up but ORAL formulations only

Drug	Medically Accepted Indication	Notes
	Schizophrenia	3 years old and up but ORAL formulations only
Lamictal (lamotrigine)		
	Epilepsy, Refractory	
Lexapro (escitalopram)		
	Major Depressive Disorder	12 years old and up
Luvox (fluvoxamine)		
	Obsessive-Compulsive Disorder	8 years old and up and immediate release formula only
Mellaril (thioridazine)		
	Schizophrenia, Refractory	
Neurontin (gabapentin)		
	Partial Seizure; Adjunct	3-12 years old
Orap (pimozide)		
	Gilles de la Tourette's syndrome	12 years and older
Prozac (fluoxetine)		
	Major Depressive Disorder	8 years old and up
	Obsessive-Compulsive Disorder	7 years old and up
Ritalin (methylphenidate)		
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years to 12 years old (extended release)
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years old and up (immediate release)
	Narcolepsy	6 years and up, and Ritalin(R) -SR only
Risperdal (risperidone)		
	Autistic Disorder – Irritability	5 years old and up
	Bipolar I Disorder	10 years old and up
	Schizophrenia	13 years old and up (Orally)
Seroquel (quetiapine)		
	Manic episodes associated with bipolar disorder	10 years old to 17 years old
	Schizophrenia	13 years old to 17 years old
Sinequan (doxepin)		
	Alcoholism - Anxiety – Depression	12 years old and up

Drug	Medically Accepted Indication	Notes
	Anxiety – Depression	12 years old and up
	Anxiety - Depression - Psychoneurotic personality disorder	12 years old and up
Strattera (atomoxetine)		
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years old and up
Tegretol (carbamazepine)		
	Epilepsy, Partial, Generalized, and Mixed types	
Tofranil (imipramine)		
	Nocturnal enuresis	6 years old and up
Trileptal (*oxcarbazepine*)		
	Partial Seizure, monotherapy	4 years old and up
	Partial seizure; Adjunct	2 years old and up
Vyvanse (lisdexamfetamine)		
	Attention Deficit Hyperactivity Disorder (ADHD)	6 years old to 12 years old
Zoloft (sertraline)		
	Obsessive-Compulsive Disorder	6 years old and up
Zyprexa (olanzapine)		
	Schizophrenia	13 years old to 17 years old
	manic or mixed episodes associated with bipolar I disorder	13 years old to 17 years old

For psychotropic drugs not listed, PsychRights respectfully suggests the parties sought to be enjoined should be prohibited from approving for payment or reimbursement by Medicaid of the United States Government's FFP share of outpatient prescriptions for psychiatric drugs to anyone under 18 unless (a) it is for an indication approved by the FDA, or (b) upon application to the Court with notice to the other parties to determine whether such use is for a medically accepted indication.

V. BOND

Under F.R.C.P. 65(c) the United States is not required to give security. Since the United States is the real party in interest in this action, *Stoner*, *supra*, 502 F.3d at 1126, no security is required.

VI. CONCLUSION

For the foregoing reasons PsychRights' motion for a preliminary injunction should be granted.

RESPECTFULLY SUBMITTED this 24th day of March, 2010.

Justice Department Announces Largest Health Care Fraud Settlement in Its History

Pfizer to Pay $2.3 Billion for Fraudulent Marketing

WASHINGTON – American pharmaceutical giant Pfizer Inc. and its subsidiary Pharmacia & Upjohn Company Inc. (hereinafter together "Pfizer") have agreed to pay $2.3 billion, the largest health care fraud settlement in the history of the Department of Justice, to resolve criminal and civil liability arising from the illegal promotion of certain pharmaceutical products, the Justice Department announced today.

Pharmacia & Upjohn Company has agreed to plead guilty to a felony violation of the Food, Drug and Cosmetic Act for misbranding Bextra with the intent to defraud or mislead. Bextra is an anti-inflammatory drug that Pfizer pulled from the market in 2005. Under the provisions of the Food, Drug and Cosmetic Act, a company must specify the intended uses of a product in its new drug application to FDA. Once approved, the drug may not be marketed or promoted for so-called "off-label" uses – *i.e.*, any use not specified in an application and approved by FDA. Pfizer promoted the sale of Bextra for several uses and dosages that the FDA specifically declined to approve due to safety concerns. The company will pay a criminal fine of $1.195 billion, the largest criminal fine ever imposed in the United States for any matter. Pharmacia & Upjohn will also forfeit $105 million, for a total criminal resolution of $1.3 billion.

In addition, Pfizer has agreed to pay $1 billion to resolve allegations under the civil False Claims Act that the company illegally promoted four drugs – Bextra; Geodon, an anti-psychotic drug; Zyvox, an antibiotic; and Lyrica, an anti-epileptic drug – and caused false claims to be submitted to government health care programs for uses that were not medically accepted indications and therefore not covered by those programs. The civil settlement also resolves allegations that Pfizer paid kickbacks to health care providers to induce them to prescribe these, as well as other, drugs. The federal share of the civil settlement is $668,514,830 and the state Medicaid share of the civil settlement is $331,485,170. This is the largest civil fraud settlement in history against a pharmaceutical company.

As part of the settlement, Pfizer also has agreed to enter into an expansive corporate integrity agreement with the Office of Inspector General of the Department of Health and Human Services. That agreement provides for procedures and reviews to be put in place to avoid and promptly detect conduct similar to that which gave rise to this matter.

Whistleblower lawsuits filed under the *qui tam* provisions of the False Claims Act that are pending in the District of Massachusetts, the Eastern District of Pennsylvania and the Eastern District of Kentucky triggered this investigation. As a part of today's resolution, six whistleblowers will receive payments totaling more than $102 million from the federal share of the civil recovery.

The U.S. Attorney's offices for the District of Massachusetts, the Eastern District of Pennsylvania, and the Eastern District of Kentucky, and the Civil Division of the Department of Justice handled these cases. The U.S. Attorney's Office for the District of Massachusetts led the criminal investigation of Bextra. The investigation was conducted by the Office of Inspector General for the Department of Health and Human Services (HHS), the FBI, the Defense Criminal Investigative Service (DCIS), the Office of Criminal Investigations for the Food and Drug Administration (FDA), the Veterans' Administration's (VA) Office of Criminal Investigations, the Office of the Inspector General for the Office of Personnel Management (OPM), the Office of the Inspector General for the United States Postal Service (USPS), the National Association of Medicaid Fraud Control Units and the offices of various state Attorneys General.

"Today's landmark settlement is an example of the Department of Justice's ongoing and intensive efforts to protect the American public and recover funds for the federal treasury and the public from those who seek to earn a profit through fraud. It shows one of the many ways in which federal government, in partnership with its state and local allies, can help the American people at a time when budgets are tight and health care costs are increasing," said Associate Attorney General Tom Perrelli. "This settlement is a testament to the type of broad, coordinated effort among federal agencies and with our state and local partners that is at the core of the Department of Justice's approach to law enforcement."

"This historic settlement will return nearly $1 billion to Medicare, Medicaid, and other government insurance programs, securing their future for the Americans who depend on these programs," said Kathleen Sebelius, Secretary of Department of Health and Human Services**.** "The Department of Health and Human Services will continue to seek opportunities to work with its government partners to prosecute fraud wherever we can find it. But we will also look for new ways to prevent fraud before it happens. Health care is too important to let a single dollar go to waste."

"Illegal conduct and fraud by pharmaceutical companies puts the public health at risk, corrupts medical decisions by health care providers, and costs the government billions of dollars," said Tony West, Assistant Attorney General for the Civil Division. "This civil settlement and plea agreement by Pfizer represent yet another example of what penalties will be faced when a pharmaceutical company puts profits ahead of patient welfare."

"The size and seriousness of this resolution, including the huge criminal fine of $1.3 billion, reflect the seriousness and scope of Pfizer's crimes," said Mike Loucks, acting U.S. Attorney for the District of Massachusetts. "Pfizer violated the law over an extensive time period. Furthermore, at the very same time Pfizer was in our office negotiating and resolving the allegations of criminal conduct by its then newly acquired subsidiary, Warner-Lambert, Pfizer was itself in its other operations violating those very same laws. Today's enormous fine demonstrates that such blatant and continued disregard of the law will not be tolerated."

"Although these types of investigations are often long and complicated and require many resources to achieve positive results, the FBI will not be deterred from continuing to ensure that pharmaceutical companies conduct business in a lawful manner," said Kevin Perkins, FBI Assistant Director, Criminal Investigative Division.

"This resolution protects the FDA in its vital mission of ensuring that drugs are safe and effective. When manufacturers undermine the FDA's rules, they interfere with a doctor's judgment and can put patient health at risk," commented Michael L. Levy, U.S. Attorney for the Eastern District of Pennsylvania. "The public trusts companies to market their drugs for uses that FDA has approved, and trusts that doctors are using independent judgment. Federal health dollars should only be spent on treatment decisions untainted by misinformation from manufacturers concerned with the bottom line."

"This settlement demonstrates the ongoing efforts to pursue violations of the False Claims Act and recover taxpayer dollars for the Medicare and Medicaid programs," noted Jim Zerhusen, U.S. Attorney for the Eastern District of Kentucky.

"This historic settlement emphasizes the government's commitment to corporate and individual accountability and to transparency throughout the pharmaceutical industry," said Daniel R. Levinson, Inspector General of the United States Department of Health and Human Services. "The corporate integrity agreement requires senior Pfizer executives and board members to complete annual compliance certifications and opens Pfizer to more public scrutiny by requiring it to make detailed disclosures on its Web site. We expect this agreement to increase integrity in the marketing of pharmaceuticals."

"The off-label promotion of pharmaceutical drugs by Pfizer significantly impacted the integrity of TRICARE, the Department of Defense's healthcare system," said Sharon Woods, Director, Defense Criminal Investigative Service. "This illegal activity increases patients' costs, threatens their safety and negatively affects the delivery of healthcare services to the over nine million military members, retirees and their families who rely on this system. Today's charges and settlement demonstrate the ongoing commitment of the Defense Criminal Investigative Service and its law enforcement partners to investigate and prosecute those that abuse the government's healthcare programs at the expense of the taxpayers and patients."

"Federal employees deserve health care providers and suppliers, including drug manufacturers, that meet the highest standards of ethical and professional behavior," said Patrick E. McFarland, Inspector General of the U.S.

Office of Personnel Management. "Today's settlement reminds the pharmaceutical industry that it must observe those standards and reflects the commitment of federal law enforcement organizations to pursue improper and illegal conduct that places health care consumers at risk."

"Health care fraud has a significant financial impact on the Postal Service. This case alone impacted more than 10,000 postal employees on workers' compensation who were treated with these drugs," said Joseph Finn, Special Agent in Charge for the Postal Service's Office of Inspector General. "Last year the Postal Service paid more than $1 billion in workers' compensation benefits to postal employees injured on the job."

Revision: HCFA-PM-91-4 (BPD) OMB No. 0938-
AUGUST 1991

STATE PLAN UNDER TITLE XIX OF THE SOCIAL SECURITY ACT
MEDICAL ASSISTANCE PROGRAM

State/Territory: ALASKA

Citation

42 CFR
430.10

As a condition for receipt of Federal funds under title XIX of the Social Security Act, the

Department of Health and Social Services
(Single State Agency)

submits the following State plan for the medical assistance program, and hereby agrees to administer the program in accordance with the provisions of this State plan, the requirements of titles XI and XIX of the Act, and all applicable Federal regulations and other official issuances of the Department.

11375 DATA REQUIREMENTS

The minimum data element file requirements for systems approval derive from State plan requirements and Federal reporting requirements. Data elements related to services not covered in the State plan need not be included.

Claim format and content varies depending upon the type of provider that submits a claim and individual State plan requirements.

NOTE: Subtitle F of Public Law 104-191 mandates that the Secretary of the Department of Health and Human Services adopt a wide range of national standards for the electronic exchange of health information. Standards are to be adopted for: 1) electronic transactions and data elements, 2) code sets, 3) unique health identifiers for individuals, providers, health plans, and employers, 4) security of health information, and 5) electronic signatures. The recommended standards for various types of standards mandated under Public Law 104-191 will be made available for public comment via Notices of Proposed Rulemaking in the Federal Register. Once standards are published as Final Rules in the Federal Register, States and all health related providers must implement standards within 2 years from the Federal Register publication date. The final standards will supersede any/all standards currently in place for electronic transactions and data elements.

The Uniform Hospital Discharge Data Set (UHDDS), developed through the National Committee on Vital and Health Statistics (NCVHS) and required by HHS departmental policy, effective January 1, 1975, and which meets current PRO requirements of §11205, contains, for hospital service only, discharge data as a file requirement and is identified in this section as:

* UHDDS as well as MMIS requirement
** UHDDS requirement only

The following data elements contained in the systems files are minimal and not exclusive requirements for source and use within the MMIS.

1. Recipient Identification Number:
   A number that uniquely identifies an individual eligible for Medicaid benefits.

*2. Recipient Social Security Number (SSN):
   The number used by SSA throughout a wage earner's lifetime to identify earnings under the Social Security program.

   For newborns and children not having a SSN but covered under Medicaid use No. 1 above to identify these eligibles.

3. Recipient Social Security Claim Number:
   The number assigned to an individual by the SSA under which monthly cash benefits (and Medicare benefits) are paid or eligibility is established.

4. Recipient's Name:
   The name of the recipient.

*5. Recipient's Address:
The address of the recipient.

*6. Recipient's Date of Birth:
The date of birth of the recipient.

7. Recipient's Race Code:
a. The racial origin of the recipient
** b. Race/Ethnic
White, Black, Hispanic, Asian/Pacific Islander, American/Indian/Alaska Native, and other

*8. Recipient's Sex Code:
The sex of the recipient.

9. Recipient's Aid Category:
The statutory category of public assistance, SSI or State supplementary payment under which a recipient is eligible for Medicaid benefits.

10. Gross Family Income:
The monthly gross income for the family of which this recipient is a member.

11. Family Size:
The number of persons in the family of which this recipient is a member.

12. Eligibility Beginning Date:
A date that begins a period in which a recipient was certified as eligible to receive Medicaid benefits.

13. Eligibility Ending Date:
A date concluding a period in which a recipient is eligible to receive Medicaid benefits.

14. Third Party Liability Code:
a. A code indicating availability to a recipient of potential third party resources.
** b. Expected Principal Source of Payment
(1) Self-pay
(2) Workmen's Compensation
(3) Medicare
(4) Medicaid
(5) Maternal and Child Health
(6) Other Government Payments
(7) Blue Cross
(8) Insurance Companies
(9) No charge (free, charity, special research, or teaching)
(10) Other

15. Buy-In Status Code:
The code indicating a recipient's status with respect to the Medicare Buy- In Program.

16. Recipient Exception Indicator:
A code indicating that all claims for a given recipient are to be manually reviewed prior to payment.

17. Money Payment Code:
A code indicating whether or not the recipient is currently receiving cash assistance.

18. Medicare Type Code:
A code indicating whether the recipient is covered by Medicare, and, if so, whether he/she has Hospital Insurance Benefits (Part A) and/or Supplementary Medical Insurance Benefits (Part B).

19. Buy-In Eligibility Date:
The date from which the recipient is eligible for the Medicare Buy-In Program.

20. Buy-In Premium Date:
The date associated with a Buy-In premium amount.

21. Buy-In Premium Amount:
The amount of money the State pays to HCFA each month per recipient for Buy-In coverage.

22. SSA-Information Exchange Code:
A code scheme consisting of various numerical codes which describe situations that can occur at SSA or at the State level.

23. Recipient's Eligibility Certification Date:
Date recipient was certified as eligible for public assistance, supplemental security income or State supplemental benefits.

24. Recipient's Location Code:
The geographic or geopolitical subdivision of a State in which the recipient resides.

25. Medicaid Premium Amount:
A recurring premium paid by medically needy individuals before they can receive Medicaid services. The amount of the fee is based upon the number of persons in the family and the gross family income.

26. Medicaid Enrollment Fee Amount:
A one-time enrollment fee paid by medically needy individuals before they can receive Medicaid services. The amount of the fee is based on the number of persons in the family and the gross family income.

27. Medicaid Deductible Amount:
The annual (or other period) amount which the recipient must pay toward the cost of medical services before Medicaid will begin to pay.

28. Date of Death:
The date of a recipient's death as indicated in the Social Services or SSI file after an official notice of death has been received.

29. Provider Number (State):
A unique number assigned by the State to each participating provider of services.

30. Provider Name:
The name of the provider of Medicaid services as used on official State records.

31. Provider Address:
The mailing address of the provider.

32. Provider Pay to Address:
The address to which Medicaid payments to a provider are sent.

33. Provider Type:
A code indicating the classification of the provider rendering health and medical services as approved under the State Medicaid plan.

34. Provider Beginning Date of Service:
A date beginning a period in which the provider was authorized to receive Medicaid payments.

35. Provider Ending Date of Service:
A date concluding a period in which the provider is authorized Medicaid payments for services rendered.

36. Provider Group Number:
The number assigned to the group practice of which an individual provider is a member.

37. Provider Type of Practice Organization:
A code identifying the organizational structure of a provider's practice.

38. Provider Employer Identification Number:
The number assigned to an employer by the Internal Revenue Service for tax reporting purposes.

39. Provider Social Security Number:
The number assigned to an individual by SSA.

*40. Medicare Provider Number:
The identification number assigned to a Medicare provider by HCFA (provider means any individual or entity furnishing Medicaid services under a provider agreement with the Medicaid agency (Reference 42 CFR 430.l).

41. Provider Year End Date:
The calendar date on which the provider's fiscal year ends.

42. Provider Specialty Code:
A code used to indicate the medical specialty of a physician.

43. Provider Exception Indicator:
A code indicating that all claims from a given provider are to be manually reviewed prior to payment.

44. Provider Credit Balance Amount:
The amount of money the Medicaid program owes a provider.

45. Provider Credit Balance Date:
The processing date on which the last amount was entered in the Provider Credit Balance amount.

46. Out-of-State Provider Code:
A code indicating that the provider is located out of State.

47. Per Diem Rate:
The payment amount for each day of care in an institution reimbursed on a per diem basis.

48. Percent-of-Charges Factor:
The percent of a provider's charges that constitutes payment for certain categories of service.

49. Rate Effective Date:
The effective date of the accompanying per diem rate or percent-of-charges factor.

50. Provider Location Code:
The geographic or geopolitical subdivision in which the provider's place of business is located.

51. Provider Enrollment Status Code:
A code indicating a provider's certification status with respect to the Medicaid program.

52. Provider Enrollment Status Date:
The effective date of the accompanying provider enrollment status code.

53. Provider Group Name and Address:
The name and mailing address of the provider group.

54. Transaction Control Number:
A unique number identifying each claim transaction received.

55. Category of Service:
A code defining the category of service rendered (e.g., general inpatient, pharmacy, physician, home health).

56. Laboratory, Medicare Certified Indicator:
A code indicating that a laboratory is approved as meeting the requirements for participation in Medicare.

57. Laboratory Service Authorized Code:
A code indicating the services/procedures that a laboratory which meets the requirements for participation in Medicare is authorized to perform.

*58. Physician Identification:
a. Attending Physician Number
The provider number of the physician attending an inpatient in a hospital, nursing home, or other institution.

This is the physician primarily responsible for the care of the patient from the beginning of this institutional episode.

**b. Operating Physician
This is the physician who performed the principal procedure. See Data Element No. 87 below, for definition of principal procedure.

59. Referring Physician Number:
The provider number of the physician referring a recipient to another practitioner or provider.

60. Prescribing Physician Number:
The provider number of the physician issuing a prescription.

*61. Principal Diagnosis Code:
a. The diagnosis code for the principal condition requiring medical attention.

**b. The condition established after study to be chiefly responsible for causing the patient's admission to the hospital for care for the current hospital stay. (HCFA requires the acceptance of ICD-9-CM coding.)

62. Other Diagnosis Code:
a. The diagnosis code of any condition other than the principal condition which requires supplementary medical treatment.

**b. Conditions (up to four) other than the principal condition that coexisted at the time of admission, or developed subsequently, which affected the treatment received and/or the length of stay. Exclude diagnoses that relate to an earlier episode which have no bearing on this hospital stay. (HCFA requires the acceptance of ICD-9-CM coding.)

*63. Admission Date:
The date a recipient was admitted to a medical institution.

64. Beginning Date of Service:
The date upon which the first service covered by a claim was rendered. If a claim is for one service only (e.g., a prescription), this is the only service date.

65. Ending Date of Service:
The date upon which the last service covered by a claim was rendered.

*66. Discharge Date:
The formal release of an inpatient from a hospital.

67. Place of Service:
A code indicating where a service was rendered by a provider.

*68. Patient Number:
Any number assigned by a provider to a recipient or claim for reference purposes, such as a medical record number.

69. Patient Status:
A code indicating the patient's status on the last date of service covered by an institutional claim.

70. Total Claim Charge:
The sum of all charges associated with an individual claim.

71. Units of Service:
A quantitative measure of the services rendered to, or for, a recipient (e.g., days, visits, miles, injections).

72. Third Party Payment Amount:
The amount of payment applied toward a claim by third party sources.

73. Medicare Cash Deductible Amount:
The unmet Medicare deductible subject to payment by Medicaid.

74. Medicare Blood Deductible Amount:
The unmet Medicare deductible for blood subject to payment by Medicaid.

75. Medicare Coinsurance Charge:
The Medicare coinsurance amount subject to payment by Medicaid.

76. Medicare Reasonable Charge:
Payment amount recognized as the reasonable charge for Medicare.

77. Medicaid Co-Payment Amount:
The portion of the claim charge which the recipient must pay, called coinsurance when expressed as a percentage of the payment amount.

78. Prior Authorization Control Number:
A number that uniquely identifies a particular instance of prior authorization.

79. Payment Amount:
The computed amount of payment due a provider for a claim transaction.

80. Date of Adjudication:
The date a claim is approved (or partially approved) or disallowed.

81. Error Code:
A code indicating the nature of an error condition associated with that claim transaction.

82. Date Entered Suspense:
The date a claim transaction was initially suspended.

83. Payment Date:
The date a payment instrument was generated for a claim transaction.

84. Allowable Procedure Payment:
The maximum allowed amount payable for a particular medical procedure, treatment, or service item.

85. Professional Fee:
The amount allowed to a dispenser of drugs as compensation for his professional services.

86. Prescription Number:
The number assigned by a pharmacist to a prescription at the time it is filled.

87. Procedure Codes:
Codes identifying medical procedures (i.e. accept and use exclusively the HCPCS in a physician or outpatient setting). (For an inpatient setting, ICD-9-CM Volume 3 is recommended).

**a. Principal Significant Procedures:
When more than one procedure is reported, designate the principal procedure. In determining which of several procedures is the principal, apply the following criteria:

(1) The principal procedure is the one which was performed for definitive treatment rather than performed for diagnostic or exploratory purposes, or was necessary to take care of a complication.

(2) The principal procedure is that procedure most closely related to the principal diagnosis.

**b. Other Significant Procedures:

(1) One which carries an operative or anesthetic risk, requires highly trained personnel, or requires special facilities or equipment.

(2) Up to four significant procedures can be reported.

(HCFA requires the acceptance of ICD-9-CM coding.)

88. Drug Code:
Codes identifying particular drugs; e.g., National Drug Code, drug tables.

89. Diagnosis Code:
A table of codes identifying medical conditions; i.e., ICD-9-CM.

90. Drug Name:
The generally accepted nomenclature for a particular drug.

91. Drug Classification:
The therapeutic group in to which a drug is categorized.

92. Minimum Days Supply of Drugs:
The minimum units of a drug prescription eligible for payment.

93. Maximum Days Supply of Drug:
The maximum units of a drug prescription eligible for a particular drug.

94. Procedures Names:
The generally accepted nomenclature for medical, surgical, dental, etc., procedure.

95. Diagnosis Name:
The generally accepted nomenclature for a diagnosis. Name is required only if not encoded by provider. (See Data Element No. 6l.)

96. Unit of Measure:
The unit in which a drug is dispensed (e.g., cc, capsule, tablet).

97. Drug Cancellation Date:
The date after which a particular drug is no longer covered under the State Medicaid program.

98. Medicaid Reasonable Charge:
Payment amount recognized as the reasonable charge for Medicaid.

*99. Discharged Patient's Destination:
A code indicating a recipient's destination upon discharge from a medical institution.

a. Discharged to home (routine discharge).
b. Left against medical advice.
c. Discharged to another short term hospital.
d. Discharged to a long term care institution.
e. Died.
f. Other.

100. Billing Date:
The date a provider indicates a claim was prepared.

101. Procedure Charge:
The charge for an individual procedure, treatment, or service item as submitted by the provider.

102. Drug Charge:
The charge submitted by a provider for a given drug prescription.

103. Adjustment Amount:
The amount (plus or minus) by which a provider's account is to be changed.

104. Date Claim Received:
The date on which a claim transaction is received by the claims processing agency.

105. Date of Surgery:
The date on which a surgical procedure(s) was performed on an inpatient.

106. Drug Wholesale Cost:
The generally accepted wholesale cost of a drug.

107. Maximum Allowed Price:
The maximum amount that will be paid for a procedure, treatment, or service item.

108. Valid Sex Indicator:
A code which indicates when a procedure or diagnosis is limited to one sex only.

109. Age Range Indicator:
A code which specifies an age range when a procedure or diagnosis is limited to a particular age group.

110. Budgeted Amount:
The planned expenditures for various Medicaid services over a given period of time.

111. Screening Results Code:
A code indicating the outcome of the various screening tests rendered.

112. Screening Referral Code:
A code indicating the nature of any referrals made as a result of screening.

113. Screening Related Treatment:
A code identifying procedures or services received as a result of screening.

114. Family Planning Code:
A code indicating whether any diagnosis, treatment, drugs, supplies, and devices, counseling service, or other billed services or materials are for the purposes of family planning.

115. Certification Review Indicator:
Indicator showing that review was made of certification of a recipient who has been admitted to institutional care including approval status.

116. Certification/Recertification Date:
The date of certification/recertification of a recipient who has been admitted to institutional care.

117. Certification Status:
An indication of initial certification status of a patient in an institution.

118. Number of Requests for Extension:
The number of times an extension of certification of stay was requested for a patient in an institution.

119. Days Certified Initially:
The number of days stay certified initially for a patient in an institution.

120. Total Days Certified:
The total number of days stay certified for a patient in an institution.

121. Date of Application:
The date that a recipient applied for eligibility status in the Medicaid program.

122. SSN of an Absent Parent:
See 42 CFR 433.138 for the conditions under which this piece of information must be captured.

disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. (See Cautions: Pediatric Precautions, in Fluoxetine Hydrochloride 28:16.04.20) Anyone considering the use of mirtazapine in a child or adolescent for any clinical use must therefore balance the potential risks with the clinical need. (See Suicidality Precautions under Dosage and Administration: Dosage.)

■ **Dosage in Renal and Hepatic Impairment** Although clearance of mirtazapine may decrease in patients with hepatic or moderate to severe renal impairment, the manufacturer does not make specific recommendations for dosage adjustment in such patients. However, the manufacturer states that since plasma concentrations of mirtazapine may be increased in patients with hepatic or moderate to severe renal impairment, the drug should be used with caution in such patients.

Description

Mirtazapine is a piperazinoazepine-derivative antidepressant agent. As a tetracyclic antidepressant agent, the drug differs structurally from selective serotonin-reuptake inhibitors (e.g., fluoxetine, sertraline), monoamine oxidase inhibitors, and tricyclic antidepressant agents.

The exact mechanism of antidepressant action of mirtazapine has not been fully elucidated, but the drug appears to act as an antagonist at central presynaptic α_2-adrenergic autoreceptors and heteroreceptors resulting in enhanced central noradrenergic and serotonergic activity. Mirtazapine is a potent antagonist of serotonin type 2 (5-HT_2) and type 3 (5-HT_3) receptors, but the drug does not exhibit high affinity for serotonin type 1A (5-HT_{1A}) or type 1B (5-HT_{1B}) receptors. Mirtazapine is a potent antagonist of histamine H_1 receptors, which may account for the prominent sedative effects of the drug. In addition, the drug exhibits moderate peripheral α_1-adrenergic blocking activity that may explain the occasional orthostatic hypotension that reportedly has been associated with mirtazapine. The drug is a moderate antagonist at muscarinic receptors, which may account for the relatively low incidence of anticholinergic effects associated with mirtazapine.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

ANTIPSYCHOTICS 28:16.08
ATYPICAL ANTIPSYCHOTICS 28:16.08.04

Aripiprazole

■ Aripiprazole is considered an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Aripiprazole is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia Aripiprazole is used orally for the acute and maintenance treatment of schizophrenia in adults and adolescents 13–17 years of age. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms and, more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

Short-term efficacy of oral aripiprazole monotherapy in the acute treatment of schizophrenia in adults was evaluated in 5 placebo-controlled studies of 4 and 6 weeks' duration principally in acutely relapsed, hospitalized patients who predominantly met DSM-III/IV criteria for schizophrenia. Four of the 5 studies were able to distinguish aripiprazole from placebo, but the smallest study did not. In the 4 positive studies, assessment of improvement in manifestations of schizophrenia was based on results of psychiatric rating scales, including the Positive and Negative Syndrome Scale (PANSS), the PANSS positive subscale, the PANSS negative subscale, and the Clinical Global Impressions (CGI) scale. Aripiprazole generally was found to be superior to placebo in improving both positive and negative manifestations in acute exacerbations of schizophrenia in these 4 studies. Efficacy of 10-, 15-, 20-, and 30-mg daily dosages of aripiprazole was established in 2 studies for each dosage; however, there was no evidence that higher dosages offered any therapeutic advantage over lower dosages in these studies. Active controls (haloperidol or risperidone) were used in addition to placebo controls in 3 of these studies, but study design did not allow for comparison between aripiprazole and the active controls. An examination of population subgroups did not reveal any clear evidence of differential responsiveness to the drug based on age, gender, or race.

In a longer-term study, adult inpatients or outpatients who met DSM-IV criteria for schizophrenia and who were, by history, symptomatically stable on other antipsychotic agents for at least 3 months were discontinued from those other agents and randomized to receive either oral aripiprazole 15 mg daily or placebo for up to 26 weeks of observation for relapse in the double-blind phase. Relapse was based on results of the CGI-Improvement and PANSS psychiatric rating scales. Patients receiving aripiprazole experienced a significantly longer time to relapse over the subsequent 26 weeks compared with those receiving placebo. In addition, pooled data from 2 double-blind, multicenter studies in acutely ill patients with schizophrenia in whom therapy with aripiprazole or haloperidol was continued for 52 weeks demonstrated a substantially higher rate of symptomatic remission across 52 weeks in the aripiprazole-treated patients compared with the haloperidol-treated patients; improved tolerability with aripiprazole may have contributed to the higher overall remission rates observed in this pooled analysis.

Short-term efficacy of oral aripiprazole in the acute treatment of schizophrenia in adolescents 13–17 years of age was evaluated in a double-blind, placebo-controlled trial of 6 weeks' duration in 302 outpatients who met DSM-IV criteria for schizophrenia and had a PANSS total score of 70 or more at baseline. Patients were randomized to receive a fixed dosage of aripiprazole 10 mg daily or 30 mg daily or to receive placebo. Both dosages of aripiprazole were found to be superior to placebo in reducing the PANSS total score, which was the primary efficacy measure; the 10-mg daily dosage also demonstrated superiority over placebo on the PANSS negative subscale score at the study

end point. However, the 30-mg daily dosage failed to demonstrate superiority over the 10-mg daily dosage. The drug was generally well tolerated.

Although the efficacy of aripiprazole as maintenance therapy in pediatric patients with schizophrenia has not been systematically evaluated, the manufacturer states that such efficacy can be extrapolated from adult data in addition to comparisons of aripiprazole pharmacokinetic parameters in adults and pediatric patients.

If aripiprazole is used for extended periods, the need for continued therapy should be reassessed periodically. (See Dosage and Administration: Dosage and see also Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

The American Psychiatric Association (APA) considers most atypical antipsychotic agents first-line drugs for the management of the acute phase of schizophrenia (including first psychotic episodes), principally because of the decreased risk of adverse extrapyramidal effects and tardive dyskinesia, with the understanding that the relative advantages, disadvantages, and cost-effectiveness of conventional and atypical antipsychotic agents remain controversial. The APA states that, with the possible exception of clozapine for the management of treatment-resistant symptoms, there currently is no definitive evidence that one atypical antipsychotic agent will have superior efficacy compared with another agent in the class, although meaningful differences in response may be observed in individual patients. Conventional antipsychotic agents may be considered first-line therapy in patients who have been treated successfully in the past with or who prefer conventional agents. The choice of an antipsychotic agent should be individualized, considering past response to therapy, adverse effect profile (including the patient's experience of subjective effects such as dysphoria), and the patient's preference for a specific drug, including route of administration.

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Aripiprazole is used as monotherapy or as an adjunct to either lithium or valproate for the acute and maintenance treatment of manic or mixed episodes associated with bipolar I disorder with or without psychotic features in adults and pediatric patients 10–17 years of age. According to DSM-IV criteria, manic episodes are distinct periods lasting 1 week or longer (or less than 1 week if hospitalization is required) of abnormally and persistently elevated, expansive, or irritable mood accompanied by at least 3 (or 4 if the mood is only irritability) of the following 7 symptoms: grandiosity, reduced need for sleep, pressure of speech, flight of ideas, distractability, increased goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation, and engaging in high-risk behavior (e.g., unrestrained buying sprees, sexual indiscretions, foolish business investments).

Efficacy of aripiprazole monotherapy in the treatment of acute manic and mixed episodes has been demonstrated in 4 short-term (i.e., 3 weeks' duration), placebo-controlled trials in hospitalized adults who met DSM-IV criteria for bipolar I disorder with manic or mixed episodes. These studies included patients with or without psychotic features and 2 of the studies also included patients with or without a rapid cycling course. The principal rating instrument used for assessing manic symptoms in these trials was the Young Mania Rating Scale (Y-MRS), an 11-item clinician-rated scale traditionally used to assess the degree of manic symptomatology in a range from 0 (no manic features) to 60 (maximum score). The main secondary rating instrument used in these trials was the Clinical Global Impression-Bipolar (CGI-BP) scale. In these trials, aripiprazole 15–30 mg once daily (with an initial dosage of 15 mg daily in 2 studies and an initial dosage of 30 mg daily in the other 2 studies) was found to be superior to placebo in the reduction of the Y-MRS total score and the CGI-BP Severity of Illness score (mania). In the 2 studies with an initial aripiprazole dosage of 15 mg daily, 48 and 44% of patients were receiving 15 mg daily at the study end point; in the 2 studies with an initial dosage of 30 mg daily, 86 and 85% of patients were receiving 30 mg daily at end point.

Aripiprazole is used as monotherapy for the acute and maintenance treatment of manic and mixed episodes associated with bipolar I disorder with or without psychotic features in pediatric patients 10–17 years of age. Efficacy of aripiprazole in the acute treatment of manic and mixed episodes has been demonstrated in a double-blind, placebo-controlled study of 4 weeks' duration in pediatric outpatients who met DSM-IV criteria for bipolar I disorder manic or mixed episodes (with or without psychotic features) and who had Y-MRS scores of 20 or greater at baseline. Patients in this study received aripiprazole 10 mg daily, aripiprazole 30 mg daily, or placebo. Aripiprazole was initiated at a dosage of 2 mg daily, then titrated to 5 mg daily after 2 days, and to the target dosage of 10 mg daily in 5 days or 30 mg daily in 13 days. Both dosages of aripiprazole were found to be superior to placebo in the reduction of the Y-MRS total score from baseline to week 4.

Efficacy of aripiprazole as an adjunct to lithium or valproate in the treatment of acute manic and mixed episodes has been demonstrated in a placebo-controlled study of 6 weeks' duration in adult outpatients who met DSM-IV criteria for bipolar I disorder manic or mixed type (with or without psychotic features). Patients initially received open-label lithium (dosage producing a serum lithium concentration of 0.6–1 mEq/L) or valproate (dosage producing a serum valproic acid concentration of 50–125 mcg/mL) monotherapy for 2 weeks during the lead-in phase. At the end of 2 weeks, patients demonstrating an inadequate response to lithium or valproate were randomized to receive either aripiprazole (15 mg daily or increased to 30 mg daily as early as day 7) or placebo as adjunctive therapy with open-label lithium or valproate during the 6-week, placebo-controlled phase. Patients who received adjunctive aripiprazole with lithium or valproate demonstrated greater reductions in the Y-MRS total score and the CGI-BP Severity of Illness score (mania) compared with patients who received adjunctive placebo with lithium or valproate.

The use of aripiprazole as an adjunct to lithium or valproate in the acute treatment of manic or mixed episodes associated with bipolar I disorder has not been evaluated in the pediatric population. However, the manufacturer states that such efficacy can be extrapolated from adult data in addition to comparisons of aripiprazole pharmacokinetic parameters in adults and pediatric patients.

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current APA recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic such as olanzapine may be adequate. For more severe manic or mixed episodes, combination therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

The efficacy of aripiprazole as longer-term therapy (i.e., longer than 3 weeks) in adults with bipolar I disorder was demonstrated in a double-blind, placebo-controlled trial in patients with a recent manic or mixed episode who had been stabilized on aripiprazole (15–30 mg daily) and then maintained on the drug for at least 6 consecutive weeks. Following this 6-week maintenance phase, patients were randomized to receive either placebo or aripiprazole and monitored for manic or depressive relapse. Patients receiving aripiprazole experienced a significant delay in time to relapse and there were fewer relapses among those receiving aripiprazole than among those receiving placebo.

An analysis of these data for possible age- and gender-related effects on treatment outcome did not suggest any difference in aripiprazole's efficacy in bipolar disorder based on the age and gender of the patient; however, there were insufficient numbers of patients in each of the ethnic groups to adequately assess race-related effects.

Although the efficacy of aripiprazole as maintenance therapy in pediatric patients with bipolar disorder has not been evaluated, the manufacturer states that such efficacy can be extrapolated from adult data in addition to comparisons of aripiprazole pharmacokinetic parameters in adults and pediatric patients.

The manufacturer states that the efficacy of aripiprazole in bipolar disorder has not been systematically evaluated for long-term use (i.e., exceeding 6 weeks) and recommends that clinicians who elect to use aripiprazole for extended periods periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

■ **Major Depressive Disorder** Aripiprazole is used orally as an adjunct to antidepressants for the acute treatment of major depressive disorder in adults. The adjunctive efficacy of aripiprazole has been demonstrated in 2 short-term, double-blind, placebo-controlled trials of 6 weeks' duration in adults who met DSM-IV criteria for major depressive disorder and who had an inadequate response to previous antidepressant therapy (1–3 courses) in the current episode and who had also demonstrated an inadequate response during a prospective treatment period to 8 weeks of antidepressant therapy with extended-release paroxetine, extended-release venlafaxine, fluoxetine, escitalopram, or sertraline. The primary instrument used for assessing depressive symptoms was the Montgomery-Asberg Depression Rating Scale (MADRS), a 10-item clinician-rated scale used to assess the degree of depressive symptomatology. The principal secondary instrument was the Sheehan Disability Scale (SDS), a 3-item self-rated instrument used to assess the impact of depression on three domains of functioning (work/school, social life, and family life), with each item scored from 0 (not at all) to 10 (extreme). In both of these trials, aripiprazole was found to be superior to placebo in reducing mean MADRS total scores; aripiprazole was also superior to placebo in reducing the mean SDS score in one study. Patients in both trials initially received an aripiprazole dosage of 5 mg daily; subsequent dosage adjustments, based on efficacy and tolerability, could be made in 5-mg increments 1 week apart. Allowable aripiprazole dosages were 2, 5, 10, and 15 mg daily; patients who were not receiving the potent cytochrome P-450 (CYP) isoenzyme 2D6 inhibitors fluoxetine and paroxetine could also receive 20 mg daily.

An analysis of population subgroups did not reveal evidence of differential response based on age, choice of prospective antidepressant, or race. With regard to gender, a smaller mean reduction in the MADRS total score was observed in males than in females.

■ **Agitation Associated with Schizophrenia or Bipolar Mania** Aripiprazole is used IM for the acute management of agitation associated with schizophrenia or bipolar disorder, mixed or manic, in adults for whom treatment with aripiprazole is appropriate and who require an IM antipsychotic agent for rapid control of behaviors that interfere with diagnosis and care (e.g., threatening behaviors, escalating or urgently distressing behavior, self-exhausting behavior). According to DSM-IV, psychomotor agitation is defined as excessive motor activity associated with a feeling of inner tension.

The efficacy of IM aripiprazole for the management of acute agitation was established in 3 short-term (i.e., single-day), placebo-controlled trials in hospitalized, agitated patients with either schizophrenia or bipolar I disorder (manic or mixed episodes, with or without psychotic features). Each of the 3

trials used a single active comparator treatment of either haloperidol injection (for the schizophrenia studies) or lorazepam (for the bipolar mania study). Patients enrolled in the studies needed to be judged by the investigators as clinically agitated and appropriate candidates for IM therapy. In addition, the patients needed to exhibit a level of agitation that met or exceeded a threshold score of 15 on the 5 items constituting the Positive and Negative Syndrome Scale (PANSS) Excited Component (i.e., poor impulse control, tension, hostility, uncooperativeness, and excitement items) with at least 2 individual item scores of 4 ("moderate") or greater using a 1–7 scoring system, where scores of 1 or 7 indicate absent or extreme agitation, respectively. The primary measure used for assessing efficacy in managing agitation in these trials was the change from baseline in the PANSS Excited Component at 2 hours postinjection. A key secondary measure was the Clinical Global Impression of Improvement (CGI-I) scale. Patients could receive up to 3 injections of IM aripiprazole; however, patients could not receive the second injection until after the initial 2-hour period when the primary efficacy measure was assessed.

In the first placebo-controlled trial, IM aripiprazole was given in fixed single doses of 1, 5.25, 9.75, or 15 mg in agitated hospitalized patients presenting predominantly with schizophrenia. All IM aripiprazole doses, with the exception of the 1-mg dose, were found to be superior to placebo in reducing the PANSS Excited Component score and on the CGI-I scale at 2 hours following injection in this study. In the second placebo-controlled trial in agitated hospitalized patients predominantly with schizophrenia, one fixed IM dose of aripiprazole 9.75 mg was evaluated and found to be superior to placebo on the PANSS Excited Component and on the CGI-I scale at 2 hours following injection. In the third placebo-controlled trial in agitated hospitalized patients with bipolar I disorder (manic or mixed), 2 fixed aripiprazole injection doses of 9.75 mg and 15 mg were evaluated; both doses were found to be superior to placebo in reducing the PANSS Excited Component score at 2 hours postinjection. An analysis of these 3 controlled studies for possible age-, race-, or gender-related effects on treatment outcome did not suggest any difference in efficacy based on these patient characteristics.

Dosage and Administration

■ **Administration** Aripiprazole conventional tablets, orally disintegrating tablets, and oral solution are administered orally once daily without regard to meals. Aripiprazole injection is administered *only* by IM injection.

Patients receiving aripiprazole orally disintegrating tablets should be instructed not to remove a tablet from the blister package until just prior to dosing. With dry hands, the blister package should be peeled open to expose a tablet. The tablet should then be removed and placed on the tongue, where it rapidly disintegrates in saliva. The manufacturer recommends that the orally disintegrating tablets be taken without liquid; however, they may be taken with liquid, if necessary. Orally disintegrating tablets should *not* be split.

Aripiprazole injection should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit. The required volume of injection should be withdrawn from the vial into a syringe and then injected slowly IM, deep into the muscle mass. Aripiprazole injection should *not* be administered IV or subcutaneously. Unused portions of the solution should be discarded.

Patients receiving aripiprazole should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

■ **Dosage** Aripiprazole oral solution may be given at the same dose on a mg-per-mg basis as the conventional tablet strengths of the drug up to a dose of 25 mg. However, if the oral solution is used in patients who were receiving aripiprazole 30 mg as conventional tablets, a dose of 25 mg of the oral solution should be used.

Since conventional tablets and orally disintegrating tablets of aripiprazole are bioequivalent, dosing for the orally disintegrating tablets is the same as for the conventional tablets. However, IM administration of a dose of the commercially available injection results in maximum plasma aripiprazole concentrations and areas under the plasma concentration-time curve (AUCs) (2 hours post-administration) that are about 19 and 90% higher, respectively, than those resulting from an identical oral dose.

Schizophrenia For the acute management of schizophrenia in adults, the recommended initial and target dosage of aripiprazole is 10 or 15 mg orally once daily. Although dosages ranging from 10–30 mg daily administered as conventional tablets were effective in clinical trials, the manufacturer states that dosages exceeding 10–15 mg daily did not result in greater efficacy. Because steady-state plasma concentrations of aripiprazole and dehydro-aripiprazole, its active metabolite, may not be attained for 2 weeks, dosage adjustments generally should be made at intervals of not less than 2 weeks.

For the acute management of schizophrenia in adolescents 13–17 years of age, the recommended target dosage of aripiprazole is 10 mg orally once daily. Therapy was initiated in a dosage of 2 mg once daily in these patients, with subsequent titration to 5 mg once daily after 2 days and to 10 mg once daily after 2 additional days. The manufacturer recommends that any subsequent dosage increases be made in 5-mg once daily increments. Although aripiprazole dosages of 10 and 30 mg once daily administered as conventional tablets have been studied in adolescents, the 30-mg daily dosage was not found to be more effective than the 10-mg daily dosage.

The optimum duration of oral aripiprazole therapy in patients with schizophrenia currently is not known, but maintenance therapy with aripiprazole 15 mg once daily as conventional tablets has been shown to be effective in preventing relapse for up to 26 weeks in adults. In addition, a combined analysis of data from 2 double-blind, multicenter studies indicates that maintenance therapy with the drug may be effective for up to 52 weeks in adults.

Although the efficacy of oral aripiprazole as maintenance therapy in pediatric patients with schizophrenia has not been systematically evaluated, the manufacturer states that such efficacy can be extrapolated from adult data in addition to comparisons of aripiprazole pharmacokinetic parameters in adults and pediatric patients.

The American Psychiatric Association (APA) states that prudent long-term treatment options in patients with schizophrenia with remitted first episodes or multiple episodes include either indefinite maintenance therapy or gradual discontinuance of the antipsychotic agent with close follow-up and a plan to reinstitute treatment upon symptom recurrence. Discontinuance of antipsychotic therapy should be considered only after a period of at least 1 year of symptom remission or optimal response while receiving the antipsychotic agent. In patients who have had multiple previous psychotic episodes or 2 psychotic episodes within 5 years, indefinite maintenance antipsychotic treatment is recommended.

The manufacturer states that it is generally recommended that patients responding to aripiprazole therapy should continue to receive the drug beyond the acute response, but at the lowest dosage needed to maintain remission. The need for continued therapy with the drug should be reassessed periodically.

There are no systematically collected data to specifically address switching patients with schizophrenia from other antipsychotic agents to aripiprazole or concerning concomitant administration with other antipsychotic agents. Immediate discontinuance of the previous antipsychotic agent may be acceptable in some patients with schizophrenia, and more gradual discontinuance may be most appropriate for other patients. In all patients, the period of overlapping antipsychotic administration should be minimized.

Bipolar Disorder For the management of manic and mixed episodes associated with bipolar I disorder in adults, the recommended initial and target aripiprazole dosage in adults is 15 mg given orally once daily as monotherapy or as adjunctive therapy with lithium or valproate. Based on clinical response, the dosage can be increased to 30 mg daily. However, safety of aripiprazole dosages exceeding 30 mg daily has not been established.

For the management of manic and mixed episodes associated with bipolar I disorder in pediatric patients 10–17 years of age, the manufacturer recommends a target aripiprazole dosage of 10 mg daily given orally as monotherapy or as adjunctive therapy with lithium or valproate. In clinical studies, aripiprazole dosages of 10 or 30 mg daily were found to be effective; initially, pediatric patients received 2 mg daily for 2 days, then 5 mg daily for an additional 2 days, and then the target dosage of 10 mg daily. Subsequent increases in the daily dosage of aripiprazole should be made in 5-mg increments.

The optimum duration of aripiprazole therapy, whether used as monotherapy or as adjunctive therapy, for bipolar I disorder currently is not known. While it is generally agreed that pharmacologic treatment beyond an acute response in mania is desirable, both for maintenance of the initial response and for prevention of new manic episodes, there are no systematically obtained data to support the use of aripiprazole beyond 6 weeks in adults. The manufacturer states that clinicians who elect to use aripiprazole in adults for extended periods should periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

The efficacy of aripiprazole for maintenance therapy of bipolar I disorder in pediatric patients has not been evaluated; however, such efficacy can be extrapolated from adult data along with comparisons of pharmacokinetic parameters of the drug in adults and pediatric patients. It is generally recommended that responding pediatric patients continue to receive aripiprazole beyond the acute response, but at the lowest dosage needed to maintain remission. Pediatric patients should be periodically reassessed to determine the need for maintenance therapy.

Major Depressive Disorder For adjunctive management of major depressive disorder in adults already receiving an antidepressant, the manufacturer recommends an initial aripiprazole dosage of 2–5 mg orally once daily for acute treatment. Subsequent dosage adjustments of up to 5 mg daily should occur gradually at intervals of at least 1 week. Efficacy of the drug was established within a dosage range of 2–15 mg daily in clinical studies.

The manufacturer states that the efficacy of aripiprazole for adjunctive maintenance treatment of major depressive disorder has not been evaluated and the optimum duration of aripiprazole maintenance therapy for major depressive disorder is not known. If aripiprazole is used for maintenance therapy, the need for continued therapy with the drug should be reassessed periodically.

Agitation associated with Schizophrenia or Bipolar Mania For the prompt control of agitation associated with schizophrenia or bipolar mania in adults, the recommended dose of aripiprazole is 9.75 mg given IM as a single dose. In clinical trials, effectiveness of IM aripiprazole in controlling agitation in schizophrenia and bipolar mania was demonstrated with doses of 5.25–15 mg IM; however, no additional benefit was demonstrated for the 15-mg dose compared with the 9.75-mg dose. A lower initial IM dose of 5.25 mg may be considered when clinically warranted.

If agitation persists following the initial dose of aripiprazole, subsequent doses up to a cumulative dose of 30 mg daily may be given. However, the

manufacturer states that the efficacy of repeated doses of IM aripiprazole in agitated patients has not been systematically evaluated in controlled trials. In addition, the safety of total daily IM doses exceeding 30 mg or IM injections given more frequently than every 2 hours has not been adequately evaluated in clinical trials.

If continued aripiprazole therapy is clinically necessary, oral aripiprazole therapy in a dosage of 10–30 mg daily should replace IM therapy as soon as possible.

■ **Special Populations** No dosage adjustment is necessary in patients with renal or hepatic impairment or in geriatric patients. In addition, no dosage adjustment is recommended based on gender or race.

Dosage of aripiprazole should be reduced to one-half the usual dosage in patients receiving concomitant therapy with potent inhibitors of cytochrome P-450 (CYP) isoenzyme 3A4 (e.g., clarithromycin, ketoconazole). Dosage of aripiprazole should be reduced to at least one-half the usual dosage in patients receiving concomitant therapy with potential inhibitors of CYP2D6 (e.g., quinidine, fluoxetine, paroxetine). The aripiprazole dosage may be increased to the usual dosage after discontinuance of the CYP3A4 or CYP2D6 inhibitor. (See Drug Interactions: Ketoconazole and Other CYP3A4 Inhibitors and see also Drug Interactions: Quinidine and Other CYP2D6 Inhibitors.)

Dosage of aripiprazole should be doubled upon initiation of concomitant therapy with drugs that induce CYP3A4 (e.g., carbamazepine); additional dosage escalation should be based on clinical evaluation. The aripiprazole dosage should be decreased to 10–15 mg daily if the CYP3A4 inducer is discontinued. (See Drug Interactions: Carbamazepine and Other CYP3A4 Inducers.)

Cautions

■ **Contraindications** Known hypersensitivity reaction to aripiprazole or any ingredient in the formulation; such reactions have ranged from pruritus/urticaria to anaphylaxis.

■ **Warnings/Precautions** ***Warnings*** **Increased Mortality in Geriatric Patients with Dementia-related Psychosis.** Geriatric patients with dementia-related psychosis treated with antipsychotic drugs appear to be at an increased risk of death compared with patients receiving placebo. Analyses of 17 placebo-controlled trials (modal duration of 10 weeks) revealed an approximate 1.6- to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., aripiprazole, olanzapine, quetiapine, risperidone) compared with that observed in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. Observational studies suggest that, similar to atypical antipsychotics, treatment with conventional (first-generation) antipsychotics may increase mortality; the extent to which the findings of increased mortality in observational studies may be attributed to the antipsychotic drug as opposed to some characteristic(s) of the patients remains unclear. In addition, an increased incidence of cerebrovascular adverse effects (e.g., stroke, transient ischemic attack), including fatalities, has been observed in geriatric patients treated with aripiprazole in several placebo-controlled studies (2 flexible-dose studies and one fixed-dose study) of dementia-related psychosis. A statistically significant dose-response relationship for adverse cerebrovascular effects was observed in patients receiving the drug in the fixed-dose study. In 3 placebo-controlled trials of 10 weeks' duration evaluating aripiprazole in geriatric patients with psychosis associated with Alzheimer's disease, adverse effects reported in 3% or more of patients and with an incidence of at least twice that of placebo included lethargy, somnolence (including sedation), incontinence (primarily urinary incontinence), excessive salivation, and lightheadedness.

The manufacturer states that the safety and efficacy of aripiprazole in the treatment of patients with psychosis associated with dementia have not been established and that the drug is not approved for the treatment of patients with dementia-related psychosis. If the clinician elects to treat such patients with aripiprazole, vigilance should be exercised, particularly for the emergence of difficulty swallowing or excessive somnolence, which could predispose to accidental injury or aspiration. (See Geriatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

Worsening of Depression and Suicidality Risk. Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients with depressive symptoms should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Aripiprazole is not approved for use in treating depression in the pediatric population. (See Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

Other Warnings and Precautions **Neuroleptic Malignant Syndrome.** Neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment, has been reported in patients receiving antipsychotic agents, including rare cases associated with aripiprazole therapy. If a patient requires antipsychotic therapy following recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. If antipsychotic therapy is reintroduced, the dosage generally should be increased gradually and an antipsychotic agent other than the agent believed to have precipitated NMS generally should be chosen. In addition, such patients should be carefully monitored since recurrences of NMS have been reported in some patients. For additional information on NMS, see Neuroleptic Malignant Syndrome under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia. Because use of antipsychotic agents, including aripiprazole, may be associated with tardive dyskinesia (a syndrome of potentially irreversible, involuntary, dyskinetic movements), aripiprazole should be prescribed in a manner that is most likely to minimize the occurrence of this syndrome. Chronic antipsychotic treatment generally should be reserved for patients who suffer from a chronic illness that is known to respond to antipsychotic agents, and for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the lowest dosage and the shortest duration of treatment producing a satisfactory clinical response should be sought, and the need for continued treatment should be reassessed periodically. The American Psychiatric Association (APA) currently recommends that patients receiving atypical antipsychotic agents be assessed clinically for abnormal involuntary movements every 12 months and that patients considered to be at increased risk for tardive dyskinesia be assessed every 6 months. For additional information on tardive dyskinesia, see Tardive Dyskinesia under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Hyperglycemia and Diabetes Mellitus. Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients treated with all atypical antipsychotic agents. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., clozapine, olanzapine, quetiapine, risperidone); it remains to be determined whether aripiprazole also is associated with this increased risk. Although there have been few reports of hyperglycemia in patients receiving aripiprazole, it is not known whether the paucity of such reports is due to relatively limited experience with the drug.

Precise risk estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., clozapine, olanzapine) than with others (e.g., quetiapine, risperidone) in the class, available data are conflicting and insufficient to provide reliable estimates of relative risk associated with use of the various atypical antipsychotics.

The manufacturers of atypical antipsychotic agents state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia (including polydipsia, polyuria, polyphagia, and weakness) during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the suspect drug; in other cases, hyperglycemia resolved with discontinuance of the antipsychotic.

For further information on managing the risk of hyperglycemia and diabetes mellitus associated with atypical antipsychotic agents, see Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications, in Clozapine 28:16.08.04.

Orthostatic Hypotension. Orthostatic hypotension and associated adverse effects (e.g., postural dizziness, syncope) have been reported in patients receiving oral or IM aripiprazole. The drug should be used with caution in patients with known cardiovascular disease (e.g., heart failure, history of myocardial infarction or ischemia, conduction abnormalities), cerebrovascular disease, and/or conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy).

If parenteral benzodiazepine therapy is necessary in patients receiving IM aripiprazole, patients should be monitored for excessive sedation and orthostatic hypotension. (See Drug Interactions: Lorazepam and Other Benzodiazepines.)

Leukopenia, Neutropenia, and Agranulocytosis. In clinical trial and/or postmarketing experience, leukopenia and neutropenia have been temporally related to antipsychotic agents, including aripiprazole. Agranulocytosis also has been reported.

Risk factors for leukopenia and neutropenia include preexisting low leukocyte count and a history of drug-induced leukopenia and neutropenia. Patients with a history of clinically important low leukocyte count or drug-induced leukopenia and neutropenia should have their complete blood count monitored frequently during the first few months of therapy. Discontinuance of aripiprazole should be considered at the first sign of a clinically important decline in leukocyte count in the absence of other causative factors.

Patients with clinically significant neutropenia should be carefully monitored for fever or other signs or symptoms of infection and promptly treated if such signs and symptoms occur. In patients with severe neutropenia (absolute neutrophil count [ANC] less than 1000/mm^3), aripiprazole should be discontinued and the leukocyte count monitored until recovery occurs. Lithium has reportedly been used successfully in the treatment of several cases of leukopenia associated with aripiprazole, clozapine, and some other drugs; however, further clinical experience is needed to confirm these anecdotal findings.

Seizures. Seizures have occurred in 0.1% of adults treated with oral aripiprazole, in 0.3% of pediatric patients 10–17 years of age, and in 0.2% of adults treated with parenteral aripiprazole. Aripiprazole should be used with caution in patients with a history of seizures or other conditions that may lower the seizure threshold (e.g., dementia of the Alzheimer's type); conditions that lower the seizure threshold may be more prevalent in geriatric patients 65 years of age or older.

Cognitive and Motor Impairment. Like other antipsychotic agents, aripiprazole potentially may impair judgment, thinking, or motor skills. In short-term clinical trials, somnolence (including sedation) was reported in 11 and 9% of adults treated with oral or parenteral aripiprazole, respectively, compared with 6% of those receiving placebo. In pediatric patients 10–17 years of age, somnolence (including sedation) was reported in 21% of aripiprazole-treated patients compared with 5% of those receiving placebo. (See Advice to Patients.)

Body Temperature Regulation. Disruption of the body's ability to reduce core body temperature has been attributed to antipsychotic agents. The manufacturer recommends appropriate caution when aripiprazole is used in patients exposed to conditions that may contribute to an elevation in core body temperature (e.g., dehydration, extreme heat, strenuous exercise, concomitant use of anticholinergic agents).

Suicide. Attendant risk with psychotic illnesses, bipolar disorder, and major depressive disorder; high-risk patients should be closely supervised. In 2 clinical trials evaluating aripiprazole as adjunctive therapy in patients with major depressive disorder, there were no reported cases of suicidal ideation or suicide attempt in the aripiprazole-treated patients; the incidence of suicidal ideation and suicide attempt was 0.5% in the placebo recipients. Aripiprazole should be prescribed in the smallest quantity consistent with good patient management to reduce the risk of overdosage. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Dysphagia. Esophageal dysmotility and aspiration have been associated with the use of antipsychotic agents, including aripiprazole. These agents should be used with caution in patients at risk for aspiration pneumonia (e.g., geriatric patients, those with advanced Alzheimer's dementia). (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions and see Geriatric Use under Warnings/Precautions: Special Populations, in Cautions.)

Phenylketonuria. Individuals with phenylketonuria (i.e., homozygous genetic deficiency of phenylalanine hydroxylase) and other individuals who must restrict their intake of phenylalanine should be warned that each aripiprazole 10- or 15-mg orally disintegrating tablet contains aspartame, which is metabolized in the GI tract to provide about 1.12 or 1.68 mg of phenylalanine, respectively, following oral administration. Aripiprazole conventional tablets do not contain aspartame.

Concomitant Illnesses. Experience with aripiprazole in patients with certain concomitant diseases is limited. (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions.)

Aripiprazole has not been adequately evaluated or used to any appreciable extent in patients with a recent history of myocardial infarction or unstable cardiovascular disease and patients with these conditions were excluded from premarketing clinical studies. Because of the risk of orthostatic hypotension associated with aripiprazole, the manufacturer states that the drug should be used with caution in patients with cardiovascular disease, cerebrovascular disease, and/or other conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy). (See Orthostatic Hypotension under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Aripiprazole is distributed into milk in rats. Not known whether aripiprazole is distributed into milk in humans. The manufacturer states that women receiving aripiprazole should not breast-feed.

Pediatric Use. Safety and efficacy of oral aripiprazole not established in pediatric patients with major depressive disorder. Safety and efficacy of IM aripiprazole not established for agitation associated with schizophrenia or bipolar mania in pediatric patients.

Safety and efficacy of oral aripiprazole for the acute management of schizophrenia in pediatric patients 13–17 years of age have been established in a placebo-controlled study of 6 weeks' duration. Although the efficacy of oral aripiprazole for maintenance treatment of schizophrenia has not been systematically evaluated, the manufacturer states that such efficacy can be extrapolated from adult data in addition to comparisons of aripiprazole pharmacokinetic parameters in adults and pediatric patients. (See Schizophrenia under Uses: Psychotic Disorders.)

Safety and efficacy of oral aripiprazole monotherapy for the acute management of bipolar mania in pediatric patients 10–17 years of age have been established in a placebo-controlled study of 4 weeks' duration. Although the efficacy of oral aripiprazole for maintenance treatment in bipolar disorder has not been established, such efficacy can be extrapolated from adult data in addition to pharmacokinetic comparisons of aripiprazole between adult and pediatric populations.

The efficacy of oral aripiprazole as an adjunct to lithium or valproate for the management of manic or mixed episodes in pediatric patients has not been evaluated. However, efficacy can be extrapolated from adult data in addition to pharmacokinetic comparisons of aripiprazole between adult and pediatric populations.

Mean weight gain of 0.13 kg was reported in pediatric patients with schizophrenia receiving aripiprazole compared with a mean loss of 0.83 kg in those receiving placebo in a short-term (6-week) study; 5% of aripiprazole-treated patients gained 7% or more of their baseline weight compared with 1% of those receiving placebo.

FDA warns that a greater risk of suicidal thinking or behavior (suicidality) occurred during the first few months of antidepressant treatment compared with placebo in children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders based on pooled analyses of 24 short-term, placebo-controlled trials of 9 antidepressant drugs (selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants). However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

These findings should be carefully considered when assessing potential benefits and risks of aripiprazole in a child or adolescent for any clinical use. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Geriatric Use. In clinical studies, approximately 8% of over 13,000 patients treated with oral aripiprazole were 65 years of age or older and approximately 6% were 75 years of age or older; the majority of these geriatric patients (81%) were diagnosed with dementia of the Alzheimer's type. Experience from placebo-controlled trials with oral aripiprazole in patients with schizophrenia, bipolar mania, or major depressive disorder who are 65 years of age and older is insufficient to determine whether they respond differently than younger adults.

In clinical studies, approximately 13% of over 700 patients treated with IM aripiprazole were 65 years of age or older and approximately 10% were 75 years of age or older. Experience from placebo-controlled trials with aripiprazole injection in patients with agitation associated with schizophrenia or bipolar mania who are 65 years of age and older is insufficient to determine whether they respond differently than younger adults.

Studies in patients with psychosis in association with dementia of the Alz-

heimer's type have suggested that aripiprazole may have a different tolerability profile in patients 65 years of age or older compared with younger patients with schizophrenia. The manufacturer states that the safety and efficacy of aripiprazole in the treatment of dementia-associated psychosis have not been established and that the drug is *not* approved for the treatment of dementia-related psychosis. If a clinician decides to treat geriatric patients with dementia-associated psychosis with aripiprazole, the manufacturer recommends that caution be exercised (see Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions). For additional information on the use of antipsychotic agents in the management of dementia-related psychosis, see Geriatric Considerations under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

■ **Common Adverse Effects** Adverse effects occurring in 10% or more of adults receiving oral aripiprazole in clinical trials include nausea, vomiting, constipation, headache, dizziness, akathisia, anxiety, insomnia, and restlessness.

Adverse effects occurring in 10% or more of pediatric patients receiving oral aripiprazole in clinical trials include somnolence, extrapyramidal disorder, headache, and nausea.

In clinical trials, nausea was the only adverse effect that occurred in more than 5% of patients with agitation associated with schizophrenia or bipolar mania receiving IM aripiprazole and at an incidence at least twice that for placebo.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes** Cytochrome P-450 (CYP) isoenzyme 3A4 (CYP3A4) inducers (e.g., carbamazepine), CYP3A4 inhibitors (e.g., clarithromycin, ketoconazole), or CYP2D6 inhibitors (e.g., fluoxetine, paroxetine, quinidine): potential pharmacokinetic interaction (altered aripiprazole metabolism); dosage adjustment generally recommended. (See Dosage and Administration: Special Populations, Drug Interactions: Carbamazepine and Other CYP3A4 Inducers, Drug Interactions: Ketoconazole and Other CYP3A4 Inhibitors, and Drug Interactions: Quinidine and Other CYP2D6 Inhibitors.)

Inhibitors or inducers of CYP isoenzyme 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, or 2E1: pharmacokinetic interaction unlikely. (See Drug Interactions: Smoking.)

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Substrates of CYP isoenzyme 1A2, 2C9, 2C19, 2D6, and 3A4: pharmacokinetic interaction unlikely.

■ **Carbamazepine and Other CYP3A4 Inducers** Concurrent administration of carbamazepine (200 mg twice daily), a potent CYP3A4 inducer, and aripiprazole (30 mg daily) resulted in an approximate 70% decrease in peak plasma concentration and area under the plasma concentration-time curve (AUC) values of both aripiprazole and its active metabolite, dehydro-aripiprazole.

When a potential CYP3A4 inducer such as carbamazepine is added to aripiprazole therapy, the dosage of aripiprazole should be doubled; additional dosage increases should be based on clinical evaluation. When the CYP3A4 inducer is withdrawn from combined therapy, the aripiprazole dosage should be reduced to 10–15 mg daily. (See Dosage and Administration: Special Populations.)

■ **Ketoconazole and Other CYP3A4 Inhibitors** Concurrent administration of ketoconazole (200 mg daily for 14 days), a potent CYP3A4 inhibitor, and a single 15-mg dose of aripiprazole increased the AUCs of aripiprazole and its active metabolite by 63 and 77%, respectively; the effect of a higher ketoconazole dosage (e.g., 400 mg daily) has not been studied.

When concurrent therapy with aripiprazole and a potent CYP3A4 inhibitor such as ketoconazole or clarithromycin is clinically indicated, the dosage of aripiprazole should be reduced to one-half of the usual dosage. Other potent inhibitors of CYP3A4 (e.g., itraconazole) would be expected to have similar effects and require similar dosage reductions; the effect of moderate inhibitors (e.g., erythromycin, grapefruit juice) has not been studied. When the CYP3A4 inhibitor is withdrawn from combined therapy, the aripiprazole dosage should be increased. (See Dosage and Administration: Special Populations.)

■ **Quinidine and Other CYP2D6 Inhibitors** Concomitant administration of a single 10-mg dose of aripiprazole with quinidine (166 mg daily for 13 days), a potent CYP2D6 inhibitor, increased the AUC of aripiprazole by 112% but decreased the AUC of its active metabolite, dehydro-aripiprazole, by 35%. Other drugs that substantially inhibit CYP2D6 (e.g., fluoxetine, paroxetine) would be expected to have similar effects as quinidine.

When aripiprazole is given concurrently with potential CYP2D6 inhibitors such as quinidine, fluoxetine, or paroxetine, the dosage of aripiprazole should be reduced to at least one-half of the usual dosage. When the CYP2D6 inhibitor is withdrawn from combined therapy, the aripiprazole dosage should then be increased. When adjunctive aripiprazole is administered to patients with major depressive disorder, aripiprazole should be given without dosage adjustment. (See Major Depressive Disorder under Dosage and Administration: Dosage, and see also Drug Interactions: Fluoxetine, Paroxetine, and Sertraline.)

■ **Anticholinergic Agents** Potential pharmacologic interaction (possible disruption of body temperature regulation); use aripiprazole with caution in patients concurrently receiving drugs with anticholinergic activity. (See Body Temperature Regulation under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Hypotensive Agents** Potential pharmacologic interaction (additive hypotensive effects); use with caution.

■ **Lorazepam and Other Benzodiazepines** Clinically important pharmacokinetic changes not reported during concurrent administration of parenteral lorazepam and IM aripiprazole. The manufacturer states that aripiprazole dosage adjustment is not necessary when aripiprazole is concurrently administered with lorazepam. However, increased sedative and orthostatic hypotensive effects have been reported in patients receiving these drugs in combination. If therapy with IM aripiprazole in conjunction with a parenteral benzodiazepine is considered necessary, the patient should be carefully monitored for excessive sedation and orthostatic hypotension. (See Orthostatic Hypotension and see also Cognitive and Motor Impairment under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Other CNS Agents or Alcohol** Potential pharmacologic interaction (additive CNS effects). Use with caution.

■ **Dextromethorphan** Clinically important pharmacokinetic interaction unlikely. Dosage adjustment of dextromethorphan is not necessary when administered concomitantly with aripiprazole.

■ **Famotidine** Potential pharmacokinetic interaction (decreased aripiprazole rate and extent of absorption); not clinically important and no dosage adjustment of aripiprazole is necessary when administered concurrently with famotidine.

■ **Lamotrigine** Combined aripiprazole and lamotrigine therapy appears to be well tolerated in patients with bipolar disorder. Pharmacokinetic interaction unlikely; no dosage adjustment of lamotrigine is necessary when aripiprazole is administered concurrently.

■ **Lithium** Clinically important pharmacokinetic interaction unlikely; no dosage adjustment of aripiprazole or lithium is necessary during concurrent administration.

■ **Omeprazole** Concurrent administration of aripiprazole 10 mg daily for 15 days in healthy individuals did not substantially alter the pharmacokinetics of a single 20-mg dose of omeprazole, a CYP2C19 substrate. Dosage adjustment of omeprazole is not necessary when administered concurrently with aripiprazole.

■ **Escitalopram** Concurrent administration of aripiprazole 10 mg daily for 14 days in healthy individuals did not substantially alter the steady-state pharmacokinetics of 10 mg daily of escitalopram, a CYP2C19 and CYP3A4 substrate. Dosage adjustment of escitalopram is not necessary when aripiprazole is added to escitalopram therapy.

■ **Fluoxetine, Paroxetine, and Sertraline** A population pharmacokinetic analysis in patients with major depressive disorder did not demonstrate substantial changes in the pharmacokinetics of fluoxetine, paroxetine, or sertraline (dosed to steady state) following the addition of aripiprazole therapy.

However, fluoxetine and paroxetine are inhibitors of CYP2D6 and the manufacturer recommends that aripiprazole dosage be reduced to one-half the usual dosage in patients receiving concomitant therapy with inhibitors of CYP2D6, including fluoxetine and paroxetine. When the CYP2D6 inhibitor is withdrawn from combined therapy with aripiprazole, the aripiprazole dosage should be increased. When adjunctive aripiprazole is concurrently administered to patients with major depressive disorder receiving fluoxetine or paroxetine, aripiprazole should be given without dosage adjustment. (See Dosage and Administration: Special Populations and see also Drug Interactions: Quinidine and Other CYP2D6 Inhibitors.)

■ **Smoking** Pharmacokinetic interaction unlikely. Dosage adjustment in patients who smoke is not necessary.

■ **Valproate** Clinically important pharmacokinetic interaction unlikely; no dosage adjustment of aripiprazole or valproate is necessary during concurrent administration.

■ **Venlafaxine** Concurrent administration of aripiprazole 10–20 mg daily for 14 days in healthy individuals did not substantially alter the steady-state pharmacokinetics of venlafaxine and O-desmethylvenlafaxine following 75 mg daily of extended-release venlafaxine, a CYP2D6 substrate. Dosage adjustment of venlafaxine is not necessary when aripiprazole is added to venlafaxine therapy.

■ **Warfarin** Concurrent administration of aripiprazole 10 mg daily for 14 days did not substantially affect warfarin pharmacokinetics or the international normalized ratio (INR), suggesting a lack of a clinically important effect of aripiprazole on CYP2C9 and CYP2C19 metabolism or the binding of highly protein-bound warfarin. Warfarin dosage adjustment is not necessary when administered concurrently with aripiprazole.

Description

Aripiprazole is a quinolinone derivative antipsychotic agent that differs chemically from other currently available antipsychotic agents (e.g., butyro-

phenones, phenothiazines) and has been referred to as an atypical or second-generation antipsychotic agent. The exact mechanism of action of aripiprazole in schizophrenia, bipolar mania, major depressive disorder, and agitation associated with schizophrenia or bipolar mania has not been fully elucidated but, like that of other drugs with efficacy in these conditions (e.g., olanzapine, risperidone, ziprasidone), may involve the drug's activity at dopamine D_2 and serotonin type 1 ($5\text{-}HT_{1A}$) and type 2 ($5\text{-}HT_{2A}$) receptors. However, aripiprazole appears to differ from other atypical antipsychotic agents because the drug demonstrates partial agonist activity at D_2 and $5\text{-}HT_{1A}$ receptors and antagonist activity at $5\text{-}HT_{2A}$ receptors. Antagonism at other receptors (e.g., α_1-adrenergic receptors, histamine H_1 receptors) may contribute to other therapeutic and adverse effects (e.g., orthostatic hypotension, somnolence) observed with aripiprazole.

Aripiprazole is extensively metabolized in the liver principally via dehydrogenation, hydroxylation, and *N*-dealkylation by the cytochrome P-450 (CYP) 2D6 and 3A4 isoenzymes. The major active metabolite of aripiprazole, dehydro-aripiprazole, exhibits affinity for D_2 receptors similar to that of the parent compound and represents approximately 40% of aripiprazole area under the concentration-time curve (AUC) in plasma. Steady-state plasma concentrations of both aripiprazole and dehydro-aripiprazole are achieved within 14 days. The elimination half-lives of aripiprazole and dehydro-aripiprazole are approximately 75 and 94 hours, respectively. Approximately 18% and less than 1% of aripiprazole is excreted unchanged in feces and urine, respectively.

Advice to Patients

Importance of providing copy of written patient information (medication guide) each time aripiprazole is dispensed. Importance of advising patients to read the patient information before taking aripiprazole and each time the prescription is refilled.

Increased mortality in geriatric patients with dementia-related psychosis; importance of advising patients and caregivers that geriatric patients with dementia-related psychosis treated with antipsychotic agents are at an increased risk of death. Patients and caregivers should also be informed that aripiprazole is *not* approved for treating geriatric patients with dementia-related psychosis.

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment.

Because somnolence and impairment of judgment, thinking, or motor skills may be associated with aripiprazole, avoid driving, operating machinery, or performing hazardous tasks while taking aripiprazole until the drug's effects on the individual are known. Importance of avoiding alcohol during aripiprazole therapy.

Risk of neuroleptic malignant syndrome (NMS), a rare but life-threatening syndrome that can cause high fever, stiff muscles, sweating, fast or irregular heart beat, change in blood pressure, confusion, and kidney damage. Importance of informing patients to immediately contact a healthcare professional if such symptoms develop.

Importance of clinicians informing patients in whom chronic aripiprazole use is contemplated of risk of tardive dyskinesia. Importance of informing patients to report any muscle movements that cannot be stopped to a healthcare professional.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., diabetes mellitus).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of avoiding overheating or dehydration.

For patients taking aripiprazole orally disintegrating tablets, importance of not removing a tablet from the blister package until just before administering a dose; importance of peeling blister open with dry hands and placing tablet on tongue to dissolve and be swallowed with saliva.

Importance of informing patients with phenylketonuria that aripiprazole orally disintegrating 10- and 15-mg tablets contain 1.12 and 1.68 mg of phenylalanine, respectively.

Importance of being aware that aripiprazole oral solution contains 400 mg of sucrose and 200 mg of fructose per mL.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview* (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Aripiprazole

Oral		
Solution	5 mg/5 mL	**Abilify* Oral Solution**, Otsuka (also promoted by Bristol-Myers Squibb)
Tablets	2 mg	**Abilify***, Otsuka (also promoted by Bristol-Myers Squibb)

Injection, for IM use only	7.5 mg/mL (9.75 mg)	**Abilify***, Otsuka (also promoted by Bristol-Myers Squibb)

Clozapine

■ Clozapine has been referred to as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Clozapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia and generally are effective in all subtypes of the disorder and subgroups of patients. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Clozapine has been shown to be an effective, relatively rapid-acting, broad-spectrum antipsychotic agent in both uncontrolled and controlled studies of patients with schizophrenia. In these studies, improvement in manifestations of schizophrenia was based on the results of various psychiatric rating scales, principally the Brief Psychiatric Rating Scale (BPRS) that assesses factors such as anergy, thought disturbance, activation, hostility/suspiciousness, and anxiety/depression. In clinical studies, clozapine improved both positive (florid symptomatology such as hallucinations, conceptual disorganization, and suspiciousness) and negative ("deficit" symptomatology such as emotional withdrawal, motor retardation, blunted affect, and disorientation) manifestations of schizophrenia; conventional (typical) antipsychotic agents appear to have lesser effects on negative manifestations of the disorder. In comparative studies, clozapine was at least as effective as, or more effective than several conventional antipsychotic agents, including chlorpromazine, haloperidol, perphenazine, or trifluoperazine.

Unlike conventional antipsychotic agents, however, clozapine generally does not induce extrapyramidal effects and has not been clearly implicated as a causative agent in tardive dyskinesia.

While the risks of adverse neurologic effects with long-term clozapine therapy remain to be fully elucidated, other adverse effects, including some potentially serious effects (e.g., agranulocytosis, seizures), may occur more frequently with clozapine therapy. Consequently, the manufacturers and most clinicians currently state that use of clozapine should be reserved for patients with severe disease that fails to respond adequately to conventional antipsychotic therapy, either because of insufficient effectiveness or the inability to achieve an effective dose due to intolerable adverse effects from those drugs. What constitutes an adequate trial of standard antipsychotic therapy, however, varies widely. The manufacturers and some clinicians recommend that a patient be given an adequate trial of at least 2 different antipsychotic agents from at least 2 different chemical classes (e.g., phenothiazines, butyrophenones, thioxanthenes) before the patient is considered a candidate for clozapine therapy. The American Psychiatric Association (APA), however, currently recommends that a trial of clozapine be considered in patients who fail to respond to adequate trials of at least one antipsychotic agent unless therapy with the drug is specifically contraindicated (e.g., patients with myeloproliferative disorders, preexisting bone marrow depression, or a history of clozapine-induced agranulocytosis or severe granulocytopenia) or patients are unable or unwilling to comply with monitoring requirements. The APA also recommends that clo-

ulating effect of dextroamphetamine is approximately twice that of amphetamine and about three or four times that of levamfetamine (no longer commercially available in the US). Levamfetamine is slightly more potent than dextroamphetamine in its cardiovascular effects. In healthy individuals, therapeutic doses of an amphetamine do not appreciably increase respiratory rate or minute volume, but when respiration is depressed by centrally acting drugs, an amphetamine stimulates respiration. The bronchodilating effect of amphetamines is less than that of ephedrine.

Amphetamines may superimpose psychic stimulation and excitability over fatigue, permitting a temporary increase in mental and physical activity. In healthy individuals, the drugs have not consistently facilitated improved mental performance and in some cases, nervousness produced by amphetamines is a distinct mental hazard. The most striking improvement caused by an amphetamine appears to occur when performance has been reduced by fatigue; such improvement may be due to alteration of unfavorable attitudes toward the task. Psychic stimulation produced by amphetamines is usually followed by depression and fatigue. Psychic effects depend on dose, mental state, and personality of the patient.

Theories of dysfunction in attention deficit hyperactivity disorder (ADHD) focus on the prefrontal cortex, which controls many executive functions (e.g., planning, impulse control). Stimulants have putative effects on central dopamine and norepinephrine pathways that are crucial in frontal lobe function. Stimulants act in the striatum by binding to the dopamine transporter, thus increasing synaptic dopamine. This effect may enhance functioning of executive control processes in the prefrontal cortex, ameliorating deficits in inhibitory control and working memory.

Amphetamines apparently produce an anorexigenic effect, leading to loss of weight. The mechanism of action of amphetamines on appetite suppression has not been elucidated. No primary effect on appetite has been demonstrated in humans and it has been postulated that anorexigenic effects of amphetamines are secondary to increased sympathetic activity resulting from amphetamine-induced release of norepinephrine and dopamine. In addition, amphetamines may cause a loss of acuity of smell and taste, which may contribute to the anorexigenic effect of the drugs. Amphetamines have little or no effect on the basal metabolic rate or on nitrogen excretion.

The anorexigenic effect of fenfluramine (no longer commercially available in the US) and dexfenfluramine (no longer commercially available in the US), amphetamine congeners, may have been associated with a different mechanism than those associated with amphetamines since the drugs appeared to stimulate release of serotonin (5-HT) at synapses and selectively inhibit the reuptake of serotonin at the presynaptic serotoninergic nerve endings, which may have resulted in increased postsynaptic concentrations of serotonin in the CNS. In the past, it has been suggested that combined therapy with fenfluramine and phentermine (an amphetamine congener that inhibits uptake of norepinephrine and dopamine) may provide complementary anorexigenic effects; therefore, such combined therapy has been used in the management of obesity. However, because of accumulated data on adverse effects associated with the drugs, fenfluramine hydrochloride (Pondimin®) and its dextrorotatory isomer dexfenfluramine hydrochloride (Redux®) were withdrawn from the US market in 1997. (See Cautions.)

Pharmacokinetics

Amphetamines are readily absorbed from the GI tract and effects persist for 4–24 hours. Amphetamines are distributed into most body tissues with high concentrations occurring in the brain and CSF.

Amphetamine appears in the urine within about 3 hours following oral administration. Urinary excretion of the amphetamines is pH-dependent and excretion is enhanced in acidic urine. Following oral administration of racemic amphetamine to humans, approximately equal amounts of both isomers were excreted during the first 12 hours; after the first 12 hours, a continually decreasing proportion of the *d*-isomer was excreted. Following oral administration of a 70-mg radiolabeled dose of lisdexamfetamine (a prodrug of dextroamphetamine), 96% of the dose was recovered in the urine; of the recovered radioactivity, 42% of the dose was related to amphetamine, 25% to hippuric acid, and 2% to the parent drug. Dextroamphetamine and levamfetamine (no longer commercially available in the US) appear to have different metabolic fates, but the relationship between the fate of the drugs and their pharmacologic activity has not been determined. There are some data to indicate stereospecific metabolism of amphetamine and its isomers, but stereospecific urinary excretion appears unlikely.

Chemistry

Amphetamine is *d,l*-α-methylphenethylamine, an adrenergic agent of the phenylisopropylamine type. The levo- and dextroisomers, racemic amphetamine, and the salts of the isomers and of racemic amphetamine are used in medical practice. Amphetamine is a noncatechol, sympathomimetic amine and has a greater CNS stimulant activity than epinephrine and other catecholamines. Lisdexamfetamine dimesylate is a prodrug and has little, if any, pharmacologic activity until converted to dextroamphetamine by first-pass intestinal and/or hepatic metabolism.

Inactivation of sympathomimetic noncatecholamines largely depends on breakdown by monoamine oxidase and since substitution of an alkyl group for hydrogen on the α-carbon atom blocks enzymatic inactivation of the amino group, the duration of action of noncatecholamines (but not of catecholamines, which are inactivated largely by a different mechanism) is prolonged by α-substitution. The absence of a hydroxyl group on the aromatic ring of amphetamine reduces inactivation of the drug in the GI tract and the amphetamines are active following oral administration.

Amphetamines are subject to control under the Federal Controlled Substances Act of 1970.

For further information on the chemistry, pharmacology, pharmacokinetics, uses, cautions, drug interactions, and dosage and administration of amphetamines, see the individual monographs in 28:20.04.

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Amphetamine

■ Amphetamine is a noncatechol, sympathomimetic amine with CNS-stimulating activity.

Uses

Amphetamine sulfate and amphetamine aspartate in fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate are used in the treatment of narcolepsy and as adjuncts to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD).

■ Narcolepsy and Attention Deficit Hyperactivity Disorder

Amphetamine sulfate and amphetamine aspartate in fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate are used in the treatment of narcolepsy and as adjuncts to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in children, adolescents, and adults.

ADHD usually is characterized by developmentally inappropriate symptoms (e.g., moderate to severe distractibility, short attention span, hyperactivity, emotional lability, impulsivity). The final diagnosis of this disorder should not be made if these symptoms are of only comparatively recent origin. Nonlocalizing (soft) neurologic signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of CNS dysfunction may or may not be warranted. Drug therapy is not indicated in all children with ADHD, and such therapy should be considered only after a complete evaluation including medical history has been performed. The decision to use amphetamines should depend on the age of the child and the clinician's assessment of the severity and duration of symptoms and should not depend solely on one or more behavioral characteristics. When symptoms of ADHD are associated with acute stress reactions, use of amphetamines usually is not recommended. For a more detailed discussion on the management of ADHD, including the use of stimulants such as amphetamine, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.92.

Dosage and Administration

■ **Administration** Amphetamine sulfate and amphetamine aspartate in fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate are administered orally. The commercially available extended-release capsules containing amphetamine sulfate and amphetamine aspartate in fixed-combination with dextroamphetamine saccharate and dextroamphetamine sulfate (Adderall® XR) may be swallowed intact with or without food or the entire contents of a capsule(s) may be sprinkled on a small amount of applesauce immediately prior to administration; subdividing the contents of a capsule is not recommended. The pellets contained in the capsules should not be chewed or crushed, and the sprinkle/food mixture must not be stored for use at a later time.

The initial dose of amphetamines (as conventional tablets or extended-release capsules) should be given on awakening; when amphetamines are administered as conventional tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours. Because of the potential for insomnia, administration of conventional tablets in the late evening or extended-release capsules in the afternoon should be avoided.

■ **Dosage** Dosage of amphetamines should be adjusted according to individual response and tolerance; the smallest dose required to produce the desired response should always be used.

Narcolepsy In the treatment of narcolepsy, the usual total dosage of amphetamines given in fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate is 5–60 mg daily, depending upon the patient's age and response, usually given in divided doses. In patients 12 years of age and older, the initial dosage is 10 mg daily; daily dosage is increased by 10 mg at weekly intervals until the optimum response is attained. Although narcolepsy seldom occurs in children younger than 12 years of age, such children also may receive dextroamphetamine alone. In patients 6–12 years of age, the recommended initial dosage is 5 mg daily; daily dosage is increased by 5 mg at

weekly intervals until optimum response is attained. When intolerable adverse effects (e.g., insomnia, anorexia) occur, dosage should be reduced.

Attention Deficit Hyperactivity Disorder As an adjunct in the treatment of attention deficit hyperactivity disorder (ADHD) in children 6 years of age and older, the initial total dosage of amphetamines given in conventional fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate is 5 mg once or twice daily; the daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained. Total daily dosage rarely should exceed 40 mg. In children 3–5 years of age, the initial dosage of amphetamines given in conventional fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate is 2.5 mg daily; the daily dosage is increased by 2.5 mg at weekly intervals until the optimum response is attained. When amphetamines are administered as conventional tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours.

Alternatively, in patients who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another stimulant, amphetamine therapy may be initiated with extended-release capsules containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate in fixed combination (Adderall® XR). In children 6–12 years of age, the initial dosage of amphetamines as extended-release capsules (Adderall® XR) is 10 mg once daily; daily dosage may be increased in increments of 5 or 10 mg at weekly intervals to a maximum dosage of 30 mg daily. Treatment may be initiated with a dosage of 5 mg once daily when, in the opinion of the clinician, a lower initial dosage is appropriate. In adolescents 13–17 years of age, the initial dosage of amphetamines as extended-release capsules (Adderall® XR) is 10 mg once daily. Dosage may be increased to 20 mg once daily after 1 week if symptoms are not adequately controlled. In adults who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another drug, the recommended dosage of amphetamines as extended-release capsules (Adderall XR®) is 20 mg once daily. Although dosages of up to 60 mg daily (as extended-release capsules) have been used in adolescents 13–17 years of age and adults in clinical studies, there is no evidence that dosages exceeding 20 mg daily provide any additional benefit in these patients. When switching from conventional tablets (Adderall®) to extended-release capsules (Adderall® XR), the total daily dosage of amphetamines may remain the same but should be given once daily.

When possible, therapy should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued treatment. Long-term use of conventional tablets or long-term use of extended-release capsules (i.e., more than 3 weeks in children or more than 4 weeks in adolescents or adults) has not been studied systematically. If conventional tablets or extended-release capsules are used for extended periods, the usefulness of the drug should be reevaluated periodically.

Chemistry and Stability

■ **Chemistry** Amphetamine, *d,l*-α-methylphenethylamine, occurs as a colorless, mobile liquid with an amine odor and is sparingly soluble in water (1:50) and soluble in alcohol. The base is volatile at room temperature and has been used as an inhalant but is no longer commercially available in the US. Amphetamine sulfate occurs as a white, odorless crystalline powder and has a slightly bitter taste. Amphetamine sulfate is freely soluble in water (1:9) and slightly soluble in alcohol (about 1:500). Amphetamine aspartate and amphetamine sulfate currently are commercially available in the US only as fixed-combination preparations containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate.

■ **Stability** The fixed-combination conventional tablets or extended-release capsules containing amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate should be stored in tight, light-resistant containers at 25°C but may be exposed to temperatures ranging from 15–30°C.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, chronic toxicity, acute toxicity, and dosage and administration of amphetamine and amphetamine sulfate, see the Amphetamines General Statement 28:20.04.

Preparations

Amphetamine sulfate preparations are subject to control under the Federal Controlled Substances Act of 1970 as schedule II (C-II) drugs.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Amphetamine Sulfate Combinations

Oral		
Capsules, extended-release	5 mg total amphetamine (as 1.25 mg, with Amphetamine Aspartate 1.25 mg, Dextroamphetamine Saccharate 1.25 mg, and Dextroamphetamine Sulfate 1.25 mg)	**Adderall® XR** (C-II), Shire
	10 mg total amphetamine (as 2.5 mg, with Amphetamine Aspartate 2.5 mg, Dextroamphetamine Saccharate 2.5 mg, and Dextroamphetamine Sulfate 2.5 mg)	**Adderall® XR** (C-II), Shire
	15 mg total amphetamine (as 3.75 mg, with Amphetamine Aspartate 3.75 mg, Dextroamphetamine Saccharate 3.75 mg, and Dextroamphetamine Sulfate 3.75 mg)	**Adderall® XR** (C-II), Shire
	20 mg total amphetamine (as 5 mg, with Amphetamine Aspartate 5 mg, Dextroamphetamine Saccharate 5 mg, and Dextroamphetamine Sulfate 5 mg)	**Adderall® XR** (C-II), Shire
	25 mg total amphetamine (as 6.25 mg, with Amphetamine Aspartate 6.25 mg, Dextroamphetamine Saccharate 6.25 mg, and Dextroamphetamine Sulfate 6.25 mg)	**Adderall® XR** (C-II), Shire
	30 mg total amphetamine (as 7.5 mg, with Amphetamine Aspartate 7.5 mg, Dextroamphetamine Saccharate 7.5 mg, and Dextroamphetamine Sulfate 7.5 mg)	**Adderall® XR** (C-II), Shire
Tablets	5 mg total amphetamine (as 1.25 mg, with Amphetamine Aspartate 1.25 mg, Dextroamphetamine Saccharate 1.25 mg, and Dextroamphetamine Sulfate 1.25 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)
	7.5 mg total amphetamine (as 1.875 mg, with Amphetamine Aspartate 1.875 mg, Dextroamphetamine Saccharate 1.875 mg, and Dextroamphetamine Sulfate 1.875 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)
	10 mg total amphetamine (as 2.5 mg, with Amphetamine Aspartate 2.5 mg, Dextroamphetamine Saccharate 2.5 mg, and Dextroamphetamine Sulfate 2.5 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)
	12.5 mg total amphetamine (as 3.125 mg, with Amphetamine Aspartate 3.125 mg, Dextroamphetamine Saccharate 3.125 mg, and Dextroamphetamine Sulfate 3.125 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)
	15 mg total amphetamine (as 3.75 mg, with Amphetamine Aspartate 3.75 mg, Dextroamphetamine Saccharate 3.75 mg, and Dextroamphetamine Sulfate 3.75 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)
	20 mg total amphetamine (as 5 mg, with Amphetamine Aspartate 5 mg, Dextroamphetamine Saccharate 5 mg, and Dextroamphetamine Sulfate 5 mg)*	**Adderall®** (C-II; double-scored), Shire **Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets** (C-II; double-scored)

30 mg total amphetamine (as 7.5 mg, with Amphetamine Aspartate 7.5 mg, Dextroamphetamine Saccharate 7.5 mg, and Dextroamphetamine Sulfate 7.5 mg)*	**Adderall** (C-II; double-scored), Shire
	Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets (C-II; double-scored)

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Dextroamphetamine

■ Dextroamphetamine is the dextrorotatory isomer of amphetamine.

Uses

Dextroamphetamine sulfate alone and in fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is used in the treatment of narcolepsy and as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD).

■ **Narcolepsy and Attention Deficit Hyperactivity Disorder** Dextroamphetamine sulfate alone and in fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is used in the treatment of narcolepsy and as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in children, adolescents, and adults.

ADHD usually is characterized by developmentally inappropriate symptoms (e.g., moderate to severe distractibility, short attention span, hyperactivity, emotional lability, impulsivity). The final diagnosis of this disorder should not be made if these symptoms are of only comparatively recent origin. Nonlocalizing (soft) neurologic signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of CNS dysfunction may or may not be warranted. Drug therapy is not indicated in all children with ADHD, and such therapy should be considered only after a complete evaluation including medical history has been performed. The decision to use amphetamines should depend on the age of the child and the clinician's assessment of the severity and duration of symptoms and should not depend solely on one or more behavioral characteristics. When symptoms of ADHD are associated with acute stress reactions, use of amphetamines usually is not recommended. For a more detailed discussion on the management of ADHD, including the use of stimulants such as dextroamphetamine, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.92.

Dosage and Administration

■ **Administration** Preparations containing dextroamphetamine sulfate are administered orally. The commercially available extended-release capsules containing dextroamphetamine sulfate and dextroamphetamine saccharate in fixed-combination with amphetamine sulfate and amphetamine aspartate (Adderall XR®) may be swallowed intact with or without food or the entire contents of a capsule(s) may be sprinkled on a small amount of applesauce immediately prior to administration; subdividing the contents of a capsule is not recommended. The pellets contained in the capsules should not be chewed or crushed, and the sprinkle/food mixture must not be stored for use at a later time.

The initial dose of dextroamphetamine sulfate (alone or in fixed-combination preparations) is given on awakening; when the drug is given as conventional (short-acting) tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours. Because of the potential for insomnia, administration of dextroamphetamine sulfate conventional tablets (Dexedrine®), dextroamphetamine sulfate extended-release capsules (Dexedrine® Spansules®), or fixed-combination conventional tablets (Adderall®) in the late evening or administration of fixed-combination extended-release capsules (Adderall XR®) in the afternoon should be avoided.

■ **Dosage** Dosage of dextroamphetamines should be adjusted according to individual response and tolerance; the smallest dose required to produce the desired response should always be used.

Narcolepsy In the treatment of narcolepsy, the usual dosage of dextroamphetamine sulfate given alone or the total dosage of amphetamines given in fixed-combination preparations containing dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is 5–60 mg daily, depending upon the patient's age and response, usually given in divided doses. In patients 12 years of age and older, the initial dosage is 10 mg daily; daily dosage is increased by 10 mg at weekly intervals until the optimum response is attained. Although narcolepsy seldom occurs in children younger than 12 years of age, in pediatric patients 6–12 years of age, the recommended initial dosage of dextroamphetamine sulfate is 5 mg daily; daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained. When intolerable adverse effects occur (e.g., insomnia, anorexia), dosage should be reduced. Dextroamphetamine sulfate extended-release capsules may be used for once-daily dosing whenever appropriate.

Attention Deficit Hyperactivity Disorder Dextroamphetamine sulfate dosage for the treatment of attention deficit hyperactivity disorder (ADHD) should be individualized based on patient response and tolerance. The first dosage that produces an observable response may not be the optimum dosage to improve function, and titration to higher dosages should continue in an attempt to achieve a better response. Such a strategy may require subsequent lowering of dosage when higher dosages produce adverse effects or no further clinical improvement. The best dosage for a given patient is the one that provides optimum therapeutic effects with minimal adverse effects. Dosing schedules also may vary, although there currently are no consistent controlled studies comparing alternative dosing schedules. Patients who require relief only during school may respond adequately to a 5-day (i.e., school day) regimen while those requiring relief at home and school may need a daily regimen throughout the week.

As an adjunct in the treatment of ADHD in children 6 years of age and older, the initial dosage of dextroamphetamine sulfate given in conventional (short-acting) preparations is 5 mg once or twice daily; daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained. The usual dosage range is 5–15 mg twice daily or 5–10 mg 3 times daily. Total daily dosage rarely should exceed 40 mg. In children 3–5 years of age, the initial daily dosage is 2.5 mg; daily dosage is increased by 2.5 mg at weekly intervals until the optimum response is attained. When the drug is administered as conventional tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours. Dextroamphetamine sulfate extended-release capsules can be substituted for their respective conventional short-acting preparations if less frequent daily dosing is desirable.

Dextroamphetamine sulfate in fixed combination with other amphetamines (dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate) also is used as an adjunct in the treatment of ADHD in children 6 years of age and older; the initial total dosage of amphetamines is 5 mg once or twice daily. The daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained; total daily dosage rarely should exceed 40 mg. In children 3–5 years of age, the initial daily dosage is 2.5 mg; daily dosage is increased by 2.5 mg at weekly intervals until the optimum response is attained. The manufacturer recommends that the initial dose of dextroamphetamine sulfate in fixed combination with other amphetamines be given on awakening; additional doses (1 or 2) are given at intervals of 4–6 hours. The usual dosage for intermediate-acting preparations (e.g., Dexedrine® Spansules®, Adderall®) in children 6 years of age and older is 5–30 mg once daily or 5–15 mg twice daily.

Alternatively, in patients who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another stimulant, dextroamphetamine therapy may be initiated with extended-release capsules containing dextroamphetamine sulfate in fixed-combination with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate (Adderall XR®). In children 6–12 years of age, the initial dosage of total amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 10 mg once daily; daily dosage may be increased in increments of 5 or 10 mg at weekly intervals to a maximum dosage of 30 mg daily. Treatment may be initiated with a dosage of 5 mg once daily when, in the opinion of the clinician, a lower initial dosage is appropriate. The usual dosage for such longer-acting preparations (e.g., Adderall XR®) is 10–30 mg daily. In adolescents 13–17 years of age, the initial dosage of total amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 10 mg once daily. Dosage may be increased to 20 mg once daily after 1 week if symptoms are not adequately controlled. In adults who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another drug, the recommended dosage of amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 20 mg once daily. Although dosages of up to 60 mg daily (as fixed-combination extended-release capsules) have been used in adolescents 13–17 years of age and adults in clinical studies, there is no evidence that dosages exceeding 20 mg daily provide any additional benefit in these patients. When switching from fixed-combination conventional tablets (Adderall®) to fixed-combination extended-release capsules (Adderall XR®), the total daily dosage of amphetamines may remain the same but should be given once daily.

When possible, therapy should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued treatment. Long-term use of fixed-combination extended-release capsules (i.e., more than 3 weeks in children or more than 4 weeks in adolescents or adults) has not been studied systematically. If fixed-combination extended-release capsules are used for extended periods, the usefulness of the drug should be periodically reevaluated.

Cautions

Dextroamphetamine shares the toxic potentials of amphetamines, and the usual cautions, precautions, and contraindications of amphetamine therapy should be observed. (See Cautions in the Amphetamines General Statement 28:20.04.)

Some commercially available preparations of dextroamphetamine (e.g., DextroStat®, Dexedrine® tablets) contain the dye tartrazine (FD&C yellow No. 5), which may cause allergic reactions including bronchial asthma in susceptible individuals. Although the incidence of tartrazine sensitivity is low, it frequently occurs in patients who are sensitive to aspirin.

Dosage and Administration

■ **Administration** Amoxapine is administered orally. Although amoxapine has been administered in 3 divided doses throughout the day, it is long-acting and, when dosage does not exceed 300 mg daily, the entire daily dose may be administered at one time, preferably at bedtime to avoid daytime sedation. When dosage exceeds 300 mg daily, the daily dose should be given in divided doses.

■ **Dosage** There is a wide range of amoxapine dosage requirements, and dosage of the drug must be carefully individualized.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

The usual effective dosage of amoxapine is 200–300 mg daily. The usual initial dosage is 100–150 mg daily. Depending on tolerance and response, dosage may be increased to 200–300 mg daily by the end of the first week of therapy. An initial dosage of 300 mg daily may be given, but considerable sedation may occur in some patients during the first few days of therapy at this dosage level. If no response occurs after administration of 300 mg of amoxapine daily for at least 2 weeks, dosage may be increased to a maximum of 400 mg daily in outpatients. Hospitalized patients under close supervision may generally be given higher dosages than outpatients; dosage may be increased cautiously up to 600 mg daily in divided doses in hospitalized patients who have not responded adequately and do not have a history of seizures. Single doses should not exceed 300 mg.

Geriatric patients should usually be given lower than average dosages. Therapy usually should be initiated with 50–75 mg daily in these patients and may be increased to 100–150 mg daily by the end of the first week of therapy, if tolerated. Some geriatric patients may require further increases in dosage; however, dosage in geriatric patients should not exceed 300 mg daily.

Antidepressant effects usually occur within 2 weeks in most patients who respond to amoxapine therapy and may occur within 4–7 days.

After symptoms are controlled, dosage should be gradually reduced to the lowest level which will maintain relief of symptoms.

Cautions

Amoxapine shares the toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. Patients should be fully advised about the risks, especially suicidal thinking and behavior (suicidality), associated with tricyclic antidepressant therapy. For a complete discussion, see Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.

Extrapyramidal reactions have occurred in less than 1% of patients receiving amoxapine. In addition, tardive dyskinesia has been reported rarely in patients receiving the drug. Like antipsychotic agents, amoxapine has been associated with neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment. For additional information on NMS, see Extrapyramidal Reactions in Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

■ **Pediatric Precautions** Safety and efficacy of amoxapine for the treatment of depression in children younger than 16 years of age have not been established.

The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. Anyone considering the use of amoxapine in a child or adolescent for any clinical use must therefore balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Pharmacokinetics

■ **Absorption** Amoxapine is rapidly and almost completely absorbed from the GI tract. Peak plasma concentrations of amoxapine occur within 1–2 hours after a single oral dose.

■ **Distribution** In rats, amoxapine is widely distributed throughout body tissues, with highest concentrations distributed into lungs, spleen, kidneys, heart, and brain and lower concentrations distributed into testes and muscle.

Amoxapine is approximately 90% bound to plasma proteins.

Amoxapine and 8-hydroxyamoxapine have been detected in human milk in concentrations of approximately one-fifth and one-third those of maternal steady-state serum concentrations, respectively.

■ **Elimination** The plasma half-life of amoxapine is approximately 8 hours. Amoxapine is metabolized in the liver principally to 8-hydroxyamoxapine and, to a lesser extent, to 7-hydroxyamoxapine; both metabolites are pharmacologically active and have half-lives of 30 hours and 6.5 hours, respectively.

Approximately 60–69% of a dose of amoxapine is excreted in urine within 6 days principally as conjugated metabolites; approximately 7–18% of the drug is excreted in feces principally as unconjugated metabolites. Less than 5% of amoxapine is excreted in urine as unchanged drug.

Chemistry and Stability

■ **Chemistry** Amoxapine, a tricyclic dibenzoxazepine derivative, is the desmethyl analog of loxapine. Amoxapine differs structurally from the dibenzazepine, dibenzocycloheptene, and dibenzoxepin tricyclic antidepressants in that it has both a nitrogen and an oxygen atom in its 7-membered ring and a piperazinyl ring rather than a propylamino chain attached to the center ring. Amoxapine occurs as a white to pale yellow, crystalline powder and is slightly soluble in water and in alcohol. The drug has an apparent pK_a of 7.6.

■ **Stability** Amoxapine tablets should be stored in tight containers at 15–30°C.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of amoxapine, see the Tricyclic Antidepressants General Statement 28:16.04.28.

Clomipramine Hydrochloride

Chlorimipramine Hydrochloride, Chloroimipramine Hydrochloride, CMI

■ Clomipramine, a dibenzazepine-derivative tricyclic antidepressant, is the 3-chloro analog of imipramine.

Uses

■ **Obsessive-Compulsive Disorder** Clomipramine is used in the treatment of obsessive-compulsive disorder when obsessions or compulsions cause marked distress, are time-consuming (take longer than 1 hour daily), or interfere substantially with the patient's normal routine, occupational or academic functioning, or usual social activities or relationships. Obsessions are recurrent and persistent thoughts, impulses, or images that, at some time during the disturbance, are experienced as intrusive and inappropriate (i.e., "ego dystonic") and that cause marked anxiety or distress but that are not simply excessive worries about real-life problems. Compulsions are repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) performed in response to an obsession or according to rules that must be applied rigidly (e.g., in a stereotyped fashion). Although the behaviors or acts are aimed at preventing or reducing distress or preventing some dreaded event or situation, they either are not connected in a realistic manner with what they are designed to neutralize or prevent or are clearly excessive. At some time during the course of the disturbance, the patient, if an adult, recognizes that the obsessions or compulsions are excessive or unreasonable; children may not make such recognition.

The efficacy of clomipramine for the management of obsessive-compulsive disorder has been established in several multicenter, placebo-controlled, parallel-group studies, including 2 studies of 10 weeks' duration in adults and one study of 8 weeks' duration in children and adolescents 10–17 years of age. In these clinical studies, clomipramine was more effective than placebo in reducing the severity of obsessive-compulsive manifestations in patients with moderate to severe obsessive-compulsive disorder. The drug produced substantial improvement in scores on both the Yale-Brown Obsessive-Compulsive Scale (YBOCS) and the National Institute of Mental Health (NIMH) Clinical Global Obsessive-Compulsive Scale (NIMH-OC), while the response with placebo was clinically insignificant. Scores on the YBOCS decreased by an average of approximately 10 from baseline values of 26–28, representing an average improvement of 35–42% in adults and 37% in children and adolescents treated with clomipramine. Scores on the NIMH-OC were reduced by an average of 3.5 units from a mean baseline of 10 in adults, children, and adolescents treated with clomipramine, which represents an improvement in obsessive-compulsive disorder from severe at baseline to subclinical after treatment with the drug. The maximum dosage of clomipramine hydrochloride was 250 mg daily for most adults and 3 mg/kg (up to 200 mg) daily for children and adolescents.

Although obsessive-compulsive manifestations often persist to some extent

in patients who respond to clomipramine, responders generally find it easier to resist the manifestations and spend less time engaged in the associated behavior. Data from a retrospective analysis suggest that clomipramine may be more effective in patients who developed obsessive-compulsive disorder during middle age (35–62 years of age) than in those in whom onset occurred during early adulthood (16–23 years old), independent of the length of illness.

Therapeutic response to clomipramine in patients with obsessive-compulsive disorder generally is evident within 2–6 weeks but may not be maximal until 3–4 months after beginning therapy with the drug. Thus, it is essential that patients receive an adequate trial of clomipramine at a therapeutic dosage in order to determine efficacy.

Many clinicians consider clomipramine or a serotonin-reuptake inhibitor (e.g., fluoxetine, fluvoxamine) to be the drugs of choice in obsessive-compulsive disorder. In addition, behavior therapy often is recommended in patients with obsessive-compulsive disorder even when pharmacologic therapy alone has been partially effective.

Results from comparative studies to date suggest that clomipramine is more effective than other tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline) and as or more effective than selective serotonin-reuptake inhibitors (e.g., fluoxetine, fluvoxamine) in the management of obsessive-compulsive disorder. In a pooled analysis of separate short-term (10–13 weeks) studies comparing clomipramine, fluoxetine, fluvoxamine, or sertraline with placebo, clomipramine was calculated as being more effective (as determined by measures on the YBOC scale) than selective serotonin-reuptake inhibitors, although all drugs were superior to placebo. Like clomipramine, selective serotonin-reuptake inhibitors reduce but do not completely eliminate obsessions and compulsions. The decision whether to initiate therapy with clomipramine or a selective serotonin-reuptake inhibitor often is made based on the adverse effect profile of these drugs. For example, some clinicians prefer clomipramine in patients who may not tolerate the adverse effect profile of selective serotonin-reuptake inhibitors (nausea, headache, overstimulation, sleep disturbances) while selective serotonin-reuptake inhibitors may be useful alternatives in patients unable to tolerate the adverse effects (anticholinergic effects, cardiovascular effects, sedation) associated with clomipramine therapy. Consideration of individual patient characteristics (age, concurrent medical conditions), the pharmacokinetics of the drug, potential drug interactions, and cost of therapy may also influence clinicians when selecting between clomipramine and selective serotonin-reuptake inhibitors as first-line therapy in patients with obsessive-compulsive disorder. Although not clearly established, it has been suggested that the mechanism of action of clomipramine and other drugs (fluoxetine, fluvoxamine) used in the management of obsessive-compulsive disorder may be related to their serotonergic activity. Clomipramine also has been effective when used in combination with clonidine in several patients with obsessive-compulsive disorder; however, additional experience is needed to confirm the safety and efficacy of this combination.

The manufacturers state that the efficacy of clomipramine for long-term use (i.e., longer than 10 weeks) in the treatment of obsessive-compulsive disorder has not been established in placebo-controlled studies. After 36 weeks of treatment with clomipramine, improvement compared with placebo was observed on measures of rituals, mood, and social adjustment, although such effects were more substantial after 18 weeks of treatment. At follow-up 22 weeks after treatment ended, clomipramine differed from placebo on one measure of rituals. Clomipramine was not distinguishable from placebo in efficacy at follow-up 6 years after the conclusion of treatment. The combination of clomipramine or placebo with the same behavioral therapy resulted in greater improvement with clomipramine on measures of rituals, mood, and social adjustment at 8 weeks of treatment, but thereafter through the last 15 weeks of treatment and at follow-up through 52 weeks, clomipramine was indistinguishable from placebo. However, clomipramine has been used in some patients for prolonged periods (e.g., up to 1 year) without apparent loss of clinical effect. If clomipramine is used for extended periods, dosage should be adjusted so that patients are maintained on the lowest effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Discontinuance of clomipramine frequently results in a progressive recurrence of symptoms in patients with obsessive-compulsive disorder, and therefore long-term continued therapy with the drug may be advisable on an individual basis. In a study conducted under double-blind conditions, most patients with obsessive-compulsive disorder who had improved clinically following 5–27 months of clomipramine therapy experienced profound worsening of manifestations after discontinuance of the drug. This worsening started at 4 weeks and continued for the rest of the 7-week placebo period and appeared to be unrelated to the duration of clomipramine therapy or to the type of obsessive-compulsive manifestations originally present. However, readministration of clomipramine resulted in clinical improvement similar to that obtained prior to discontinuance of the drug.

Disorders with an Obsessive-Compulsive Component Depressive episodes may be associated with obsessive-compulsive disorder. Clomipramine and selective serotonin-reuptake inhibitors are effective antidepressants when obsessive manifestations accompany an episode of major depression. However, the antiobsessional effectiveness of clomipramine does not appear to depend on the presence of depression.

Clomipramine also may reduce obsessive-compulsive manifestations in some patients with schizophrenia and such accompanying manifestations. However, exacerbation of psychosis has been reported in some patients treated with clomipramine. Therefore, the possibility of exacerbating psychosis should be considered in patients with obsessive-compulsive manifestations and schizophrenia, and such patients receiving clomipramine should be observed closely for early signs of worsening psychosis.

There is a high incidence of obsessive-compulsive disorder in patients with Tourette's disorder (Gilles de la Tourette's syndrome), and clomipramine can reduce obsessive-compulsive manifestations associated with Tourette's and suppress associated motor and vocal tics. However, in at least one controlled study, clomipramine did not differ from placebo in the number of tics observed during 4 weeks of treatment.

Obsessive thoughts were decreased with the combination of clomipramine and lithium carbonate in a limited number of patients who had obsessive manifestations that previously failed to respond to clomipramine therapy alone. However, in a study of patients with obsessive-compulsive disorder treated with clomipramine for at least 6 months and who were partial responders to the drug, the addition of lithium carbonate for 4 weeks did not result in improvement in scores on the YBOCS.

■ **Panic Disorder** Clomipramine has been used effectively for the treatment of panic disorder† with or without agoraphobia†. In an uncontrolled study, clomipramine reduced both the weekly frequency and severity of panic attacks when given in an average dosage of 45 mg daily (range: 6.25–75 mg daily). In many patients, complete or nearly complete relief from panic attacks was reported during therapy. The number of days that panic attacks occurred was less with clomipramine (mean dosage of 83 mg daily) than with placebo after 8 weeks of treatment in one study. Therapeutic response generally is seen within about 1–3 weeks but may take up to 6 weeks. Although clomipramine therapy generally is well tolerated, a transient increase in the number and intensity of panic attacks may occur during initial therapy with the drug. (See Dosage and Administration: Dosage.) Clomipramine (mean dosage of 109 mg daily; range: 25–200 mg daily) was at least as effective as imipramine (mean dosage of 109 mg daily; range: 25–200 mg daily) in patients with panic disorder and had a faster onset of action in reducing panic attacks and improving phobic avoidance and associated anxiety.

Clomipramine generally is equally effective in patients with panic disorder with or without agoraphobia. In a limited number of patients whose panic disorder with agoraphobia did not respond to exposure-based behavioral treatment, measures of fear (i.e., fear of bodily incapacitation, fear of losing control), state and trait anxiety, depression, severity of condition, and avoidance of separation situations indicated improvement compared with placebo after receiving clomipramine for about 5 weeks (3 weeks at the maximum dosage of 150 mg daily). Despite such improvement, the efficacy of clomipramine in the treatment of such patients was uncertain. A clinical response, as indicated by improvement by at least 50% on assessment of avoidance of separation situations with the Phobic Avoidance Rating Scale, was produced by clomipramine in 29% of the patients, while such response was observed with behavioral treatment in 47% of the patients.

Preliminary results from an uncontrolled study suggest that clomipramine is effective in patients with panic disorder or agoraphobia with panic attacks who have concurrent mitral valve prolapse.

Although it has been suggested that the mechanism of action of clomipramine in patients with panic disorder may be related to the drug's serotonergic activity, the absence of clear superiority compared with less selective antidepressants (e.g., desipramine) suggests that this may not be the case.

For further information on treatment of panic disorder, see Uses: Panic Disorder, in the Tricyclic Antidepressants General Statement 28:16.04.28.

■ **Major Depressive Disorder** Clomipramine has been used effectively in the treatment of major depressive disorder†. Clinical studies have shown that the antidepressant effect of clomipramine exceeds that of placebo and is comparable to that of usual dosages of other tricyclic antidepressants (e.g., amitriptyline, doxepin, imipramine) or selective serotonin-reuptake inhibitors (e.g., fluoxetine, paroxetine). Several (e.g., 4–6) weeks may be required for optimal antidepressant effect at a given clomipramine dosage. Despite comparable efficacy, the adverse effect profile (e.g., anticholinergic effects) of clomipramine may limit its usefulness relative to other antidepressants, and antidepressant therapy should be individualized based on patient response and tolerance. Clomipramine appears to offer no substantial advantage over other tricyclic antidepressants for the management of typical depression in the absence of obsessive-compulsive manifestations and may be more poorly tolerated, particularly compared with tricyclics exhibiting only mild to moderate anticholinergic effects. Although some clinicians have preferred clomipramine to other tricyclic antidepressants for atypical depression (e.g., because of clomipramine's dopaminergic activity), other agents (e.g., selective serotonin-reuptake inhibitors such as fluoxetine) generally have replaced this preference for clomipramine in such depression.

For further information on treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidal risks, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in the Tricyclic Antidepressants General Statement 28:16.04.28.

■ **Chronic Pain** Like other tricyclic antidepressants, clomipramine has been used for the treatment of chronic pain†, including central pain, idiopathic pain disorder, tension headache, diabetic peripheral neuropathy, and pain of other neuropathic origin (e.g., cancer pain). Antidepressants have been used alone or as adjuncts to conventional analgesics in the management of such

pain. In patients with central pain (e.g., phantom or stump pain; post-herpetic neuralgia, deafferentation pain secondary to posttraumatic nerve lesions), reduction in pain intensity, as indicated by scores on a visual analog scale for pain, was greater during treatment with clomipramine for 3 weeks than with placebo. Treatment of idiopathic pain disorder with clomipramine (mean dosage of 97 mg daily) for 6 weeks resulted in improvement, as indicated by the physicians' global assessment, in 63% of patients. The patients' scores on visual analog scales that included assessment of pain also were improved. In patients with tension headache, a greater decrease in headache pain, as indicated by scores on a visual analog scale, occurred with clomipramine administered for 6 weeks than with placebo. Treatment of diabetic peripheral neuropathy with clomipramine for 2 weeks resulted in a greater decrease compared with placebo in the severity of symptoms overall, as evaluated by a physician through use of a scale that quantified pain, paresthesia, dysesthesia, numbness, nightly deterioration, and sleep disturbances.

■ **Cataplexy and Associated Narcolepsy** Clomipramine has been used for the symptomatic management of cataplexy† in a limited number of patients with cataplexy and associated narcolepsy. Cataplexy attacks and sleep paralysis resolved or were reduced in frequency during clomipramine therapy (25–200 mg daily); however, the drug did not consistently improve sleep attacks. Although the precise mechanism of clomipramine's anticataplectic action is not known, it has been suggested that its serotonergic and REM-suppressing activity may be involved.

■ **Autistic Disorder** Clomipramine has been effective in a limited number of patients with autistic disorder†. In a double-blind study, clomipramine therapy (mean dosage: 152 mg daily) was superior to both desipramine and placebo in improving standardized ratings of autistic manifestations, including repetitive and obsessive-compulsive behaviors and hyperactivity in a limited number of pediatric outpatients aged 6–18 years with autistic disorder. However, in an open study involving younger inpatients aged 3–9 years with autistic disorder but with relatively low intellectual functioning and without prominent obsessive-compulsive manifestations, clomipramine was not found to be effective and was commonly associated with adverse effects, including acute urinary retention.

■ **Trichotillomania** Clomipramine has been used in a limited number of patients with trichotillomania† (an urge to pull out one's hair). In one double-blind, crossover study, clomipramine (mean dosage of 181 mg daily; range: 100–250 mg daily) was shown to be more effective than desipramine (mean dosage of 173 mg daily; range: 150–200 mg daily) in the short-term management of trichotillomania. However, relapse has been reported in some patients receiving long-term treatment with clomipramine.

■ **Onychophagia** Clomipramine has been used in a limited number of patients with severe onychophagia† (nail biting) and no history of obsessive-compulsive disorder. In one study, the severity of nail biting decreased in patients treated with clomipramine hydrochloride 25–200 mg daily for 5 weeks. However, the relatively high dropout rate secondary to adverse effects and drug intolerance suggests that clomipramine should not be considered as first-line therapy in most patients with onychophagia.

■ **Stuttering** Clomipramine has been used in a limited number of patients with stuttering†. Following 5 weeks of therapy (mean dosage: 147 mg daily), clomipramine improved the severity of stuttering, preoccupation with thoughts about stuttering, amount of energy spent resisting stuttering, and expectancy of stuttering. Additional study of the efficacy of clomipramine in the management of stuttering is necessary.

■ **Eating Disorders** Clomipramine has been used in a limited number of patients with anorexia nervosa†. In a placebo-controlled study, clomipramine therapy was associated with increased appetite, hunger, and calorie consumption during initial therapy; however, the drug was not associated with improved eating behavior after 8 weeks of therapy or greater weight gain. In addition, body weight did not differ between the clomipramine and placebo groups at 1-year follow-up and a measure of outcome based on nutritional status, sexual adjustment, socioeconomic adjustment, and mental state did not differ between the 2 groups at 4-year follow-up. Few controlled studies on the pharmacotherapy for anorexia nervosa have been published, and results with most drugs have been unimpressive. Because malnourished depressed patients may be particularly susceptible to the adverse cardiovascular effects or other severe toxicities (including death) of tricyclic antidepressants, the American Psychiatric Association (APA) states that tricyclic antidepressants should be avoided in underweight individuals and in those exhibiting suicidal ideation. For further information on use of antidepressants in the treatment of eating disorders see Uses: Eating Disorders, in Fluoxetine Hydrochloride 28:16.04.20.

■ **Premature Ejaculation** Clomipramine has been used with some success in the treatment of premature ejaculation†. In a controlled study, mean ejaculatory latency was prolonged in patients receiving 25 or 50 mg of the drug daily. Sexual and relationship satisfaction also was improved. A trial with drug therapy may be particularly useful in patients who fail or refuse behavioral or psychotherapeutic treatment or when partners are unwilling to cooperate with such therapy.

■ **Premenstrual Syndrome** Clomipramine has been used in the management of premenstrual syndrome†. In a limited number of women with severe premenstrual irritability and/or depressed mood, clomipramine given either continuously or intermittently (i.e., premenstrual administration) during 3 menstrual cycles at a dosage of 25–75 mg daily was more effective than placebo in reducing premenstrual irritability and depressed mood. However, preliminary data suggest that patients with premenstrual syndrome may be particularly sensitive to the adverse effects associated with the drug.

Dosage and Administration

■ **Administration** Clomipramine hydrochloride is administered orally. The drug also has been administered IM† or IV†, but a parenteral dosage form is not commercially available in the US.

During initial therapy when the dosage is being titrated, the manufacturers recommend that clomipramine be given in divided doses with meals to lessen adverse GI effects. After dosage titration, the total daily dose may be given once daily at bedtime to minimize adverse effects such as sedation during waking hours and enhance patient compliance.

■ **Dosage** Dosage of clomipramine hydrochloride is expressed in terms of the hydrochloride.

Because there is wide interindividual variation in dosage and dosage may differ in various disease states, the dosage of clomipramine hydrochloride must be individualized carefully.

Patients receiving clomipramine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications.)

Obsessive-Compulsive Disorder For the management of obsessive-compulsive disorder in adults, children, or adolescents, the recommended initial dosage of clomipramine hydrochloride is 25 mg daily. During the first 2 weeks of therapy, dosage should be increased gradually as tolerated to approximately 100 mg daily in adults. In children and adolescents, dosage should be increased gradually, as tolerated, during the first 2 weeks of therapy up to a maximum of 3 mg/kg or 100 mg daily, whichever is lower. This initial period of titration is intended to minimize adverse effects by permitting tolerance to develop or allowing the patient time to adapt if tolerance does not develop.

During the next several weeks, the dosage of clomipramine hydrochloride may be increased gradually up to a maximum of 250 mg daily in adults and 3 mg/kg or 200 mg daily (whichever is lower) in children and adolescents. Daily clomipramine hydrochloride dosages exceeding 250 mg in adults or 3 mg/kg (up to 200 mg) in children and adolescents should be avoided because of the increased risk of seizures (see Cautions: Nervous System Effects).

Because of the long elimination half-lives of both clomipramine and its active metabolite, desmethylclomipramine, clinicians should take into consideration that steady-state plasma concentrations may not be achieved for 2–3 weeks or even longer. Therefore, the manufacturers state that it may be appropriate to wait 2–3 weeks between any further dosage adjustments after the initial dosage titration period.

Although the optimum duration of clomipramine therapy has not been established, obsessive-compulsive disorder is a chronic condition and it seems reasonable to consider continuation of therapy in responding patients. Although the manufacturers state that the efficacy of clomipramine when given for periods exceeding 10 weeks has not been established systematically in controlled studies, the drug has been given under double-blind conditions for up to 1 year without loss of clinical efficacy. Pending further accumulation of data, some clinicians recommend that clomipramine therapy be continued for at least 18 months in patients with obsessive-compulsive disorder before attempting to discontinue therapy. However, the dosage should be adjusted during maintenance therapy so that patients are maintained on the minimum effective dosage and patients should be reassessed periodically to determine the need for continued therapy.

Clomipramine should not be used concomitantly with MAO inhibitors and it is recommended that at least 2 weeks elapse between discontinuance of therapy with a MAO inhibitor and initiation of clomipramine therapy and vice versa. A similar interval is recommended between discontinuance of therapy with a selective serotonin-reuptake inhibitor (e.g., citalopram, escitalopram, fluvoxamine, paroxetine, sertraline) and initiation of therapy with a tricyclic antidepressant agent such as clomipramine and vice versa. However, because fluoxetine and its active metabolite have a long half-life, at least 5 weeks should elapse between discontinuance of fluoxetine therapy and initiation of clomipramine therapy.

Abrupt discontinuance of clomipramine therapy should be avoided since a variety of withdrawal symptoms have been reported. (See Cautions: Nervous System Effects and also see Chronic Toxicity.) In addition, patients may experience a worsening of psychiatric status when the drug is discontinued abruptly. Therefore, it is recommended that dosage be tapered gradually (e.g., over a period of approximately 2 weeks) and the patient monitored carefully when clomipramine therapy is discontinued.

Panic Disorder For the management of panic disorder† with or without agoraphobia†, clomipramine hydrochloride usually has been effective in dosages ranging from 12.5–150 mg (maximum: 200 mg) daily. Most patients with panic attacks respond to a clomipramine hydrochloride dosage of less than 50 mg daily; however, patients with agoraphobia may require a higher dosage. Because clomipramine may worsen anxiety symptoms during initial therapy, some clinicians recommend that patients be started on a low dosage initially, and then the dosage can be increased gradually until therapeutic response or bothersome adverse effects occur.

Other Uses For the management of major depressive disorder† or chronic pain†, clomipramine hydrochloride is generally given in dosages ranging from 100–250 mg daily.

For the management of cataplexy and associated narcolepsy†, clomipramine hydrochloride has been given in dosages ranging from 25–200 mg daily.

■ **Dosage in Geriatric Patients** The manufacturers and some clinicians recommend selecting an initial clomipramine dosage at the lower end of the recommended range since decreased hepatic, renal, or cardiac function and concomitant illness and medications are more frequent in geriatric patients.

Cautions

Clomipramine shares the toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. (See Cautions in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Common adverse effects of clomipramine are extensions of its pharmacologic activity, principally anticholinergic effects; adverse effects secondary to antihistaminic and α-adrenergic activity also may occur. Like other tricyclics, adverse effects of clomipramine could affect compliance and result in dosage reduction; however, the possibility that such reductions could affect response should be considered.

In controlled studies, the most common adverse effects occurring more frequently in patients receiving clomipramine than in those receiving placebo included GI effects such as dry mouth, constipation, nausea, dyspepsia, anorexia, and increased appetite; nervous system effects such as somnolence, tremor, dizziness, nervousness, fatigue, and myoclonus; genitourinary effects such as changed libido, ejaculatory failure, impotence, and micturition disorder; sweating; weight gain; and visual changes. Approximately 20% of the 3616 patients who participated in US premarketing clinical trials for obsessive-compulsive or other disorders discontinued clomipramine therapy because of an adverse effect. About one-half of those who discontinued therapy (9% of the total) experienced multiple adverse effects, none of which could be classified as the principal reason. However, in the cases in which a principal reason for discontinuing therapy could be identified, most of the patients did so because of nervous system effects (5.4%), mainly somnolence, and GI effects (1.3%), mainly nausea and vomiting.

The incidences of adverse effects reported by the manufacturers to have occurred in at least 1% of clomipramine-treated patients were obtained from pooled data from placebo-controlled clinical trials involving 322 adults and 46 children or adolescents who received clomipramine for the treatment of obsessive-compulsive disorder. However, clinicians prescribing clomipramine should be aware that these figures cannot be used to predict the incidence of adverse effects during usual medical practice, in which patient characteristics and other factors differ from those that prevailed during these trials. Similarly, the cited incidences cannot be compared with the incidences obtained from other trials involving different treatments, uses, and investigators. However, the incidences from these trials provide the clinician with a basis for estimating the relative contribution of both drug and nondrug factors to the incidence of adverse effects in the populations studied. Various other adverse effects have been reported in 3525 out of approximately 3600 individuals who received multiple doses of clomipramine for obsessive-compulsive or other disorders during premarketing trials in the US; however, these adverse effects have not been definitely attributed to the drug.

Some evidence suggests that patients with depression may tolerate clomipramine relative to placebo more poorly than those with obsessive-compulsive disorder.

■ **Nervous System Effects** *Seizures* Seizure is the most clinically important risk associated with clomipramine therapy. However, seizure remains a relatively uncommon adverse effect of clomipramine therapy. The cumulative incidence of seizures in patients treated with clomipramine hydrochloride dosages of up to 300 mg daily was 0.64, 1.12, and 1.45% at 90, 180, and 365 days, respectively. The cumulative rates correct the crude incidence of 0.7% (25 of 3519 patients) for the variable duration of exposure to clomipramine in clinical trials. Seizures also have been associated with abrupt withdrawal of the drug.

Dose appears to be a predictor of the development of seizures. However, the influence of dose is confounded by the duration of exposure to the drug, making independent assessment of the effect of either factor alone difficult. Seizures occurred in about 0.5, or 2% of patients who received a maximum daily dose of 250 mg or higher than 250 mg, respectively, of the drug. The ability to predict seizures with daily doses exceeding 250 mg is limited because plasma concentrations achieved during clomipramine therapy may be dose dependent and vary considerably among individuals administered the same dosage.

Rare reports of fatalities in association with clomipramine-associated seizures have been reported in foreign postmarketing surveillance, but not in US clinical trials. In some of these cases, clomipramine had been administered with other epileptogenic agents, while in other cases the patients had possible predisposing medical conditions. Thus, a causal relationship between clomipramine therapy and these fatalities has not been established. (See Cautions: Precautions and Contraindications.)

Withdrawal Effects Withdrawal syndrome has been reported rarely in patients receiving clomipramine. In a limited number of patients, abrupt discontinuance of clomipramine resulted in a variety of withdrawal manifestations, including dizziness, nausea, vomiting, headache, malaise, sleep disturbance, hyperthermia, sweating, and irritability. Abrupt discontinuance of the drug also reportedly has resulted in seizures. In addition, some patients have experienced a worsening of psychiatric status when the drug was discontinued abruptly. Therefore, abrupt discontinuance of clomipramine therapy should be avoided. (See Cautions: Precautions and Contraindications.)

Serotonin Syndrome The manifestation of a group of adverse effects (e.g., tremor, myoclonus, diaphoresis, shivering, restlessness, fever, mental status changes, diarrhea) that resembles the serotonin syndrome observed in animals has been reported with clomipramine monotherapy. In an open study in which patients received clomipramine 150 mg daily for about 4 weeks for the treatment of depression, tremor of the tongue and myoclonus occurred most commonly (42 and 36% of patients, respectively). Tremor of the tongue or fingers and myoclonus were accompanied by diaphoresis and shivering in over a quarter of the patients. In most cases, these manifestations were transient and resolved despite continued therapy. More severe and sometimes fatal reactions resembling the serotonin syndrome have been reported when clomipramine has been given concurrently with other serotonergic agents such as MAO inhibitors, fluoxetine, lithium, or alprazolam. (See Drug Interactions.)

Other Nervous System Effects In controlled trials, somnolence, dizziness, or tremor was each reported in about 54% of adults and in about 46, 41, or 33%, respectively, of children and adolescents receiving clomipramine. Headache occurred in about 52% of adults and 28% of children and adolescents receiving clomipramine. Fatigue occurred in about 39% of adults and 35% of children and adolescents receiving the drug. Insomnia occurred in about 25% of adults and 11% of children and adolescents and nervousness occurred in about 18% of adults and 4% of children and adolescents treated with clomipramine.

Myoclonus occurred in about 13% of adults and 2% of children and adolescents receiving clomipramine. Motor hyperactivity that included jerking of the arms and legs during nocturnal sleep also has been reported. Memory impairment occurred in about 9 or 7% of adults or children and adolescents, respectively, receiving clomipramine. Paresthesia and anxiety each occurred in about 9 or 2% of adults or children and adolescents, respectively, receiving the drug. Twitching occurred in about 7 or 4% of adults or children and adolescents, respectively, receiving clomipramine. Impaired concentration and depression each occurred in about 5% of adults receiving clomipramine. Sleep disorder occurred in about 4 or 9% of adults or children and adolescents, respectively, treated with the drug. Disturbance of sleep by fright that was accompanied by myoclonus also has been reported in association with clomipramine therapy. Hypertonia occurred in about 4 or 2% of adults or children and adolescents, respectively, receiving the drug.

Confusion occurred in about 3 or 2% of adults or children and adolescents, respectively, receiving clomipramine. Psychosomatic disorder, speech disorder, dream abnormalities, agitation, or migraine occurred in about 3% of adults treated with the drug. Depersonalization or irritability occurred in about 2% of both adults and children or adolescents receiving clomipramine. Emotional lability occurred in about 2% of adults and aggressive reaction occurred in about 2% of children and adolescents treated with the drug. Paresis and asthenia each occurred in about 2% of children and adolescents and panic reaction occurred in about 1 or 2% of adults or children and adolescents, respectively, receiving clomipramine.

During premarketing clinical trials in patients with affective disorder, hypomania or mania was precipitated infrequently in patients receiving clomipramine therapy. Activation of mania or hypomania also has been reported in patients treated with other tricyclic antidepressants.

More than 30 cases of hyperthermia with clomipramine have been reported by foreign postmarketing surveillance systems. Most of these cases occurred in patients receiving clomipramine in combination with other drugs (e.g., antipsychotic agents). When clomipramine and an antipsychotic agent were used concomitantly, the cases sometimes were considered to be examples of neuroleptic malignant syndrome (NMS).

Abnormal thinking and vertigo each occurred in 1% or more of patients receiving clomipramine; however, a causal relationship to the drug has not been established.

Dyskinesia occurred in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Persistent tardive dyskinesia has been reported after initiation of clomipramine in a patient who was already receiving dextroamphetamine. A severe tardive dyskinesia-like syndrome consisting of orobuccal movements, choreoathetosis of the arms and other abnormal movements of the extremities, motor restlessness, and incoordination has been reported in another patient who was receiving clomipramine concurrently with thiothixene, buspirone, and trihexyphenidyl.

Other adverse nervous system effects occurring in less than 1% of clomipramine-treated patients include apathy, ataxia, coma, abnormal coordination, delirium, delusions, dysphonia, EEG abnormalities, encephalopathy, euphoria, extrapyramidal disorder, abnormal gait, hallucinations, hostility, hyperkinesia, hypnagogic hallucinations, hypokinesia, neuralgia, paranoia, phobic disorder, psychosis, sensory disturbance, somnambulism, stimulation, and teeth grinding; however, a causal relationship to the drug has not been established.

Rarely reported adverse nervous system effects for which a causal relationship to clomipramine has not been established include anticholinergic syndrome, aphasia, apraxia, catalepsy, cholinergic syndrome, choreoathetosis, hemiparesis, hyperesthesia, hyperreflexia, hypoesthesia, illusion, impaired im-

pulse control, indecisiveness, mutism, neuropathy, nystagmus, oculogyric crisis, oculomotor nerve paralysis, schizophrenic reaction, generalized spasm, stupor, and torticollis. Dystonia has been reported rarely in clomipramine-treated patients, although a causal relationship to the drug has not been established. Acute dystonia that included oculogyric crisis, torticollis, and lead-pipe rigidity has occurred in a patient receiving clomipramine. Exacerbation of motor tics and development of vocal tics also have been reported in a patient receiving the drug.

Suicidal ideation and suicide attempt have been reported in less than 1% of patients receiving clomipramine and suicide has been reported rarely. (See Cautions: Precautions and Contraindications.)

■ **Cardiovascular Effects** During clinical trials, modest orthostatic decreases in blood pressure and modest tachycardia each occurred in about 20% of patients receiving clomipramine, although patients frequently were asymptomatic. Postural hypotension occurred in about 6 or 4% of adults or children and adolescents, respectively, and tachycardia occurred in about 4 or 2% of adults or children and adolescents, respectively, receiving clomipramine in controlled clinical trials. Flushing occurred in about 8 or 7% of adults or children and adolescents, respectively, treated with the drug in controlled clinical trials.

Palpitations occurred in about 4% of both adults and children or adolescents receiving clomipramine in controlled clinical trials. Chest pain occurred in about 4 or 7% of adults or children and adolescents, respectively, and syncope occurred in about 2% of children and adolescents receiving clomipramine in controlled clinical trials.

Among approximately 1400 patients who received clomipramine during the premarketing evaluation, ECG abnormalities were observed in about 1.5% of the patients compared with 3.1% of those who received an active control and 0.7% of those receiving placebo. The most commonly observed ECG changes were ventricular premature contractions, ST-T wave changes, and intraventricular conduction abnormalities. These changes rarely were associated with clinically important symptoms; nevertheless, caution is necessary when treating patients with known cardiovascular disease with clomipramine, and gradual dosage titration is recommended in such patients.

Arrhythmia, bradycardia, cardiac arrest, extrasystoles, and pallor occurred in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Aneurysm, atrial flutter, bundle-branch block, cardiac failure, cerebral hemorrhage, heart block, myocardial infarction, myocardial ischemia, peripheral ischemia, thrombophlebitis, vasospasm, and ventricular tachycardia have occurred rarely, but these adverse effects also have not been attributed definitely to the drug. Hypertension also has been reported.

General edema, greater susceptibility to infection, malaise, and parosmia have been reported in less than 1% of clomipramine-treated patients and dependent edema has been reported rarely, although these adverse effects have not been attributed definitely to the drug.

There have been reports of fatigue and dizziness during physical exertion in children and adolescents receiving clomipramine. Because the cardiovascular effects of the drug have not been studied during such stress in this age group, some clinicians state that clomipramine should be used with caution in children and adolescents who participate in active sports.

■ **GI Effects** Adverse GI effects are encountered commonly during initial clomipramine therapy and in some cases can lead to early withdrawal of the drug. Dry mouth occurs in about 84 or 63% of adults or children and adolescents, respectively, and constipation occurs in about 47 or 22% of adults or children and adolescents, respectively, receiving clomipramine.

Nausea has been reported in about 33 or 9% of adults or children and adolescents, respectively, receiving clomipramine. Dyspepsia occurred in about 22 or 13% of adults or children and adolescents, respectively, and diarrhea occurred in about 13 or 7% of adults or children and adolescents, respectively, receiving the drug. Anorexia occurred in about 12 or 22% of adults or children and adolescents, respectively, receiving the drug. Abdominal pain occurred in about 11 or 13% of adults or children and adolescents, respectively, receiving clomipramine. Increase in appetite occurred in 11% of adults treated with the drug. Taste perversion occurred in about 8 or 4% of adults or children and adolescents, respectively, receiving clomipramine. Vomiting occurred in about 7% of clomipramine-treated adults, children, and adolescents. Flatulence has been reported in about 6% of adults receiving the drug. GI disorder or dysphagia occurred in about 2% of clomipramine-treated adults, and eructation, ulcerative stomatitis, or halitosis occurred in about 2% of children and adolescents receiving the drug. Esophagitis occurred in about 1% of adults receiving clomipramine.

Blood in stool, colitis, duodenitis, gastric ulcer, gastritis, gastroesophageal reflux, gingivitis, glossitis, hemorrhoids, increased salivation, irritable bowel syndrome, peptic ulcer, rectal hemorrhage, taste loss, and tongue ulceration were reported in less than 1% of patients receiving clomipramine, but a causal relationship to the drug has not been established. Cheilitis, chronic enteritis, discolored feces, gastric dilatation, gingival bleeding, intestinal obstruction, oral/pharyngeal edema, paralytic ileus, and salivary gland enlargement have occurred rarely but have not been attributed definitely to clomipramine.

■ **Dermatologic and Sensitivity Reactions** In controlled trials, increased sweating occurred in about 29 or 9% of adults or children and adolescents, respectively, receiving clomipramine. Rash occurred in about 8% of adults and 4% of children and adolescents treated with the drug. Pruritus occurred in about 6% of adults and 2% of children and adolescents receiving clomipramine. Dermatitis, acne, or dry skin occurred in about 2% of clomipramine-treated adults. Abnormal skin odor occurred in about 2% of children and adolescents receiving clomipramine therapy. Urticaria occurred in about 1% of adults and allergy occurred in about 3% of adults and 7% of children and adolescents treated with the drug.

Alopecia, cellulitis, cyst, eczema, genital pruritus, psoriasis, and rash that was erythematous, maculopapular, or pustular have been reported in less than 1% of patients receiving clomipramine, but these effects have not been attributed definitely to the drug. Lupus erythematosus rash has occurred rarely. Photosensitivity reaction or skin discoloration has occurred in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Pseudocyanotic (e.g., slate-gray, blue-black, purplish) pigmentation that affected areas of the body exposed to sunlight and therefore may have been a photosensitivity reaction also has occurred with clomipramine. Chloasma has been reported rarely. Folliculitis, hypertrichosis, pilocrection, polyarteritis nodosa, seborrhea, skin hypertrophy, or skin ulceration has been reported rarely in patients receiving clomipramine, although a causal relationship has not been established.

■ **Metabolic and Electrolyte Effects** In controlled studies, weight gain occurred in about 18% of adults who received clomipramine therapy for the treatment of obsessive-compulsive disorder compared with 1% of those receiving placebo. In these studies, a weight gain of at least 7% of initial body weight occurred in about 28% of clomipramine-treated patients compared with 4% of those receiving placebo. In several patients, weight gain exceeded 25% of the initial body weight. Conversely, weight losses of at least 7% of initial body weight occurred in about 5% of clomipramine-treated patients compared with 1% of those who received placebo. In controlled studies, weight gain or weight loss occurred in about 2 or 7% of children and adolescents, respectively, receiving clomipramine.

Thirst occurred in about 2% of adults receiving clomipramine. Dehydration, gout, hypercholesterolemia, hyperglycemia, hyperuricemia, and hypokalemia have been reported in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Fat intolerance and glycosuria have been reported rarely in patients receiving clomipramine, although these adverse effects have not been attributed definitely to the drug.

■ **Ocular and Otic Effects** Abnormal vision occurred in about 18 or 7% of adults or children and adolescents, respectively, receiving clomipramine. Abnormal lacrimation, mydriasis, and conjunctivitis occurred in about 3, 2, and 1% of adults, respectively, receiving the drug. Anisocoria, blepharospasm, and ocular allergy occurred in about 2% of children and adolescents receiving clomipramine. Adverse ocular effects reported in less than 1% of clomipramine-treated patients include abnormal accommodation, diplopia, ocular pain, foreign body sensation, photophobia, and scleritis; however, a causal relationship to the drug has not been established.

Glaucoma has been reported rarely in patients receiving clomipramine, although a causal relationship to the drug has not been established. Angle-closure glaucoma that presented clinically as amaurosis fugax (transient monocular blindness) attacks that were precipitated by rising from a sitting or supine position has been reported in at least one female patient treated with the drug. Although the precise mechanism is unclear, it was suggested that an abnormally large fall in blood pressure upon standing up combined with an increase in intraocular pressure may have been responsible. Blepharitis, chromatopsia, conjunctival hemorrhage, exophthalmos, keratitis, night blindness, retinal disorder, strabismus, and visual field defect occurred rarely in patients receiving clomipramine, but have not been attributed definitely to the drug.

Tinnitus occurred in about 6 or 4% of adults or children and adolescents, respectively, receiving clomipramine. Otitis media or vestibular disorder occurred in about 4 or 2% of children and adolescents, respectively, receiving clomipramine. Adverse otic effects reported in less than 1% of clomipramine-treated patients include hyperacusis, deafness, earache, and labyrinth disorder; however, these effects have not been attributed definitely to the drug.

■ **Musculoskeletal Effects** Myalgia occurred in about 13% of adults receiving clomipramine. Back pain and arthralgia occurred in about 6 and 3% of adults, respectively, receiving clomipramine. Muscle weakness occurred in about 1 or 2% of adults or children and adolescents, respectively, receiving clomipramine. Arthrosis and leg cramps have been reported in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Exostosis, bruising, myopathy, and myositis have been reported rarely in clomipramine-treated patients, although these effects have not been attributed definitely to the drug.

■ **Hematologic Effects** Purpura has been reported in about 3% of adults receiving clomipramine. Although no cases of severe hematologic toxicity were reported during the premarketing evaluation of clomipramine, there subsequently have been rare reports of bone marrow depression in patients receiving the drug, including leukopenia, agranulocytosis, thrombocytopenia, anemia, and pancytopenia. In controlled trials, anemia occurred in about 2% of children and adolescents receiving the drug.

■ **Respiratory Effects** Pharyngitis occurred in about 14% of adults receiving clomipramine. Rhinitis occurred in about 12 or 7% of adults or children and adolescents, respectively, receiving clomipramine. Cough occurred in about 6 or 4% of adults or children and adolescents, respectively, receiving clomipramine. Sinusitis occurred in about 6 or 2% of adults or children and

adolescents, respectively, treated with the drug. Yawning occurred in about 3% of adults receiving clomipramine. Bronchospasm occurred in about 2 or 7% of adults or children and adolescents, respectively, receiving clomipramine.

Epistaxis occurred in about 2% of adults receiving clomipramine. Dyspnea or laryngitis occurred in about 2% of clomipramine-treated children and adolescents. The development of adverse respiratory effects (e.g., dry sore throat, cough) severe enough to result in aphonia also has been reported.

Although a causal relationship has not been established, bronchitis, hyperventilation, increased sputum, and pneumonia have been reported in less than 1% of patients receiving clomipramine, and cyanosis, hemoptysis, hiccup, hypoventilation, and laryngismus have been reported rarely.

■ **Genitourinary Effects** ***Sexual Dysfunction*** One characteristic of clomipramine therapy that may be troublesome to some patients is its relatively high incidence of sexual dysfunction. The incidence of sexual dysfunction in male patients receiving clomipramine therapy for obsessive-compulsive disorder during premarketing clinical trials was substantially higher than in those receiving placebo. Normal sexual functioning usually returns within a few days after discontinuing clomipramine therapy.

Libido change occurred in about 21% of adults receiving clomipramine. Ejaculatory failure occurred in about 42% of adult males treated with clomipramine compared with 2% of those receiving placebo, and impotence occurred in 20% of clomipramine-treated adult males compared with about 3% of those receiving placebo. Approximately 85% of adult males who experienced sexual dysfunction during clomipramine therapy chose to continue therapy with the drug. About 6% of adolescent males experienced ejaculation failure while receiving clomipramine. Premature ejaculation has been reported rarely but has not been attributed definitely to the drug. On the other hand, clomipramine has been used in the treatment of premature ejaculation† in a limited number of patients. Painful ejaculation or orgasm has been reported in a limited number of male patients receiving the drug.

Anorgasmy has been reported in both male and female patients receiving clomipramine. In u controlled trial, difficulty or inability to reach orgasm was the most common adverse sexual effect in clomipramine-treated patients; sexual function generally returned to normal within 3 days after discontinuance of the drug. Anorgasmy associated with clomipramine has responded to anticipatory administration of yohimbine in several patients. Orgasm during yawning also has been reported in a limited number of patients receiving clomipramine.

Other Genitourinary Effects Micturition disorder occurred in about 14 or 4% of adults or children and adolescents, respectively, receiving clomipramine. Urinary tract infection and frequent micturition occurred in about 6 and 5%, respectively, of adults receiving the drug. Urinary retention occurred in about 2 or 7% of adults or children and adolescents, respectively, receiving clomipramine while dysuria, including painful urination in men, and cystitis have been reported in about 2% of adults receiving clomipramine.

Dysmenorrhea has been reported in about 12 and 10% of adult and adolescent females, respectively, receiving clomipramine, and menstrual disorder (including irregular menstruation) has been reported in about 4% of adult females receiving the drug. Vaginitis and leukorrhea each occurred in about 2% of adult females receiving clomipramine therapy. Amenorrhea occurred in about 1% of adult females receiving clomipramine.

Although not attributed definitely to the drug, endometriosis, epididymitis, hematuria, nocturia, oliguria, ovarian cyst, perineal pain, polyuria, prostatic disorder, urethral disorder, urinary incontinence, uterine hemorrhage, or vaginal hemorrhage has been reported in less than 1% of clomipramine-treated patients. Albuminuria, cervical dysplasia, endometrial hyperplasia, pyuria, uterine inflammation, and vulvar disorder have occurred rarely; however, a causal relationship to the drug has not been established.

■ **Hepatic Effects** During premarketing evaluation, potentially clinically important elevations in serum ALT (SGOT) and AST (SGPT) concentrations exceeding 3 times the upper limit of normal were reported in approximately 1 and 3%, respectively, of patients receiving clomipramine. In most cases, these elevations in hepatic enzyme concentrations were not associated with other clinical findings suggestive of hepatic injury, and jaundice was not observed. Severe hepatic injury that was fatal in some cases has been reported rarely in foreign postmarketing experience. (See Cautions: Precautions and Contraindications.) Abnormal hepatic function and hepatitis have been reported in less than 1% of patients receiving clomipramine, although a causal relationship to the drug has not been established. Cross hepatotoxicity (e.g., elevated values on hepatic function tests, abdominal pain) involving different tricyclic antidepressants including clomipramine also has been reported.

■ **Other Adverse Effects** Hot flushes occurred in about 5% of adults and 2% of children and adolescents receiving clomipramine. Fever occurred in about 4% of adults and 2% of children and adolescents treated with the drug. Pain has been reported in about 3% of adults and 4% of children and adolescents receiving clomipramine therapy. Chills and local edema each occurred in about 2% of adults receiving the drug.

Tooth disorder occurred in about 5% of clomipramine-treated adults, and dental caries has been reported in less than 1% of patients receiving the drug. Although the exact mechanism for these effects is unclear, it has been suggested that long-term therapy with clomipramine or other antidepressants with prominent anticholinergic activity can lead to dental caries through inhibition of saliva secretion.

Elevations in serum prolactin concentrations have been reported following single and multiple doses of clomipramine. Nonpuerperal lactation has been reported in about 4% of adult females receiving clomipramine therapy. Breast enlargement and breast pain have been reported in about 2 and 1% of adult females, respectively, receiving the drug. Breast engorgement, breast fibroadenosis, and gynecomastia have been reported rarely in patients receiving clomipramine; however, these effects have not been attributed definitely to the drug.

Lymphadenopathy has been reported in less than 1% of clomipramine-treated patients, and leukemoid reaction and lymphoma-like disorder have been reported rarely, although a causal relationship to the drug has not been established.

Diabetes mellitus and hypothyroidism each have been reported in less than 1% of patients receiving clomipramine, and goiter and hyperthyroidism have been reported rarely; however, these effects have not been attributed definitely to the drug.

Oliguria, renal calculus, and renal pain have been reported in less than 1% of patients receiving clomipramine, and pyelonephritis and renal cyst have been reported rarely; however, a causal relationship to the drug has not been established. Hyponatremia also has occurred with clomipramine.

■ **Precautions and Contraindications**

[redacted] changes in behavior may occur in both adult and pediatric (see Cautions: Pediatric Precautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age, and a reduced risk was observed in adults 65 years of age or older. It currently is unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. If a decision is made to discontinue therapy, clomipramine dosage should be tapered as rapidly as is feasible but with recognition of the risks of abrupt discontinuance. (See Dosage and Administration.) FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression). Clomipramine is *not* approved for use in treating bipolar depression.

As with closely related tricyclic antidepressants, clomipramine should be used with caution in patients with concurrent cardiovascular disease; hyperthyroidism; increased intraocular pressure, a history of angle-closure glaucoma, or urinary retention; tumors of the adrenal medulla; clinically important renal impairment; or hepatic disease.

In patients with cardiovascular disease, gradual dosage titration of clomipramine is recommended. In hyperthyroid patients or patients receiving thyroid agents, the possibility of cardiac toxicity also should be considered. The manufacturers state that clomipramine should be used with caution in patients with increased intraocular pressure, a history of angle-closure glaucoma, or urinary retention, since its anticholinergic effects may exacerbate these conditions. Caution also should be exercised in patients with tumors of the adrenal medulla

(e.g., pheochromocytoma, neuroblastoma), since hypertensive crises may be provoked by clomipramine.

Clomipramine should be used with caution in patients with known hepatic disease, and the manufacturers recommend periodic monitoring of hepatic enzyme concentrations in such patients.

A variety of neuropsychiatric manifestations, including delusions, hallucinations, psychotic episodes, confusion, and paranoia, have been reported in patients receiving clomipramine. (See Cautions: Nervous System Effects.) However, because of the uncontrolled design of many of these studies, it is not possible to provide a precise estimate of the extent of the risk of such effects in clomipramine-treated patients. In patients whose schizophrenia has been unrecognized, an acute psychotic episode may be precipitated by clomipramine or other antidepressants. Another possibility is that clomipramine, like other antidepressants, may precipitate mania or hypomania in patients with affective disorder.

As with other tricyclic antidepressants, the development of fever and sore throat in any patient receiving clomipramine therapy should prompt the clinician to obtain leukocyte and differential blood cell counts. (See Cautions: Hematologic Effects.)

Male patients for whom clomipramine therapy is considered should be informed about the relatively high incidence of sexual dysfunction associated with the drug. Sexual dysfunction occurred in more males with obsessive-compulsive disorder treated with clomipramine than with placebo in premarketing experience. (See Cautions: Genitourinary Effects.)

As with closely related tricyclic antidepressants, the risks associated with electroconvulsive therapy (ECT) may be increased during concurrent clomipramine therapy. Because of the limited clinical experience to date, the manufacturers recommend that the combination of clomipramine and ECT be limited to those patients for whom it is essential.

Prior to elective surgery with general anesthetics, the manufacturers state that clomipramine therapy should be discontinued for as long as is clinically feasible, and the anesthetist should be so advised.

The withdrawal effects of clomipramine have not been systematically evaluated in controlled studies, although such effects have been reported following abrupt withdrawal of closely related tricyclic antidepressants. (See Cautions: Nervous System Effects and also see Chronic Toxicity in the Tricyclic Antidepressants General Statement 28:16.04.28.) Therefore, gradual tapering of clomipramine dosage and careful monitoring of the patient is recommended during discontinuance of clomipramine therapy.

Clomipramine can produce somnolence and impaired concentration, and patients should be cautioned that the drug may impair the mental and/or physical abilities required for the performance of these complex tasks. Patients also should be cautioned about the use of alcohol, barbiturates, or other CNS depressants because the effects of these agents may be exaggerated during concurrent clomipramine therapy.

The possibility of seizure is the most clinically important risk associated with clomipramine therapy (see Cautions: Nervous System Effects), and the drug should be used with caution in patients with a history of seizures or other predisposing factors (e.g., brain damage of various etiology, alcoholism, concurrent use of other drugs that lower the seizure threshold). The ability to predict the occurrence of seizures with daily doses exceeding 250 mg is limited because plasma concentrations may be dose dependent and may vary considerably among individuals administered the same dosage. Nevertheless, the manufacturers recommend limiting the daily dose of clomipramine to a maximum of 250 mg in adults or 3 mg/kg (up to 200 mg) in children and adolescents. Patients receiving clomipramine should be informed about the risk of seizures associated with the drug. In addition, physicians should discuss with patients the risk and the possibility of serious injury to themselves or other people resulting from sudden loss of consciousness while engaged in certain complex and hazardous activities (e.g., operation of complex machinery, driving a motor vehicle, swimming, climbing).

Clomipramine is contraindicated in patients with known hypersensitivity to the drug or other tricyclic antidepressants. The drug also is contraindicated in patients currently receiving, or having recently received (i.e., within 2 weeks), monoamine oxidase (MAO) inhibitor therapy. (See Drugs Associated with Serotonin Syndrome: Monoamine Oxidase Inhibitors, under Drug Interactions.) Clomipramine also is contraindicated during the acute recovery phase following myocardial infarction.

■ **Pediatric Precautions** Safety and efficacy of clomipramine in children younger than 10 years of age have not been established. Therefore, the manufacturers state that no specific recommendations can be made for the use of the drug in this age group.

Safe use of clomipramine in pediatric patients 10 years of age or older for the treatment of obsessive-compulsive disorder (OCD) is based on relatively short-term studies in this patient population and from extrapolation of experience gained with adult patients. The potential risks associated with long-term clomipramine therapy have not been systematically evaluated in children and adolescents. Although there is no evidence that the drug adversely affects growth, development, or maturation in these patients, the absence of such findings does not rule out a potential for such effects with long-term use.

In a controlled study, clomipramine has been administered for up to 8 weeks to 46 children and adolescents 10–17 years of age. In addition, 150 adolescent patients have received clomipramine therapy for periods ranging from several months to several years in uncontrolled studies. Out of a total of 196 children and adolescents studied, 50 patients were 13 years of age or younger and 146 patients were 14–17 years of age. The adverse effect profile in this age group is similar to that observed in adults.

FDA warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. The risk of suicidality for these drugs was identified in a pooled analysis of data from a total of 24 short-term (4–16 weeks), placebo-controlled studies of 9 antidepressants (i.e., bupropion, citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, venlafaxine) in over 4400 children and adolescents with major depressive disorder, OCD, or other psychiatric disorders. The analysis revealed a greater risk of adverse events representing suicidal behavior or thinking (suicidality) during the first few months of treatment in pediatric patients receiving antidepressants than in those receiving placebo. The average risk of such events was 4% among children and adolescents receiving these drugs, twice the risk (2%) that was observed among those receiving placebo. However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

The risk of suicidality in FDA's pooled analysis differed across the different psychiatric indications, with the highest incidence observed in the major depressive disorder studies. In addition, although there was considerable variation in risk among the antidepressants, a tendency toward an increase in suicidality risk in younger patients was found for almost all drugs studied. It is currently unknown whether the suicidality risk in pediatric patients extends to longer-term use (i.e., beyond several months).

As a result of this analysis and public discussion of the issue, FDA has directed manufacturers of all antidepressants to add a boxed warning to the labeling of their products to alert clinicians of this suicidality risk in children and adolescents and to recommend appropriate monitoring and close observation of patients receiving these agents. (See Cautions: Precautions and Contraindications.) The drugs that are the focus of the revised labeling are all drugs included in the general class of antidepressants, including those that have not been studied in controlled clinical trials in pediatric patients, since the available data are not adequate to exclude any single antidepressant from an increased risk. In addition to the boxed warning and other information in professional labeling on antidepressants, FDA currently recommends that a patient medication guide explaining the risks associated with the drugs be provided to the patient each time the drugs are dispensed.

Anyone considering the use of clomipramine in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need.

■ **Geriatric Precautions** The manufacturers state that clinical studies with clomipramine did not include sufficient numbers of patients 65 years of age or older to determine whether they respond differently than younger patients. No unusual age-related adverse effects were identified in 152 patients at least 60 years of age participating in US clinical studies who received the drug for periods of several months to several years. In addition, other clinical experience revealed no evidence of age-related differences in response to clomipramine.

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Cautions: Precautions and Contraindications.)

Clomipramine is eliminated more slowly in geriatric patients. In addition, older patients may not tolerate the drug's adverse effects as well as younger patients. The manufacturers and some clinicians recommend cautiously selecting a clomipramine dosage regimen in geriatric patients, usually starting at the lower end of the recommended dosage range, since decreased hepatic, renal, or cardiac function and concomitant illnesses and medications are more frequent in this population.

■ **Mutagenicity and Carcinogenicity** No clear evidence of carcinogenicity was seen in rats receiving oral clomipramine hydrochloride dosages of 20 times the maximum recommended human daily dosage in a 2-year bioassay. Hemangioendothelioma was observed in 3 out of 235 rats administered clomipramine; the relationship between this rare tumor and the drug is not known.

■ **Pregnancy, Fertility, and Lactation** Teratogenic effects were not observed in rats and mice receiving clomipramine hydrochloride dosages up to 20 times the maximum human daily dosage. Slight, nonspecific fetotoxic effects were observed in the offspring of pregnant mice receiving 10 times the maximum human daily dosage. Slight, nonspecific embryotoxicity occurred in rats receiving 5–10 times the maximum human daily dosage.

There are no adequate and controlled studies using clomipramine in pregnant women, and the drug should be used during pregnancy only if the possible benefits justify the potential risk to the fetus. Women should be advised to notify their physician if they are or plan to become pregnant during clomipramine therapy. Neonates whose mothers had received clomipramine throughout pregnancy in dosages of 75–250 mg daily have exhibited withdrawal manifestations or adverse effects, including jitteriness, tremor, seizures, twitching, hypertonia, hypotonia, tachypnea, respiratory acidosis, cyanosis, feeding difficulties, hypothermia, lethargy, and diaphoresis. Phenobarbital has been recommended by some clinicians for the management of neurologic withdrawal

symptoms. Abrupt discontinuance of clomipramine at 32 weeks of pregnancy resulted in premature birth of a neonate who developed seizures soon after delivery. Because of the risk of neonatal withdrawal, some clinicians state that clomipramine therapy particularly should be avoided during late pregnancy.

Reproduction studies in rats using clomipramine hydrochloride dosages approximately 5 times the maximum human daily dosage have not revealed evidence of impaired fertility.

Clomipramine is distributed into milk. (See Pharmacokinetics: Distribution.) Adverse effects were absent in an infant who was breast-feeding from a woman who continued treatment with clomipramine at a dosage of 150 mg daily. However, because of the potential for adverse reactions, including concern about the potential for tricyclic antidepressants to affect development of the CNS of infants, a decision should be made whether to discontinue nursing or clomipramine, taking into account the importance of the drug to the woman. Women should be advised to notify their physician if they are breast-feeding.

Drug Interactions

Because of the similarity of clomipramine to other tricyclic antidepressants, all drug interactions that may occur with this class of drugs should be considered when clomipramine is used. (See Drug Interactions in the Tricyclic Antidepressants General Statement 28:16.04.28.) In addition, the possibility that clomipramine may interact with any concomitantly administered drug has not been evaluated systematically but should be considered.

■ **Drugs Associated with Serotonin Syndrome** ***Serotonin Syndrome*** Use of clomipramine concurrently or in close succession with other serotonergic drugs may result in serotonin syndrome. Although the syndrome appears to be relatively uncommon and usually mild in severity, serious complications, including seizures, disseminated intravascular coagulation, respiratory failure, severe hyperthermia, and death occasionally have been reported.

The syndrome most commonly occurs when 2 or more serotonergic agents with different mechanisms of action are administered either concurrently or in close succession. Serotonergic agents include those that increase serotonin synthesis (e.g., the serotonin precursor tryptophan), stimulate synaptic serotonin release (e.g., some amphetamines, dexfenfluramine, fenfluramine), inhibit the reuptake of serotonin after release (e.g., selective serotonin-reuptake inhibitors, tricyclic antidepressants, trazodone, dextromethorphan, meperidine, tramadol), decrease the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), have direct serotonin postsynaptic receptor activity (e.g., buspirone), or nonspecifically induce increases in serotonergic neuronal activity (e.g., lithium salts).

The combination of selective serotonin-reuptake inhibitors and MAO inhibitors appears to be responsible for most of the recent case reports of serotonin syndrome. The syndrome also has been reported when MAO inhibitors have been combined with tricyclic antidepressants such as clomipramine, tryptophan, meperidine, or dextromethorphan. In rare cases, the serotonin syndrome reportedly has occurred with the recommended dosage of a single serotonergic agent (e.g., clomipramine) or during accidental overdosage (e.g., sertraline intoxication in a child). Some other drugs that have been implicated in certain circumstances include buspirone, bromocriptine, dextropropoxyphene, methylenedioxymethamphetamine (MDMA; ecstasy), selegiline (a selective MAO-B inhibitor), and sumatriptan. Other drugs that have been associated with the syndrome but for which less convincing data are available include carbamazepine, fentanyl, and pentazocine.

Clinicians should be aware of the potential for serious, possibly fatal reactions associated with the serotonin syndrome in patients receiving 2 or more drugs that increase the availability of serotonin in the CNS, even if no such interactions with the specific drugs have been reported to date in the medical literature. Pending further accumulation of data, all drugs with serotonergic activity should be used cautiously in combination and such combinations avoided whenever clinically possible. Some clinicians state that patients who have experienced serotonin syndrome may be at higher risk for recurrence of the syndrome upon reinitiation of serotonergic drugs. Pending further experience in such cases, some clinicians recommend that therapy with serotonergic agents be limited following recovery. In cases in which the potential benefit of the drug is thought to outweigh the risk of serotonin syndrome, lower potency agents and reduced dosages should be used, combination serotonergic therapy should be avoided, and patients should be monitored carefully for symptoms of serotonin syndrome.

For further information on serotonin syndrome, including manifestations and treatment, see Serotonin Syndrome under Drug Interactions: Drugs associated with Serotonin Syndrome, in Fluoxetine Hydrochloride 28:16.04.20.

Monoamine Oxidase Inhibitors Concomitant administration of clomipramine and MAO inhibitors is contraindicated, and at least 2 weeks elapse between discontinuance of clomipramine therapy and initiation of MAO inhibitor therapy and vice versa. Concomitant administration of clomipramine and an MAO inhibitor is potentially hazardous and may result in severe adverse effects associated with serotonin syndrome such as hyperpyrexia, seizures, and coma. Other adverse effects that have occurred with this combination of drugs include confusion, agitation, myoclonus, tremor, diaphoresis, shivering, rigors, rigidity, hypotension, tachycardia, cardiac arrhythmia, and disseminated intravascular coagulation. Some reactions occurring in patients receiving clomipramine and an MAO inhibitor have been fatal.

Clonus, hyperreflexia, tremor, rigidity, and diaphoresis were observed in some patients after administration of clomipramine about 1 month after discontinuance of a selective inhibitor of monoamine oxidase-A. Status epilepticus developed in a patient after treatment with clomipramine was started approximately 24 hours after discontinuance of phenelzine sulfate. Although the mechanism has not been clearly established, the reactions resemble serotonin syndrome and may be caused by excessive serotonergic activity in the CNS.

Other Serotonergic Agents Concurrent administration of clomipramine and other serotonergic drugs (e.g., lithium, alprazolam) has resulted in the development of adverse effects similar to those reported with the combination of clomipramine and an MAO inhibitor and which resemble the serotonin syndrome.

Concurrent administration of clomipramine and fluoxetine has resulted in seizures. Concurrent administration of clomipramine and fluvoxamine has resulted in a severalfold elevation of the plasma clomipramine concentration.

■ **CNS Depressants** Like other tricyclic antidepressants, clomipramine may be additive with or may potentiate the action of other CNS depressants such as alcohol and barbiturates. In addition, concomitant administration of clomipramine with phenobarbital reportedly resulted in an increase in the plasma concentration of phenobarbital.

■ **Drugs Affecting the Seizure Threshold** Caution should be observed with concurrent administration of clomipramine and drugs (e.g., other antidepressants, antipsychotic agents) that lower the seizure threshold. (See Cautions: Nervous System Effects.)

■ **Haloperidol** Concomitant administration of clomipramine with haloperidol reportedly resulted in increases in the plasma concentrations of clomipramine, presumably because of haloperidol-induced inhibition of clomipramine metabolism.

■ **Valproic Acid** The initiation of clomipramine therapy in a patient with a seizure disorder that was well controlled by valproic acid resulted in status epilepticus. The serum clomipramine concentration at the time of the seizures was elevated despite the relatively small dosage of clomipramine received (75 mg daily for 12 days). Although the mechanism has not been established clearly, it was suggested that valproic acid may have inhibited the metabolism and/or elimination of clomipramine. Pending further experience, it should be kept in mind that elevated serum concentrations of clomipramine and possibly its metabolites may occur when clomipramine and valproic acid are used concomitantly and that these changes may precipitate seizures in predisposed individuals.

■ **Other CNS Agents** The risks associated with concurrent administration of clomipramine and other CNS-active agents have not been fully evaluated to date; therefore, caution should be exercised when such agents are administered concomitantly.

■ **Oral Contraceptives** Limited data suggest that oral contraceptives do not interfere with the therapeutic effects of clomipramine. No difference in adverse effects or depression was observed in patients receiving clomipramine and oral contraceptives compared with those receiving clomipramine alone in one study. However, the clomipramine dosage given (25 mg daily) was lower than those commonly used in the treatment of obsessive-compulsive disorder or depression. Further study to confirm the safety and efficacy of combined clomipramine and oral contraceptive therapy is necessary.

■ **Smoking** Substantially lower plasma clomipramine concentrations have been reported in cigarette smokers receiving clomipramine when compared with nonsmokers. The presumed mechanism appears to be induction of clomipramine metabolism by nicotine or other substances present in cigarette smoke.

■ **Protein-bound Drugs** Clomipramine and its active metabolite, desmethylclomipramine, are highly protein bound; therefore, they theoretically could be displaced from binding sites by or could displace from binding sites other protein-bound drugs such as oral anticoagulants (e.g., warfarin) and digoxin. Pending further accumulation of data, patients receiving clomipramine with any highly protein-bound drug should be observed for potential adverse effects associated with combined therapy.

■ **Other Drugs** Concomitant use of clomipramine with anticholinergic or sympathomimetic drugs requires close supervision and careful adjustment of the dosage of clomipramine because of potential additive effects.

Consideration of the structural similarity of clomipramine with other tricyclic antidepressants would suggest that blockade of the pharmacologic effects (such as hypotension) and possibly the adverse effects of guanethidine, clonidine, or other similar hypotensive agents, as has been reported with several other tricyclic antidepressants, may be anticipated with clomipramine.

The plasma concentrations of several tricyclic antidepressants closely related to clomipramine reportedly were increased with concomitant administration of methylphenidate or drugs that inhibit hepatic microsomal enzyme systems (e.g., cimetidine, fluoxetine) and were decreased with concomitant administration of drugs that induce hepatic microsomal enzymes (e.g., barbiturates, phenytoin). Such effects also may be anticipated with clomipramine.

Acute Toxicity

Limited information is available on the acute toxicity of clomipramine.

■ **Pathogenesis** Postmarketing reports from the UK suggest that clomipramine overdosage results in lethality similar to that reported for other closely related tricyclic antidepressants.

In 10 out of 12 patients who overdosed on clomipramine taken alone or with other drugs during US clinical studies, complete recovery occurred with overdosages of up to 5 g that produced plasma concentrations of up to 1010 ng/mL. In the 2 remaining patients, who were suspected of ingesting overdosages of 7 g and 5.75 g, death occurred. Other fatalities have been reported after overdosages of clomipramine were ingested. The lowest dosage of clomipramine associated with fatality outside of the US is 750 mg.

■ **Manifestations** Overdosage with clomipramine produces signs and symptoms similar to that with other tricyclic antidepressants. (See Acute Toxicity: Manifestations, in the Tricyclic Antidepressants General Statement 28:16.04.28.) Acute pancreatitis accompanied by prolonged ileus has occurred following an overdose of clomipramine in one patient.

The signs and symptoms of clomipramine overdosage vary in severity depending on a number of factors, including the amount of drug absorbed, the patient's age, and the amount of time elapsed since ingestion. Plasma concentrations of clomipramine should not guide management of the patient. However, they may be of qualitative value when the diagnosis is not clear. In addition, evidence from one patient who experienced biphasic absorption (delayed) and elimination of clomipramine in which, after an initial decline, the serum concentration of clomipramine and desmethylclomipramine increased to a peak and declined subsequently, suggests that monitoring such concentrations until the patient is stable may be of diagnostic benefit, since manifestations of severe toxicity and the need for aggressive management also were biphasic, recurring 3–4 days after the initial toxic episode. Although clomipramine and desmethylclomipramine have low cross-reactivity (e.g., 40–50% to antibody for clomipramine at concentrations of 189–472 ng/mL) with a fluorescent polarization immunoassay (FPIA) for tricyclic antidepressants, clomipramine concentrations of 100 ng/mL are detectable by the assay, and therefore this nonspecific assay may still be useful in diagnosing overdosage with the drug.

■ **Treatment** For information on the management of tricyclic antidepressant overdosage, see Acute Toxicity: Treatment, in the Tricyclic Antidepressants General Statement 28:16.04.28. In addition, clinicians should consult a poison control center for current information about therapy for overdoses of tricyclic antidepressants because such treatment is complex and changeable.

Chronic Toxicity

Clomipramine has not been evaluated systematically in animals or humans to determine its potential for abuse, tolerance, or physical dependence. Although discontinuance of therapy has been associated with a variety of withdrawal manifestations (see Cautions: Nervous System Effects), there is no evidence of drug-seeking behavior, except for one patient with a history of dependence on codeine, benzodiazepines, and multiple psychoactive drugs. This patient received clomipramine for depression and panic attacks and appeared to become dependent on the drug after hospital discharge.

Although foreign clinical experience has not revealed substantial evidence for abuse potential with clomipramine, it is impossible to predict the extent to which the drug may be misused or abused. Because of such uncertainty, clinicians should carefully evaluate patients for a history of substance abuse and such patients who receive clomipramine should be monitored closely.

Pharmacology

The pharmacology of clomipramine is complex and in many ways resembles that of other antidepressants, particularly those agents (e.g., selective serotonin-reuptake inhibitors, trazodone) that predominantly potentiate the pharmacologic effects of serotonin (5-HT). Although clomipramine's principal pharmacologic effect in vitro is the selective inhibition of serotonin reuptake, in vivo the drug's pharmacologic activity is not so selective because of the action of its demethylated metabolite, desmethylclomipramine, as an inhibitor of norepinephrine reuptake. As a result of this and other effects, clomipramine also shares the pharmacologic profile of other tricyclic antidepressants.

■ **Nervous System Effects** The precise mechanism of action that is responsible for the efficacy of clomipramine in the treatment of obsessive-compulsive disorder is unclear. However, because of its pronounced potency in blocking serotonin reuptake at the presynaptic neuronal membrane and its efficacy in the treatment of obsessive-compulsive disorder, a serotonin hypothesis has been developed to explain the pathogenesis of the condition. The hypothesis postulates that a dysregulation of serotonin is responsible for obsessive-compulsive disorder and that clomipramine is effective because it corrects this imbalance. The potency of clomipramine relative to other tricyclic antidepressants as a serotonin-reuptake inhibitor and its superiority in obsessive-compulsive disorder provide additional support to this hypothesis. Although the available evidence supports the serotonergic hypothesis of obsessive-compulsive disorder (see Pharmacology: Serotonergic Effects), additional studies are necessary to confirm this hypothesis.

Like other tricyclic antidepressants, the exact mechanism of clomipramine's antidepressant action is unclear. Clomipramine and its principal metabolite, desmethylclomipramine, have been shown to block the reuptake of serotonin and norepinephrine, respectively, at the presynaptic neuronal membrane. The effects of serotonin and norepinephrine may thus be potentiated. However, it has been suggested that postsynaptic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of antidepressant agents. During long-term therapy with most antidepressants (e.g., tricyclic antidepressants, monoamine oxidase [MAO] inhibitors), these adaptive changes generally consist of subsensitivity of the noradrenergic adenylate cyclase system in association with a decrease in the number of β-adrenergic receptors; such effects on noradrenergic receptor function commonly are referred to as "down-regulation." In addition, some antidepressants reportedly decrease the number of 5-HT binding sites following chronic administration.

Like other tricyclic antidepressants, clomipramine may produce sedation. The drug also may lower the seizure threshold, particularly at relatively high dosages. (See Cautions: Nervous System Effects.)

Serotonergic Effects Clomipramine is a potent and somewhat selective inhibitor of serotonin reuptake at the presynaptic neuronal membrane. Clomipramine-induced inhibition of serotonin reuptake causes increased synaptic concentrations of the neurotransmitter, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission.

Clomipramine is the most potent inhibitor of serotonin reuptake among currently available tricyclic antidepressants. Data from in vitro studies suggest that clomipramine is approximately equivalent to or more potent than fluoxetine as a serotonin-reuptake inhibitor; however, in vivo studies indicate that the serotonin-reuptake inhibiting effect of fluoxetine may be more potent than that of clomipramine on a weight as well as an equimolar basis. This apparent discrepancy may be explained at least in part by the relatively long elimination half-lives of fluoxetine and its principal metabolite, norfluoxetine. In addition, metabolism by *N*-demethylation decreases the potency and specificity of serotonin-reuptake inhibition by clomipramine but not fluoxetine.

Clomipramine appears to decrease the turnover of serotonin in the CNS, probably as a result of a decrease in the release and/or synthesis of serotonin. Several studies have investigated the effects of clomipramine on serotonin concentrations in patients with obsessive-compulsive disorder. The concentration of serotonin in platelets has been shown to be substantially lower in patients with obsessive-compulsive disorder treated with the drug, and this decrease has been shown to correlate with clinical improvement in obsessive-compulsive manifestations in these patients.

Clomipramine reportedly decreases the concentration of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of serotonin, in the CSF of patients with obsessive-compulsive disorder or depression. Limited data suggest a possible relationship between improvement of obsessive-compulsive manifestations and decreased concentrations of 5-HIAA in the CSF.

Manifestations of obsessive-compulsive disorder worsened after administration of a serotonin agonist, metachlorophenylpiperazine (mCPP), compared with placebo. Manifestations of obsessive-compulsive disorder also appeared to worsen after administration of a nonselective serotonin antagonist, metergoline, compared with placebo in patients receiving clomipramine. In contrast, such exacerbation was not observed with administration of mCPP in patients treated with clomipramine for several weeks or longer. If obsessive-compulsive disorder is related to increased serotonergic responsiveness, then these data suggest that clomipramine's efficacy following long-term administration may be related to induction of subsensitivity in the serotonergic system; such an effect has been referred to as "down-regulation" of serotonin receptors.

Effects on Other Neurotransmitters Clomipramine's principal metabolite, desmethylclomipramine, is an inhibitor of norepinephrine reuptake. Clomipramine decreases the concentration of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, in CSF in patients with obsessive-compulsive disorder. Patients with depressive affective (mood) disorders (e.g., major depressive episode) also exhibit decreases in concentrations of 5-HIAA and MHPG in CSF during treatment with clomipramine. The decrease in the concentration of 5-HIAA in CSF was correlated with inhibition of the in vitro uptake of ^{3}H-serotonin in plasma. The change in concentration of MHPG in CSF during clomipramine therapy was correlated with amelioration of depression.

Preliminary evidence suggests that clomipramine may inhibit dopaminergic activity. Unlike many other antidepressants, clomipramine exhibited extensive binding to postsynaptic receptors of dopamine antagonists (^{3}H-spiroperidol) in vitro. In animals, dopamine antagonism has been demonstrated by clomipramine's ability to reduce apomorphine-induced behavioral stereotypy. The drug also increases the CSF concentration of the dopamine metabolite homovanillic acid secondary to increased dopamine turnover. Because obsessive-compulsive disorder is common in patients with certain disorders of dopamine regulation (e.g., Sydenham's chorea, Tourette's disorder [Gilles de la Tourette's syndrome]), additional studies are needed to determine whether these initial findings are clinically important. (See Uses: Obsessive-Compulsive Disorder.)

Like other tricyclic antidepressants, clomipramine binds to cholinergic receptors and exhibits marked anticholinergic activity. As a result, clomipramine therapy may cause adverse effects commonly associated with blockade of muscarinic cholinergic receptors (e.g., dry mouth, blurred vision, urinary retention, constipation, confusion). In addition, clomipramine binds to α_1-adrenergic and histaminergic receptors and consequently exhibits α_1-adrenergic blocking and antihistaminic activity at usual therapeutic dosages. The drug also has been shown to bind to α_2-adrenoceptors and opiate receptors.

CNS Metabolic Effects Brain imaging studies using positron emission tomography (PET) have demonstrated metabolic abnormalities (usually hypermetabolism) in certain regions of the brain (including the orbitofrontal cortex, caudate nucleus, and prefrontal gyri) in patients with obsessive-compulsive disorder. Clomipramine appears to produce a return of metabolism to a more normal level in the regions of the brain that may be involved in the

pathology of obsessive-compulsive disorder (orbitofrontal cortex and the caudate nucleus). For example, the metabolic rate of glucose was decreased in regions of the orbitofrontal cortex and the left caudate nucleus and was increased in other areas of the basal ganglia, including the right anterior putamen, in patients with obsessive-compulsive disorder treated with clomipramine compared with pretreatment measurements.

Other limited data suggest a relationship between decreases in the metabolic rate of glucose in the orbitofrontal cortex and the efficacy of clomipramine in obsessive-compulsive disorder. The decrease from baseline in the metabolic rate of glucose in the left orbitofrontal region was greater in patients whose obsessive-compulsive symptoms improved during clomipramine or fluoxetine therapy than in nonresponders to such therapy. In these patients, the decrease from baseline in the metabolic rate of glucose in the right orbitofrontal region was correlated with improvement in the manifestations of obsessive-compulsive disorder.

Effects on Sleep Like tricyclic and most other antidepressants, clomipramine suppresses rapid eye movement (REM) sleep. The drug appears to be the most potent suppressor of REM sleep in the tricyclic antidepressant class. The REM-suppressing effect may be sustained following discontinuance of clomipramine therapy, and chronic therapy leads to substantial REM rebound upon withdrawal of the drug.

■ **Cardiovascular Effects** Clomipramine shares the cardiovascular effects of other tricyclic antidepressants (see Pharmacology in the Tricyclic Antidepressants General Statement 28:16.04.24) and may produce ECG changes (e.g., increases from baseline in QRS duration, QT interval corrected for rate [QT_c], and QRS axis; inversion or flattening of the T waves), cardiac urrhythmias, tachycardia, and postural hypotension.

■ **Neuroendocrine Effects** Clomipramine affects the endocrine system. IV administration of clomipramine produced a dose-related increase in plasma prolactin and corticotropin (ACTH) concentrations in healthy individuals; an increase in the plasma cortisol concentration also was observed. Patients with depressive affective (mood) disorders (e.g., major depressive episode) also exhibited increases in plasma prolactin, ACTH, and cortisol concentrations following IV administration of clomipramine; however, the increase in plasma prolactin noted in patients with a major depressive episode was less than in nondepressed individuals. Clomipramine-induced increases in prolactin secretion appear to be serotonergically mediated.

Clomipramine appears to affect the CSF concentration of neuropeptides that are elevated in patients with obsessive-compulsive disorder. The concentrations of such neuropeptides (e.g., corticotropin-releasing hormone, vasopressin) are decreased during long-term (e.g., 20 months) therapy with the drug. In addition, an increase in the CSF concentration, corrected for age, of oxytocin has been observed.

For further information on the pharmacology of clomipramine, see Pharmacology in the Tricyclic Antidepressants General Statement 28:16.04.24.

Pharmacokinetics

In all human studies described in the Pharmacokinetics section, clomipramine was administered as the hydrochloride salt.

■ **Absorption** Clomipramine hydrochloride appears to be well absorbed from the GI tract following oral administration. However, extensive first-pass metabolism decreases its oral bioavailability to about 50%. The oral capsules and solution of clomipramine hydrochloride reportedly are bioequivalent. Food does not appear to substantially affect the bioavailability of clomipramine from the capsules.

Peak plasma clomipramine concentrations of approximately 56–154 ng/mL (mean: 92 ng/mL) usually occur within 2–6 hours (mean: 4.7 hours) following oral administration of a single 50-mg dose of clomipramine hydrochloride. Like other tricyclic antidepressants, clomipramine exhibits considerable interindividual variation in plasma concentrations achieved with a given dose due, at least in part, to genetic differences in the metabolism of the drug. (See Pharmacokinetics: Elimination.)

Following multiple-dose oral administration of clomipramine, steady-state plasma concentrations of the drug generally are achieved within about 1–2 weeks. Steady-state plasma desmethylclomipramine (the principal metabolite) concentrations may be achieved at about the same time as steady-state plasma clomipramine concentrations or later. In some cases, plasma desmethylclomipramine concentrations have been observed to continue to increase during 4–6 weeks of administration of a constant dosage of clomipramine hydrochloride. Plasma concentrations of desmethylclomipramine generally exceed those of the parent drug following multiple daily dosing of clomipramine hydrochloride.

The manufacturers state that, after multiple daily dosing of clomipramine hydrochloride 150 mg, the accumulation factors for clomipramine and desmethylclomipramine are approximately 2.5 and 4.6, respectively. However, it may take 2 weeks or more to achieve this extent of accumulation at a constant dosage because of the relatively long elimination half-lives of clomipramine and desmethylclomipramine. At steady state, peak plasma concentrations of 94–339 (mean: 218) and 134–532 (mean: 274) ng/mL of clomipramine and desmethylclomipramine, respectively, were attained following multiple daily doses of 150 mg of clomipramine hydrochloride. Pharmacokinetic data in patients receiving clomipramine hydrochloride dosages ranging from 150–250 mg daily are lacking.

In a dose-proportionality study involving multiple dosing, steady-state plasma concentrations and the areas under the plasma concentration-time curve (AUCs) of clomipramine and desmethylclomipramine were not proportional to dose at dosages ranging from 25–150 mg daily. However, at dosages ranging from 100–150 mg daily there was an approximately linear relationship between these variables and dose. The manufacturers state that the relationship between dose and plasma clomipramine or desmethylclomipramine concentrations has not been systematically evaluated at higher dosages. However, if there is a substantial dose dependency at dosages exceeding 150 mg daily, the potential exists for dramatically higher steady-state plasma concentrations and AUCs of clomipramine and desmethylclomipramine even in patients receiving dosages within the recommended range. Such an effect may pose a potential risk in some patients. (See Cautions: Precautions and Contraindications.)

The effect of age on plasma concentrations of clomipramine and desmethylclomipramine is not fully known. However, substantially lower plasma concentrations of clomipramine and desmethylclomipramine have been reported in younger adults (18–40 years of age) compared with those obtained in individuals older than 65 years of age. Children younger than 15 years of age also had substantially lower plasma concentration-dose ratios of clomipramine when compared with adults. In addition, clomipramine appears to be better tolerated in younger than in older patients.

Substantially lower steady-state plasma clomipramine concentrations have been reported in smokers when compared with nonsmokers. However, smoking appears to have less effect on plasma concentrations of desmethylclomipramine.

The relationship between plasma clomipramine and desmethylclomipramine concentrations and the therapeutic and/or toxic effects of the drug has not been clearly established. The results of studies involving plasma concentration monitoring in patients with obsessive-compulsive disorder and/or depression have been equivocal. In some studies, the sum of plasma clomipramine and desmethylclomipramine concentrations has been used as the drug concentration. In depressed patients, preliminary evidence suggests that lower plasma concentrations of clomipramine plus desmethylclomipramine (less than 150 ng/mL) are associated with nonresponse while higher concentrations (exceeding 450 ng/mL) may be associated with an increased risk of adverse effects and perhaps nonresponse. In patients with obsessive-compulsive disorder, the results of 2 studies in which a relationship between plasma concentration and therapeutic response was found suggested that optimal therapeutic response may be obtained in patients with plasma clomipramine concentrations ranging from 100–250 ng/mL and plasma desmethylclomipramine concentrations ranging from 230–550 ng/mL.

■ **Distribution** Distribution of clomipramine and its metabolites into human body tissues and fluids has not been fully characterized. However, both clomipramine and desmethylclomipramine are highly lipophilic and are widely distributed in body tissues, with moderate to high concentrations occurring in organs such as the lungs, adrenals, kidneys, heart, and brain. The apparent volume of distribution of clomipramine in healthy adults averages 17 L/kg (range: 9–25 L/kg).

Both clomipramine and desmethylclomipramine cross the blood-brain barrier; the manufacturers state that desmethylclomipramine is distributed into CSF at a concentration about 2.6 times higher than in plasma. However, in one study of patients with depression or obsessive-compulsive disorder, the concentration of desmethylclomipramine in CSF was 2.6% that of the plasma concentration, corresponding to the fraction of desmethylclomipramine not bound to plasma proteins.

Clomipramine is approximately 97–98% bound to plasma proteins, principally to albumin and possibly to α_1-acid glycoprotein (α_1-AGP). The extent of protein binding of clomipramine appears to be independent of plasma concentration. Desmethylclomipramine is approximately 97–99% bound to plasma proteins. Because protein binding of both clomipramine and desmethylclomipramine is extensive, the manufacturers state that, while the possibility that clomipramine interacts with other highly protein-bound drugs has not been fully evaluated, such interactions may be important. (See Drug Interactions: Protein-bound Drugs.)

Clomipramine crosses the placenta and also is distributed into human milk. In one case report, plasma clomipramine concentrations were measured in an infant whose mother was receiving clomipramine hydrochloride 125 mg daily during pregnancy. The plasma clomipramine concentration in the infant was 267 ng/mL at birth; subsequently, the plasma concentration in the infant decreased although nursing began 7 days after delivery and continued. After the first week postpartum, the mother's dosage of clomipramine hydrochloride was increased to 150 mg daily and the concentration of clomipramine in milk was 80–160% of the concurrent plasma clomipramine concentration at steady state. The infant's plasma concentration of clomipramine was at the limit of detection (9.8 ng/mL) 35 days postpartum. Serum concentrations of clomipramine and its metabolites (i.e., desmethylclomipramine, 8-hydroxyclomipramine, 8-hydroxydesmethylclomipramine) were not observed or were below the limit of detection in a limited number of healthy, full-term neonates and infants who were breast-fed by mothers whose only medication was clomipramine administered at a constant dosage for at least 3 weeks.

■ **Elimination** Evidence that the steady-state plasma concentrations and AUCs of clomipramine and desmethylclomipramine may increase disproportionately with increasing oral doses of the drug suggests that the metabolism of clomipramine and desmethylclomipramine may be capacity-limited (saturable). The manufacturers caution that this fact should be considered when

evaluating the available data concerning the pharmacokinetic parameters of clomipramine as these data often were obtained in individuals receiving 150-mg daily doses. If clomipramine and desmethylclomipramine exhibit nonlinear pharmacokinetics at dosages exceeding 150 mg daily, their elimination half-lives may be considerably prolonged at dosages near the upper limit of the recommended dosage range (i.e., 200–250 mg daily). At such dosages, clomipramine and desmethylclomipramine may accumulate, which may increase the incidence of any dose- or plasma concentration-dependent adverse effects, particularly seizures.

The elimination half-life of clomipramine averages approximately 32 hours (range: 19–37 hours) and that of desmethylclomipramine averages about 69 hours (range: 54–77 hours) following a single, 150-mg oral dose of the drug.

The exact metabolic fate of clomipramine has not been fully elucidated. Clomipramine appears to be extensively metabolized to desmethylclomipramine and other metabolites and their glucuronide conjugates. Desmethylclomipramine, the principal metabolite, is formed by *N*-demethylation of clomipramine. Other metabolites of clomipramine include 8-hydroxyclomipramine, 2-hydroxyclomipramine, and clomipramine *N*-oxide, which appear to be formed via 8-hydroxylation, 2-hydroxylation, and *N*-oxidation, respectively. The metabolites of desmethylclomipramine include 8-hydroxydesmethylclomipramine and didesmethylclomipramine, which apparently are formed via 8-hydroxylation and *N*-demethylation, respectively. Although desmethylclomipramine is pharmacologically active, its efficacy in obsessive-compulsive disorder is not known. 8-Hydroxyclomipramine and 8-hydroxydesmethylclomipramine also are pharmacologically active but the clinical importance of their presence remains unknown.

The hydroxylation of clomipramine and desmethylclomipramine appears to be under genetic control (similar to that of debrisoquine and sparteine). In healthy adults who were phenotyped for debrisoquine hydroxylation, extensive metabolizers were distinguishable from poor metabolizers with regard to the extent of hydroxylation of desmethylclomipramine. Blood concentrations of desmethylclomipramine were higher than expected in a limited number of patients who subsequently were found to be poor metabolizers. Limited data suggest that CYP2D6, a cytochrome P-450 isoenzyme implicated in the sparteine/debrisoquine oxidation polymorphism, is involved in the 8-hydroxylation of clomipramine and desmethylclomipramine and in the 2-hydroxylation of clomipramine. In addition, demethylation of clomipramine may involve CYP2C, which is implicated in the *S*-mephenytoin oxidation polymorphism, and CYP1A2.

Possible differences in the metabolism of clomipramine among ethnic populations were suggested by a study in a limited number of healthy individuals that showed plasma clomipramine concentrations after a single oral dose of the drug to be higher in Asians (e.g., Indian, Pakistani) than in whites (e.g., British). In Japanese patients treated with clomipramine, substantial interindividual variation in demethylation and hydroxylation was observed; however, the prevalence of possibly poor demethylators and poor hydroxylators of clomipramine was estimated to be 0 and 1%, respectively. Further study is needed to clarify whether the pharmacokinetics of clomipramine truly differ in individuals of various ethnic backgrounds.

Following oral administration, clomipramine and its metabolites are excreted in urine and in feces (via biliary elimination). In 2 healthy individuals, approximately 51–60 and 24–32% of an orally administered, radiolabeled, 25-mg dose of clomipramine hydrochloride were excreted in urine and feces, respectively, after 14 days. Unchanged clomipramine and desmethylclomipramine were excreted in urine in quantities that together comprised approximately 0.8–1.3% of the dose. In a limited number of healthy individuals who received a single oral dose of clomipramine, 8-hydroxyclomipramine glucuronide was the principal metabolite found in urine. Although the urinary recovery of 8-hydroxyclomipramine glucuronide in these individuals who were phenotyped for metabolism of sparteine and mephenytoin was lower in poor metabolizers of sparteine compared with extensive metabolism of sparteine, estimates of clearance via glucuronidation did not differ between phenotypes, suggesting that the capacity for glucuronidation is not contingent on the capacity for 8-hydroxylation of clomipramine.

The effects of renal and hepatic impairment on the disposition of clomipramine have not been fully elucidated.

Limited data suggest that demethylation of clomipramine may be reduced with chronic alcohol consumption. In one study, the clearance of clomipramine via demethylation was decreased substantially and the ratio of blood clomipramine to desmethylclomipramine concentrations at steady state was higher in recently detoxified alcoholic patients (abstinence periods ranged from 4–20 weeks) compared with a control group of patients with no history of alcoholism.

Induction of drug-metabolizing enzymes (as measured by antipyrine half-life) does not appear to occur with clomipramine.

Hemodialysis, peritoneal dialysis, forced diuresis, and/or exchange transfusion are unlikely to remove clomipramine and desmethylclomipramine substantially because of the drug's rapid distribution into body tissues.

Chemistry and Stability

■ **Chemistry** Clomipramine, a dibenzazepine-derivative tricyclic antidepressant, is the 3-chloro analog of imipramine. Clomipramine is commercially available as the hydrochloride salt, which occurs as a white to off-white crystalline powder. The drug is freely soluble in water, methanol, and methylene chloride, and insoluble in ethyl ether and hexane. The drug has a pK_a of 9.5.

■ **Stability** Clomipramine hydrochloride capsules should be stored in tight containers at a temperature of 20–25°C and protected from moisture. When stored as directed, the capsules have an expiration date of 3 years following the date of manufacture.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of clomipramine, see the Tricyclic Antidepressants General Statement 28:16.04.28.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Desipramine Hydrochloride

■ Desipramine is a dibenzazepine-derivative tricyclic antidepressant.

Dosage and Administration

■ **Administration** Desipramine hydrochloride is administered orally. Although desipramine has been administered in up to 3 divided doses throughout the day, it is long-acting and the entire daily dose may be administered at one time. Administration of the entire daily dose at bedtime may reduce daytime sedation; patients who experience insomnia and stimulation from the drug may receive the entire daily dose in the morning.

■ **Dosage** There is a wide range of dosage requirements, and dosage of desipramine hydrochloride must be carefully individualized. Initial dosages in adults should be low and generally range from 75–150 mg daily, depending on the severity of the condition being treated. Dosage may be gradually adjusted to the level that produces maximal therapeutic effect with minimal toxicity. In seriously ill patients, desipramine dosage may be gradually increased to 300 mg daily if necessary. Desipramine hydrochloride dosages exceeding 300 mg daily are not recommended. Hospitalized patients under close supervision may generally be given higher doses than outpatients. Geriatric and adolescent patients should usually be given lower than average doses. Manufacturers state that therapy should be initiated with 25–50 mg daily in these patients and that dosages greater than 100 mg daily are usually not necessary. In geriatric and adolescent patients who are seriously ill, desipramine dosage may be further increased to 150 mg daily if necessary. Desipramine hydrochloride dosages exceeding 150 mg daily are not recommended in these age groups. Maximum antidepressant effects may not occur for 2 or more weeks after therapy is begun.

After symptoms are controlled, dosage should be gradually reduced to the lowest level that will maintain relief of symptoms. To avoid the possibility of precipitating withdrawal symptoms, desipramine should not be terminated abruptly in patients who have received high dosages for prolonged periods.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Cautions

Desipramine shares the pharmacologic actions, uses, and toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. Patients should be fully advised about the risks, especially suicidal thinking and behavior (suicidality), associated with tricyclic antidepressant therapy. For a complete discussion, see Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.

■ **Pediatric Precautions** Because collapse and sudden death occurred in at least one child (an 8-year-old boy) receiving desipramine for 2 years for attention deficit hyperactivity disorder (ADHD) and sudden death also has been reported in other children receiving the drug, at least one manufacturer of

phenones, phenothiazines) and has been referred to as an atypical or second-generation antipsychotic agent. The exact mechanism of action of aripiprazole in schizophrenia, bipolar mania, major depressive disorder, and agitation associated with schizophrenia or bipolar mania has not been fully elucidated but, like that of other drugs with efficacy in these conditions (e.g., olanzapine, risperidone, ziprasidone), may involve the drug's activity at dopamine D_2 and serotonin type 1 ($5\text{-}HT_{1A}$) and type 2 ($5\text{-}HT_{2A}$) receptors. However, aripiprazole appears to differ from other atypical antipsychotic agents because the drug demonstrates partial agonist activity at D_2 and $5\text{-}HT_{1A}$ receptors and antagonist activity at $5\text{-}HT_{2A}$ receptors. Antagonism at other receptors (e.g., α_1-adrenergic receptors, histamine H_1 receptors) may contribute to other therapeutic and adverse effects (e.g., orthostatic hypotension, somnolence) observed with aripiprazole.

Aripiprazole is extensively metabolized in the liver principally via dehydrogenation, hydroxylation, and *N*-dealkylation by the cytochrome P-450 (CYP) 2D6 and 3A4 isoenzymes. The major active metabolite of aripiprazole, dehydro-aripiprazole, exhibits affinity for D_2 receptors similar to that of the parent compound and represents approximately 40% of aripiprazole area under the concentration-time curve (AUC) in plasma. Steady-state plasma concentrations of both aripiprazole and dehydro-aripiprazole are achieved within 14 days. The elimination half-lives of aripiprazole and dehydro-aripiprazole are approximately 75 and 94 hours, respectively. Approximately 18% and less than 1% of aripiprazole is excreted unchanged in feces and urine, respectively.

Advice to Patients

Importance of providing copy of written patient information (medication guide) each time aripiprazole is dispensed. Importance of advising patients to read the patient information before taking aripiprazole and each time the prescription is refilled.

Increased mortality in geriatric patients with dementia-related psychosis; importance of advising patients and caregivers that geriatric patients with dementia-related psychosis treated with antipsychotic agents are at an increased risk of death. Patients and caregivers should also be informed that aripiprazole is *not* approved for treating geriatric patients with dementia-related psychosis.

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment.

Because somnolence and impairment of judgment, thinking, or motor skills may be associated with aripiprazole, avoid driving, operating machinery, or performing hazardous tasks while taking aripiprazole until the drug's effects on the individual are known. Importance of avoiding alcohol during aripiprazole therapy.

Risk of neuroleptic malignant syndrome (NMS), a rare but life-threatening syndrome that can cause high fever, stiff muscles, sweating, fast or irregular heart beat, change in blood pressure, confusion, and kidney damage. Importance of informing patients to immediately contact a healthcare professional if such symptoms develop.

Importance of clinicians informing patients in whom chronic aripiprazole use is contemplated of risk of tardive dyskinesia. Importance of informing patients to report any muscle movements that cannot be stopped to a healthcare professional.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., diabetes mellitus).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of avoiding overheating or dehydration.

For patients taking aripiprazole orally disintegrating tablets, importance of not removing a tablet from the blister package until just before administering a dose; importance of peeling blister open with dry hands and placing tablet on tongue to dissolve and be swallowed with saliva.

Importance of informing patients with phenylketonuria that aripiprazole orally disintegrating 10- and 15-mg tablets contain 1.12 and 1.68 mg of phenylalanine, respectively.

Importance of being aware that aripiprazole oral solution contains 400 mg of sucrose and 200 mg of fructose per mL.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[a] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Clozapine

■ Clozapine has been referred to as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Clozapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia and generally are effective in all subtypes of the disorder and subgroups of patients. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Clozapine has been shown to be an effective, relatively rapid-acting, broad-spectrum antipsychotic agent in both uncontrolled and controlled studies of patients with schizophrenia. In these studies, improvement in manifestations of schizophrenia was based on the results of various psychiatric rating scales, principally the Brief Psychiatric Rating Scale (BPRS) that assesses factors such as anergy, thought disturbance, activation, hostility/suspiciousness, and anxiety/depression. In clinical studies, clozapine improved both positive (florid symptomatology such as hallucinations, conceptual disorganization, and suspiciousness) and negative ("deficit" symptomatology such as emotional withdrawal, motor retardation, blunted affect, and disorientation) manifestations of schizophrenia; conventional (typical) antipsychotic agents appear to have lesser effects on negative manifestations of the disorder. In comparative studies, clozapine was at least as effective as, or more effective than several conventional antipsychotic agents, including chlorpromazine, haloperidol, perphenazine, or trifluoperazine.

Unlike conventional antipsychotic agents, however, clozapine generally does not induce extrapyramidal effects and has not been clearly implicated as a causative agent in tardive dyskinesia.

While the risks of adverse neurologic effects with long-term clozapine therapy remain to be fully elucidated, other adverse effects, including some potentially serious effects (e.g., agranulocytosis, seizures), may occur more frequently with clozapine therapy. Consequently, the manufacturers and most clinicians currently state that use of clozapine should be reserved for patients with severe disease that fails to respond adequately to conventional antipsychotic therapy, either because of insufficient effectiveness or the inability to achieve an effective dose due to intolerable adverse effects from those drugs. What constitutes an adequate trial of standard antipsychotic therapy, however, varies widely. The manufacturers and some clinicians recommend that a patient be given an adequate trial of at least 2 different antipsychotic agents from at least 2 different chemical classes (e.g., phenothiazines, butyrophenones, thioxanthenes) before the patient is considered a candidate for clozapine therapy. The American Psychiatric Association (APA), however, currently recommends that a trial of clozapine be considered in patients who fail to respond to adequate trials of at least one antipsychotic agent unless therapy with the drug is specifically contraindicated (e.g., patients with myeloproliferative disorders, preexisting bone marrow depression, or a history of clozapine-induced agranulocytosis or severe granulocytopenia) or patients are unable or unwilling to comply with monitoring requirements. The APA also recommends that clo-

zapine should be considered in patients with a history of chronic and persistent suicidal ideation and behavior and in patients with persistent hostility and aggression.

Schizophrenia Clozapine is used for the symptomatic management of schizophrenia in severely ill patients whose disease fails to respond adequately to other antipsychotic therapy. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

Evidence from both retrospective and controlled prospective studies indicates that clozapine is effective in many patients who fail to respond adequately to other antipsychotic therapy and/or in whom such therapy produces intolerable adverse effects. In a controlled, comparative study in patients with at least moderately severe schizophrenia whose disease was refractory to at least 3 antipsychotic agents from at least 2 different chemical classes during the past 5 years, an adequate clinical response (a 20% or greater decrease in total BPRS score and either a posttreatment Clinical Global Impressions [CGI] scale rating of mildly ill or a posttreatment BPRS score of 35 or less) was noted after 1–6 weeks of therapy in 30% of patients receiving clozapine (mean maximum dosage exceeding 600 mg daily) compared with 4% of patients receiving chlorpromazine (mean maximum dosage exceeding 1200 mg daily) plus benztropine. In addition, clozapine was substantially more effective than chlorpromazine plus benztropine in improving both positive and negative manifestations of schizophrenia. In this study, resistance to antipsychotic treatment prior to entry into the clozapine/chlorpromazine comparative phase was confirmed by a 6-week trial of haloperidol (mean dosage of 61 mg daily) combined with benztropine. This study provides evidence from both categorical and continuous measures not only of clozapine's efficacy as an antipsychotic agent but also of its superiority over conventional antipsychotic drug therapy in a well-defined group of antipsychotic-resistant patients. Similar 6-week response rates in treatment-resistant schizophrenia have been reported in other studies with the drug. Clinically important improvement in quality of life and social functioning, including deinstitutionalization, interpersonal relationships, and ability to hold a job or attend school, also have been reported following initiation of clozapine therapy in patients with antipsychotic-resistant schizophrenia.

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

Pediatric Considerations. Although the safety and efficacy of clozapine in children and adolescents younger than 16 years of age have not been established, the drug has been successfully used for the management of childhood-onset schizophrenia in a limited number of treatment-resistant children and adolescents†. While the lower risk of extrapyramidal adverse effects and tardive dyskinesia during treatment with atypical antipsychotic agents such as clozapine compared with conventional antipsychotic agents represents an advantage in the treatment of childhood-onset schizophrenia, concerns regarding serious adverse effects (e.g., neutropenia; seizures) associated with clozapine limit its use in clinical practice. (See Cautions: Pediatric Precautions.) Therefore, the American Academy of Child and Adolescent Psychiatry (AACAP) states that clozapine is not considered a first-line agent, and the drug is recommended only in patients who have failed to respond to adequate therapeutic trials (i.e., use of sufficient dosages over a period of 4–6 weeks) of at least 2 other antipsychotic agents (at least one of which is an atypical antipsychotic) and/or have experienced substantial adverse effects (e.g., tardive dyskinesia) while receiving other antipsychotic agents. For additional information on the symptomatic management of childhood-onset schizophrenia, see Pediatric Considerations under Psychotic Disorders: Schizophrenia, in Uses in the Phenothiazines General Statement 28:16.08.24.

In one randomized, double-blind, clinical study conducted by the National Institute of Mental Health (NIMH), a limited number of children and adolescents (mean: 14 years of age) with childhood-onset schizophrenia (i.e., development of the disorder by 12 years of age or younger) who were intolerant and/or nonresponsive to at least 2 different antipsychotic agents were treated with either clozapine (up to a 525 mg daily; mean final dosage 176 mg daily) or haloperidol (up to 27 mg daily; mean final dosage 16 mg daily) for 6 weeks. In this study, children and adolescents receiving clozapine had substantially greater reductions in both positive and negative symptoms of schizophrenia than those receiving haloperidol. Additional follow-up of these patients over a 2-year period indicated that, as reported in adults, maximal antipsychotic effects in schizophrenic children and adolescents may not be evident until after 6–9 months of clozapine therapy. For most children and adolescents in the study, clozapine improved interpersonal functioning and enabled a return to a less restrictive setting. However, mild to moderate neutropenia occurred in 24% of the patients, and 29% required therapy with an anticonvulsant.

Suicide Risk Reduction in Schizophrenia and Schizoaffective Disorder Clozapine is used to reduce the risk of recurrent suicidal behavior in patients with schizophrenia or schizoaffective disorder who are judged to be at chronic risk for such behavior, based on history and recent clinical state. Efficacy of clozapine for this indication has been established in a multicenter, randomized, open-label clinical study (the International Suicide Prevention Trial [Inter SePT]) of 2 years' duration comparing clozapine and olanzapine in patients with schizophrenia (62%) or schizoaffective disorder (38%) who were judged to be at risk for recurrent suicidal behavior. These patients either had attempted suicide or had been hospitalized to prevent a suicide attempt within the 3 years prior to their baseline evaluation or had demonstrated moderate-to-severe suicidal ideation with a depressive component or command hallucinations to do self-harm within 1 week prior to their baseline evaluation. Treatment resistance (i.e., resistance to standard antipsychotic drug therapies) was not a requirement for inclusion in this study, and only 27% of the total patient population was identified as being treatment resistant at baseline.

In the Inter SePT study, patients who received flexible dosages of clozapine (mean dosage: 274.2 mg daily) for approximately 2 years had a 26% reduction in their risk for suicide attempts or hospitalization to prevent suicide compared with those who received flexible dosages of olanzapine (mean dosage: 16.6 mg daily); the treatment-resistant status of patients was not predictive of response to clozapine or olanzapine. The cumulative probability of experiencing a suicide attempt, including a completed suicide, or hospitalization due to imminent suicide risk (including increased level of surveillance for suicidal behavior for patients already hospitalized) also was lower for patients receiving clozapine (24%) than for those receiving olanzapine (32%) at year 2. In addition, patients receiving clozapine had a statistically significant longer delay in the time to recurrent suicidal behavior than those receiving olanzapine. These results, however, may have been confounded by extensive use of other treatments to reduce the suicide risk, including concomitant psychotropic agents (84% with antipsychotics; 65% with anxiolytics; 53% with antidepressants, 28% with mood stabilizers), hospitalization and psychotherapy, the contributions of which to clozapine's efficacy are unknown.

Some clinicians state that methodologic problems (e.g., lack of actively suicidal patients in the study, possible bias and unblinding of suicide monitoring board members during the study, use of concomitant psychotropic agents) associated with the Inter SePT study limit definitive conclusions about the efficacy of clozapine for prevention of suicide in patients with schizophrenia or schizoaffective disorder. The US Food and Drug Administration (FDA) currently is advising clinicians to interpret the results of the Inter SePT study only as evidence of the efficacy of clozapine in delaying time to recurrent suicidal behavior, and not as efficacy of the drug for treatment of suicidal behaviors or as a demonstration of the superior efficacy of clozapine over olanzapine. However, the APA states that, based on the available evidence from the Inter SePT study, clozapine should be preferentially considered for schizophrenia patients with a history of chronic and persistent suicidal ideation and behaviors. Decisions to initiate clozapine therapy or switch patients from other antipsychotics to clozapine, therefore, should be individualized. In addition, safety and efficacy of clozapine in actively suicidal patients have yet to be determined.

■ **Parkinsonian Syndrome** Clozapine has been used in a limited number of patients with advanced, idiopathic parkinsonian syndrome for the management of dopaminomimetic psychosis† associated with antiparkinsonian drug therapy, but adverse effects such as sedation, confusion, and increased parkinsonian manifestations may limit the benefit of clozapine therapy in these patients. Attempts to relieve antiparkinsonian drug-induced delusions, paranoia, and hallucinations by reduction of antiparkinsonian drug dosage or administration of typical antipsychotic agents often aggravate parkinsonian symptoms. Limited data suggest that administration of clozapine in dosages of 6.25–400 mg daily can improve psychotic symptoms within a few days, reportedly without exacerbating parkinsonian manifestations. However, in a controlled study in a limited number of patients receiving clozapine dosages up to 250 mg daily, exacerbation of parkinsonian manifestations and development of delirium occurred frequently despite prevention of antiparkinsonian drug-induced deterioration of psychosis; it has been suggested that rapid clozapine dosage escalation may have contributed to the observed negative effect on parkinsonian manifestations and delirium. Clozapine dosages of 100–250 mg daily reportedly have been associated with hypersalivation, hypophonia, bradykinesia, and considerable sedation in patients with idiopathic parkinsonian syndrome, and withdrawal of clozapine therapy or a decrease in dosage also has exacerbated parkinsonian manifestations. Some clinicians suggest that the dosage of clozapine required to treat drug-induced dopaminomimetic psychosis may be substantially less than that required for treatment of psychosis in young, otherwise healthy individuals and that clozapine therapy should be initiated at low dosages (e.g., 6.25–50 mg daily) with cautious upward titration (e.g., to a maximum of 100–200 mg daily). Other clinicians have suggested that clozapine be used only as a last resort in patients with drug-induced dopaminomimetic psychosis.

Dosage and Administration

■ **Administration** Because of the risk of potentially life-threatening agranulocytosis, clozapine is available only through distribution systems that ensure baseline and periodic blood tests prior to delivery of the next supply of medication; dispensing is contingent on the results of the white blood cell (WBC) count and the absolute neutrophil count (ANC). (See Granulocytopenia and Agranulocytosis under Cautions: Hematologic Effects.) Although the amount of clozapine dispensed usually should not exceed a weekly supply, the manufacturers state that additional amounts (up to a 1-week supply) of the drug may be dispensed in exceptional circumstances (e.g., weather, holidays). In addition, patients may receive a supply sufficient for therapy for a period of time equal to that of the monitoring period; patients monitored weekly may receive a 1-week (7 day) supply of medication, patients monitored biweekly may receive a 2-week (14 day) supply, and patients eligible for monitoring every 4 weeks may receive a 28-day supply of medication, depending on WBC count and ANC results.

While availability of clozapine previously was exclusively through Novartis' Clozaril® Patient Monitoring System (CPMS), run jointly with CareMark and Roche Biomedical Laboratories, other distribution systems currently are in place; the individual manufacturers should be contacted for additional information on current mechanisms for obtaining the drug. Before initiating clozapine therapy in any patient, clinicians should check with the Clozaril® National Registry (phone number: [800]448-5938) to ensure that the patient does not have a history of clozapine-induced agranulocytosis or severe leukopenia/granulocytopenia; clozapine should *not* be administered to patients with such a history. (See Cautions: Hematologic Effects.)

Clozapine is administered orally, without regard to meals. Clozapine also has been administered IM†, but a parenteral preparation currently is not commercially available in the US.

Patients receiving clozapine orally disintegrating tablets should be instructed not to remove a tablet from the blister until just prior to dosing. The tablet should not be pushed through the foil; instead, the blister backing should be peeled completely off the blister. The tablet should then be gently removed and immediately placed on the tongue, where it rapidly disintegrates in saliva, and then subsequently swallowed with or without liquid. When clozapine orally disintegrating tablets are divided, the remaining half of the tablet that is not taken should be destroyed.

■ **Dosage** Dosage of clozapine should be carefully adjusted according to individual requirements and response using the lowest possible effective dosage.

Cautious dosage titration and administration of clozapine in divided doses are necessary to minimize the risk of certain adverse effects such as hypotension, seizures, and sedation. (See Cautions: Nervous System Effects and also see Cautions: Cardiovascular Effects.) The sedative effects of the drug may necessitate administration of most or all of the daily dose at bedtime, but some clinicians recommend that doses exceeding 500 mg generally be divided (e.g., a portion in the evening and the remainder at bedtime). Some clinicians also suggest that administration of clozapine in the morning be avoided, particularly in outpatients, at least until the patient has developed tolerance to the sedative effects of the drug.

Schizophrenia **Adult Dosage.** For the management of schizophrenia, the usual initial adult dosage of clozapine is 12.5 mg (one-half of a 25-mg tablet) once or twice daily. (If therapy is initiated with orally disintegrating tablets, the remaining half tablet should be destroyed.) Some clinicians advise that, if practical, consideration should be given to administering the first dose in a setting where facilities for cardiopulmonary resuscitation are available for at least a few hours after the first dose. If the drug is well tolerated, dosage may be increased by 25–50 mg daily over a 2-week period until a dosage of 300–450 mg daily is achieved. Subsequent dosage increases should be made no more frequently than once or twice weekly, in increments not exceeding 50–100 mg. The manufacturers state that cautious titration is necessary to minimize the risks of hypotension, myoclonic jerks, generalized seizures, and sedation. (See Cautions: Nervous System Effects.) If myoclonic jerks or generalized seizures occur, dosage of clozapine should be reduced and, if necessary, anticonvulsant therapy initiated.

Daily administration of clozapine in divided doses should continue until an effective and tolerable dosage is reached, usually within 2–5 weeks. Although many patients may respond adequately to dosages between 200–600 mg daily, a dosage of 600–900 mg daily may be required in some patients. In the multicenter study that provides the principal support for the effectiveness of clozapine in patients resistant to standard antipsychotic therapy, the maximum dosage of clozapine ranged from 100–900 mg daily, which was given in 3 divided doses. The mean and median clozapine dosages in this study both were approximately 600 mg daily. Although some clinicians suggest that dosages exceeding 450–500 mg daily have not been shown to be associated with increased therapeutic benefit, others state that added response is observed at higher dosages in some patients and stress the need for individualized therapy. The manufacturers and most clinicians recommend that the maximum daily dosage of clozapine not exceed 900 mg. Because of the possibility that high dosages of clozapine may be associated with an increased risk of adverse reactions, particularly seizures, patients generally should be given adequate time to respond to a given dosage before dosage escalation is considered.

Pediatric Dosage. The dosage of clozapine for the management of schizophrenia in children and adolescents† has not been established. However, the National Institute of Mental Health (NIMH) protocol used an initial dosage of 6.25–25 mg daily depending on the patient's weight. Dosages could be increased in this study every 3–4 days by 1–2 times the initial dose on an individual basis up to a maximum of 525 mg daily.

Duration of Therapy. The optimum duration of clozapine therapy for the management of schizophrenia currently is not known. While some clinicians state that clozapine therapy should be continued for longer than 6 weeks only in patients who exhibit substantial benefit within this period, others state that even less than substantial degrees of benefit may warrant continued therapy and that an adequate trial of clozapine may require at least 12 weeks (e.g., at 200–600 mg daily) or possibly 5–9 months or longer unless clinical deterioration or intolerable or potentially serious toxicity precludes it. The manufacturers currently recommend that patients who respond continue to receive clozapine therapy but at the lowest dosage needed to maintain remission of symptoms; following effective control of symptoms, dosage may be reduced gradually to determine the minimum therapeutic maintenance dose. In addition, patients should be reassessed periodically to determine the need for continued therapy with the drug. Extended therapy in patients failing to show an acceptable response to clozapine generally should be avoided because of the substantial, continuing risks of agranulocytosis and seizures. (See Cautions: Hematologic Effects and also see Seizures under Cautions: Nervous System Effects.)

Suicide Risk Reduction For suicide risk reduction in schizophrenia and schizoaffective disorder, the usual initial adult dosage of clozapine is 12.5 mg once or twice daily. If the drug is well tolerated, dosage may be increased by 25–50 mg daily over a 2-week period until a dosage of 300–450 mg daily is achieved. Subsequent dosage increases should be made no more frequently than once or twice weekly, in increments not exceeding 50–100 mg. In the multicenter Inter SePT study that provides the principal support for the effectiveness of clozapine for suicide risk reduction, mean dosage was about 300 mg daily (range: 12.5–900 mg daily).

Because efficacy of clozapine for this indication was demonstrated over a 2-year treatment period in this study, clozapine therapy to reduce the risk of suicidal behavior should be continued for at least 2 years. After 2 years, it is recommended that the patient's risk of suicidal behavior be reassessed. If the clinician's assessment indicates that a clinically important risk for suicidal behavior is still present, clozapine therapy should be continued. Thereafter, the need to continue therapy with the drug should be reevaluated at regular intervals, based on thorough assessments of the patient's risk for suicidal behavior during treatment. If the clinician determines that the patient is no longer at risk for suicidal behavior, clozapine therapy may be discontinued gradually (see Dosage: Discontinuance of Therapy) and treatment of the underlying disorder with an antipsychotic agent to which the patient has previously responded may be resumed.

Discontinuance of Therapy In the event of planned termination of clozapine therapy, gradual reduction in dosage over a 1- to 2-week period is recommended. However, should abrupt discontinuance of therapy be required (e.g., because of leukopenia or agranulocytosis), the patient should be observed carefully for recurrence of psychotic symptoms and symptoms related to cholinergic rebound such as headache, nausea, vomiting, and diarrhea. Sudden withdrawal from clozapine therapy can lead to rapid decompensation and rebound psychosis. (See Other Nervous System Effects under Cautions: Nervous System Effects.)

Reinitiation of Therapy If clozapine therapy is restarted in patients who have had even brief interruptions (i.e., 2 days or more) in therapy, dosage generally should be titrated as with initial therapy (i.e., 12.5 mg once or twice daily). If this dosage is well tolerated, dosage may be titrated back to the therapeutic dosage more quickly than during initial treatment. The manufacturers state that clozapine therapy should be reinstituted with extreme caution, even following brief interruptions of only 24 hours, in patients who have previously experienced respiratory or cardiac arrest during initial dosing but subsequently were titrated to a therapeutic dosage.

Because the mechanisms underlying clozapine-induced adverse reactions are unknown and it is conceivable that reexposure might enhance the risk of an adverse effect and/or increase its severity (e.g., when immune-mediated mechanisms are involved), the manufacturers advise additional caution during reinitiation of therapy. When reinitiating therapy, consider WBC count and ANC monitoring recommendations. (See Table 2: WBC and ANC Monitoring for Clozapine Reinitiation under Cautions.)

Patients in whom clozapine therapy is discontinued because of leukocyte counts less than 2000/mm^3 or an ANC less than 1000/ mm^3 must *not* be restarted on the drug. (See Cautions: Hematologic Effects.)

Cautions

Although clozapine differs chemically from the phenothiazines, the drug may be capable of producing many of the toxic manifestations of phenothiazine derivatives. Not all adverse effects of the phenothiazines have been reported with clozapine, but the possibility that they may occur should be considered. Adverse effects of clozapine and the phenothiazines are numerous and may involve nearly all organ systems. Although these effects usually are reversible when dosage is reduced or the drug is discontinued, some effects may be irreversible and, rarely, fatal. In some patients, unexpected death associated with

antipsychotic therapy has been attributed to cardiac arrest or asphyxia resulting from failure of the gag reflex. (See Cautions: Cardiovascular Effects.) In other cases, the cause of death could not be determined or definitely attributed to antipsychotic drug therapy. An increased risk of death has been observed in geriatric patients with dementia-related psychoses receiving atypical antipsychotics. (See Cautions: Geriatric Precautions.)

The most frequent adverse effects of clozapine involve the central and autonomic nervous systems (e.g., drowsiness or sedation, hypersalivation) and the cardiovascular system (e.g., tachycardia, hypotension). While the frequency and severity of some adverse effects (e.g., extrapyramidal reactions, tardive dyskinesia) appear to be less with clozapine than with other antipsychotic agents, other potentially serious adverse effects (e.g., agranulocytosis, seizures) may occur more frequently with clozapine therapy, and the potential risks and benefits should be evaluated carefully whenever therapy with the drug is considered. Because of the substantial risk of clozapine-associated agranulocytosis, which may persist over an extended period of time and be life-threatening or fatal if not detected early and therapy interrupted, clozapine is available for use only through patient-management systems that ensure baseline and periodic blood tests prior to delivery of the next supply of medication; dispensing is contingent on the results of the white blood cell (WBC) count and absolute neutrophil count (ANC). Before initiating clozapine therapy in any patient, clinicians should check with the Clozaril® National Registry to ensure that the patient has no history of clozapine-induced agranulocytosis or severe leukopenia/granulocytopenia; clozapine should *not* be administered to patients with such a history. (See Cautions: Hematologic Effects.)

■ **Hematologic Effects** ***Granulocytopenia and Agranulocytosis***

Agranulocytosis, defined as an absolute neutrophil count (ANC) less than 500/mm³ and characterized by leukopenia (WBC count less than 2000/mm³) and relative lymphopenia, has an estimated cumulative incidence of 1–2% after 1 year of clozapine therapy, as compared with an estimated incidence of 0.1–1% for phenothiazine-induced agranulocytosis. The rate of clozapine-induced agranulocytosis is based on the occurrence of 15 cases out of 1743 patients who received clozapine during clinical trials in the US. Some evidence suggests that the incidence of clozapine-induced agranulocytosis is at least 10 times greater than that of other antipsychotic agents, although it also has been suggested that the incidence of clozapine-induced agranulocytosis may be no higher than that associated with phenothiazines. Of the 149 cases of clozapine-induced agranulocytosis reported worldwide as of December 31, 1989, 32% were fatal. Few of these fatalities have occurred since 1977 when the knowledge of clozapine-induced agranulocytosis became widespread and close monitoring of WBC count became widely practiced. In the US, under a weekly leukocyte monitoring system in premarketing studies and in postmarketing experience with clozapine, 585 cases of agranulocytosis, including 19 fatalities, had occurred as of August 21, 1997; one patient receiving concomitant therapy with carbamazepine and clozapine died following development of an unusual hypoplastic anemia with agranulocytosis, a pancytopenic condition not usually characteristic of clozapine-induced hematologic effects. Based on analysis of data pooled from a confidential national master file of information (the Clozaril® National Registry), the incidence of agranulocytosis appears to rise steeply during the first 2 months of therapy and peaks in the third month. The incidence gradually declines with continued therapy and reaches a rate of 3 per 1000 person-years by 6 months of therapy. After 6 months, the incidence of agranulocytosis declines still further. However, the manufacturer of Clozaril® cautions that a reduction in the frequency of leukocyte monitoring may result in an increase in incidence of agranulocytosis.

The precise mechanism by which clozapine induces agranulocytosis is not known, but both immunologic and toxic mechanisms (including a direct myelotoxic effect of the drug and/or its metabolites) have been implicated. Some evidence suggests that granulocyte antibodies may be involved. Except for the evidence of marked bone marrow depression during initial clozapine therapy and a disproportionate number of females, there are no established risk factors, based on worldwide experience, for developing clozapine-induced agranulocytosis. However, a disproportionate number of US cases have occurred in patients of Eastern European Jewish heritage compared with the overall proportion of such patients exposed to clozapine during domestic trials. Results of genetic typing indicate that genetic factors marked by a major histocompatibility complex haplotype (HLA-B38, DR4, DQw3) may be associated with the susceptibility of certain Jewish patients with schizophrenia to develop agranulocytosis when treated with clozapine; the incidence of some phenotypes common among Ashkenazi Jews has been found to be greatly increased in patients with clozapine-induced agranulocytosis.

Most cases of clozapine-induced agranulocytosis in the US have occurred within 4–16 weeks of exposure to the drug. Although no patient characteristics predictive of an increased risk of agranulocytosis with clozapine have been identified conclusively, agranulocytosis associated with the use of other antipsychotic agents has been reported to occur more frequently in women, geriatric patients, and patients who are cachectic or have serious underlying medical conditions (e.g., immunocompromised patients, patients with human immunodeficiency virus [HIV] infection); such patients also may be at increased risk for developing agranuloeytosis with clozapine therapy.

Investigation of 16 cases of clozapine-associated granuloeytopenia occurring within a 2-month period in 1975 in southwest Finland, including 13 cases of agranulocytosis, revealed characteristics similar to those of phenothiazine-induced agranulocytosis. In all of these cases, the reaction occurred during first exposure to the drug and followed a latent period of 17–109 days at a cumulative dose of 4.5–42 g; reduced values for hemoglobin and peripheral erythrocyte and thrombocyte counts were found infrequently, and granulopoiesis in sternal marrow usually was severely depressed or absent. Erythropoiesis was below normal in only one case, and thrombopoiesis was normal or even increased. Hematologic values returned to baseline within 1–3 weeks after withdrawal of clozapine. All fatalities were attributed to secondary infection in patients in whom granulocytopenia was not diagnosed early or clozapine discontinued promptly. In patients who died, the clinical course typically consisted of fever with tonsillitis, which progressed to pneumonia and septicemia; the immediate cause of death usually was renal or cardiac failure. The frequency of clozapine-induced agranulocytosis or granulocytopenia in the Finnish experience was 7.1 per thousand—approximately 21 times higher than that reported in other countries. Although it has been suggested that a local genetic or environmental factor or factors may have been involved in the Finnish cases, the existence of such a factor has not been documented.

The most likely time of occurrence of granulocytopenia appears to be 4–16 weeks after initiation of treatment with clozapine. However, neither dose nor duration of therapy is a reliable predictor of agranulocytosis. Most patients develop agranulocytosis within the first 10 weeks of therapy, but a latent period of up to 1 year or longer also has been reported. Within the first 18 weeks of therapy, 77–90% of all cases of granulocytopenia and agranuloeytosis have been reported and 85% of fatalities secondary to agranulocytosis have occurred. The latent period between the fall in leukocyte count and the development of a secondary infection usually is moderately long. Leukooyte count usually declines gradually (e.g., over a period of weeks), but it also may decline precipitously. Patients receiving clozapine may have a transient and benign reduction in leukocyte count without progression to agranulocytosis, and may or may not develop manifestations of infection (e.g., fever, sore throat).

Patients in whom granulocytopenia is diagnosed and clozapine therapy discontinued before the occurrence of infection generally have a favorable prognosis. Early diagnosis of granulocytopenia and appropriate medical management can forestall serious consequences and reduce morbidity and mortality substantially since the condition generally is reversible if clozapine is discontinued promptly. In contrast, agranulocytosis is more likely to be fatal in patients in whom clozapine therapy is not halted before the development of infection.

Because of the substantial, persistent risk of agranulocytosis associated with clozapine use, patients must have a WBC count and ANC performed before initiation of therapy with the drug. Clozapine therapy should not be initiated if the baseline WBC count is less than 3500/mm³ or the ANC is less than 2000/mm³. While some clinicians suggest that WBC counts be done weekly during the first 4–12 months of therapy and then less frequently (e.g., every 2 weeks or monthly) thereafter, other clinicians state that patients must have weekly WBC counts for the duration of therapy. However, the manufacturers suggest that the frequency of monitoring depends in part on the duration of therapy, adherence to therapy, and development of adverse hematologic effects. The manufacturers state that patients must have WBC counts and ANC monitored at least weekly for the first 6 months of continuous treatment and then every other week for the next 6 months if WBC counts and ANC remain acceptable (WBC count equal to or exceeding 3500/mm³, ANC equal to or exceeding 2000/mm³). After a further 6 months, if acceptable WBC counts and ANCs continue to be maintained, the frequency of monitoring may be reduced to every 4 weeks for the remainder of clozapine therapy. After discontinuance of therapy, continue to monitor WBC count and ANC weekly for at least 4 weeks from the day of discontinuance or until WBC count is equal to or exceeding 3500/mm³ and ANC is equal to or exceeding 2000/mm³. The current recommendations for WBC count and ANC monitoring based on the stage of therapy and the results from WBC and ANC monitoring are provided in Table 1 below. Dispensing of clozapine is contingent upon compliance with these *required* WBC and ANC tests. (See Dosage and Administration: Administration.)

Table 1. Frequency of Monitoring based on Stage of Therapy or Results from WBC and ANC Monitoring

Situation	Hematological Values	Frequency of WBC and ANC Monitoring
Initiation of therapy	WBC ≥3500/mm³ ANC ≥2000/mm³ Do not initiate in patients with a history of myeloproliferative disorder or clozapine-induced agranulocytosis or granulocytopenia.	Weekly for 6 months.
During 6–12 months of therapy	All results for WBC ≥3500/mm³ and ANC ≥2000/mm³	Every 2 weeks for 6 months.
After 12 months of therapy	All results for WBC ≥3500/mm³ and ANC ≥2000/mm³	Every 4 weeks thereafter.
Immature forms present	Not applicable	Repeat WBC and ANC.

Discontinuance of therapy	Not applicable	Weekly for at least 4 weeks from day of discontinuance or until WBC ≥3500/mm³ and ANC ≥2000/mm³.
Substantial decrease in WBC or ANC	Single decrease or cumulative decrease within 3 weeks of WBC≥3000/mm³ or ANC ≥1500/mm³	Repeat WBC and ANC. Carefully monitor for manifestations of infection.** If repeat values for WBC ≥3000/mm³ and ≤3500/mm³ and ANC <2000/mm³, monitor twice weekly.
Mild leukopenia/mild granulocytopenia	WBC ≥3000/mm³ but <3500/mm³ and/or ANC ≥1500/mm³ but <2000/mm³	Monitor twice weekly until WBC >3500/mm³ and ANC >2000/mm³, then resume previous monitoring frequency. Carefully monitor for manifestations of infection.**
Moderate leukopenia/moderate granulocytopenia	WBC ≥2000/mm³ but <3000/mm³ and/or ANC ≥1000/mm³ but <1500/mm³	Interrupt therapy and carefully monitor for manifestations of infection.** Monitor daily until WBC >3000/mm³ and ANC >1500/mm³, then monitor twice weekly until WBC >3500/mm³ and ANC >2000/mm³. May rechallenge when WBC >3500/mm³ and ANC >2000/mm³. If rechallenged, monitor weekly for 1 year before returning to the usual monitoring schedule of every 2 weeks for 6 months then every 4 weeks indefinitely.
Severe leukopenia/severe granulocytopenia	WBC <2000/mm³ and/or ANC <1000/mm³	Discontinue therapy and *do not rechallenge patient.** Carefully monitor for manifestations of infection.** Monitor until normal and for at least 4 weeks from day of discontinuance as follows: daily until WBC >3000/mm³ and ANC >1500/mm³, twice weekly until WBC >3500/mm³ and ANC >2000/mm³, then weekly after WBC >3500/mm³. Consider bone marrow aspiration to determine granulopoietic status; if granulopoiesis is deficient, protective isolation with close observation may be indicated. If infection develops, perform cultures and institute appropriate anti-infective therapy.
Agranulocytosis	ANC ≤500/mm³	Discontinue therapy and *do not rechallenge patient.** Carefully monitor for manifestations of infection.** Monitor until normal and for at least 4 weeks from day of discontinuance as follows: daily until WBC >3000/mm³ and ANC >1500/mm³, twice weekly until WBC >3500/mm³ and ANC >2000/mm³, then weekly after WBC >3500/mm³. Consider bone marrow aspiration to determine granulopoietic status; if granulopoiesis is deficient, protective isolation with close observation may be indicated. If infection develops, perform cultures and institute appropriate anti-infective therapy.

* Agranulocytosis develops upon rechallenge, often with a shorter latency. Patients who have experienced substantial bone marrow suppression during therapy are listed in a national master file. (See Dosage and Administration: Administration.)

** Carefully monitor for flu-like symptoms or other manifestations of infection; institute appropriate anti-infective therapy if necessary.

If clozapine therapy is reinitiated after interruption of therapy, WBC counts and ANC should be monitored after reinitiating therapy based on the duration of previous therapy, length of interruption of therapy, and previous WBC counts and ANC in the patient according to the schedule in Table 2 below:

Table 2. WBC and ANC Monitoring for Clozapine Reinitiation

Previous therapy duration <6 months, with no abnormal blood event (WBC ≥3500/mm³ and ANC ≥2000/mm³) and interruption in therapy ≥3 days but≤1 month	Continue with weekly WBC and ANC monitoring where left off in schedule; do not restart 6-month period. When 6-month period complete, may decrease monitoring frequency to every other week.
Previous therapy duration <6 months, with no abnormal blood event and interruption in therapy >1 month	Monitor WBC and ANC weekly for *additional* 6 months before decreasing to biweekly testing.
Previous therapy duration <6 months, *with* abnormal blood event (WBC <3500/mm³ or ANC <2000/mm³) but rechallengeable (i.e., WBC ≥2000/mm³ and ANC ≥1000/mm³ during previous therapy)	See Table 1.
Previous therapy duration 6–12 months, with no abnormal blood event and interruption in therapy ≥3 days but ≤1 month	Monitor WBC and ANC weekly for 6 weeks, then resume monitoring every other week for an additional 6 months.*
Previous therapy duration 6–12 months, with no abnormal blood event and interruption in therapy >1 month	Monitor WBC and ANC weekly for 6 months, then resume monitoring every other week for an additional 6 months.*
Previous therapy duration 6–12 months, *with* abnormal blood event (WBC <3500/mm³ or ANC <2000/mm³) but rechallengeable (i.e., WBC ≥2000/mm³ and ANC ≥1000/mm³ during previous therapy)	See Table 1.*
Previous therapy duration >12 months, with no abnormal blood event and interruption in therapy ≥3 days but ≤1 month	Monitor WBC and ANC weekly for 6 weeks, then resume monitoring every 4 weeks.*
Previous therapy duration >12 months, with no abnormal blood event and interruption in therapy >1 month	Monitor WBC and ANC weekly for 6 months, then resume monitoring every other week for an additional 6 months, then resume monitoring every 4 weeks.*
Previous therapy duration >12 months, *with* abnormal blood event (WBC <3500/mm³ or ANC <2000/mm³) but rechallengeable (i.e., WBC ≥2000/mm³ and ANC ≥1000/mm³ during previous therapy)	See Table 1.

*Transition to reduce frequency of monitoring only permitted if all WBC counts are equal to or exceeding 3500/mm³ and ANC values are equal to or exceeding 2000/mm³.

Although some clinicians suggest that body temperature be measured at least once daily for the first 18 weeks of clozapine therapy, others state that such monitoring is not an adequate means of assessing infection in clozapine-treated patients because of the drug's pharmacologic potential for causing temperature elevation. Patients receiving clozapine should be advised to report immediately the appearance of lethargy, weakness, fever, sore throat, or any other potential manifestation of infection.

Supportive therapy with biosynthetic hematopoietic agents, including filgrastim, a recombinant human granulocyte colony-stimulating factor (G-CSF), and sargramostim, a recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF), has been effective in a limited number of patients with clozapine-induced neutropenia and agranulocytosis. Consultation with a hematologist and infectious disease expert is recommended.

When granulocytopenia is diagnosed and clozapine therapy is discontinued, patients usually recover in 7–28 days. Most of these patients require further antipsychotic therapy because of a recurrence of psychotic symptoms. (See Other Nervous System Effects under Cautions: Nervous System Effects.) Since there appears to be no cross-sensitivity between clozapine and other antipsychotics in terms of hematologic toxicity, other antipsychotic drugs generally may be used without causing further hematologic complications in patients who develop clozapine-induced agranulocytosis. However, patients who develop clozapine-induced agranulocytosis (or those in whom the total WBC count and ANC decrease to less than 2000/mm³ and less than 1000/mm³, respectively) should *not* be rechallenged with clozapine. Patients in whom clozapine therapy has been discontinued due to substantial leukocyte suppression have been found to develop agranulocytosis upon rechallenge with the drug, often with a shorter latency on reexposure. To reduce the chance of rechallenge in patients who

have experienced substantial bone marrow suppression with clozapine therapy, the manufacturer of Clozaril® maintains a confidential national master file of information (the Clozaril® National Registry) on all nonrechallengeable patients.

Eosinophilia Eosinophilia has been reported in approximately 1% of patients who received clozapine therapy in clinical trials. The manufacturers state that if the total eosinophil count exceeds 4000/mm³, clozapine therapy should be temporarily discontinued until the count falls below 3000/mm³.

Other Hematologic Effects Other hematologic effects reported with clozapine therapy include leukopenia, neutropenia, and thrombocytopenia, which have been reported in 1–3% of patients. Anemia, leukocytosis, and increased platelet count have been reported in less than 1% of patients receiving clozapine. Other clozapine-induced hematologic effects reportedly include basophilia, a substantial reduction in B cells, and an increase in hemoglobin concentration. Elevated erythrocyte sedimentation rate (ESR) and sepsis have been reported in patients receiving clozapine during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Nervous System Effects** ***Seizures*** Clozapine lowers the seizure threshold and can cause EEG changes, including the occurrence of spike and wave complexes. Seizures reportedly occurred in approximately 3.5% of patients exposed to the drug during clinical trials in the US (cumulative annual incidence of approximately 5%). In contrast, a seizure incidence of approximately 1% has been reported in patients treated with other antipsychotic agents. The risk of seizures with clozapine therapy appears to be related to dosage and/or plasma concentrations of the drug, with a reported incidence of approximately 0.6–2% at dosages less than 300 mg daily, 1.4–5% at 300–600 mg daily, and 5–14% at high dosages (600–900 mg daily). Clozapine-induced seizures may be associated with rapid dosage escalations, particularly in patients with preexisting epilepsy, and in those receiving concomitant therapy with drugs that may lead to increased plasma concentrations of clozapine. If myoclonic jerks or generalized seizures occur, clozapine dosage should be reduced and, if necessary, anticonvulsant treatment initiated.

One patient receiving clozapine experienced a generalized tonic-clonic (grand mal) seizure following accidental ingestion of an extra dose (total dose ingested within 24 hours: 1050 mg); the same patient had another seizure several weeks later, 2 hours after a usual 450-mg morning dose. Results of plasma clozapine determinations obtained at the time of the seizures revealed plasma clozapine concentrations of approximately 2000 ng/mL in each case. Another patient who had been taking clozapine for 27 months had a generalized tonic-clonic seizure following an apparent intentional overdosage (total dose ingested within 24 hours: approximately 3 g), after which the patient made an uneventful recovery. One hour after the seizure, the patient's plasma clozapine concentration was 1313 ng/mL.

Discontinuance of clozapine therapy, at least temporarily, should be seriously considered in patients who experience seizures while receiving the drug; however, some clinicians state that reduced clozapine dosage and/or, occasionally, addition of anticonvulsant therapy may adequately ameliorate this effect. If clozapine therapy is to be continued in such patients, many clinicians recommend obtaining additional informed consent from the patient. In patients in whom clozapine is withheld, it has been suggested that therapy with the drug can be reinitiated at one-half the previous dosage. Clozapine dosage may then be increased gradually, if clinically indicated, and the need for concomitant anticonvulsant therapy should be considered. Some clinicians recommend that patients who have experienced a clozapine-induced seizure *not* be given clozapine dosages exceeding 600 mg daily unless the results of an EEG performed prior to the anticipated dosage increase are normal; others suggest addition of anticonvulsant therapy and/or consultation with a neurologist in managing such patients. In patients with preexisting seizure disorders who are treated concomitantly with certain anticonvulsants and clozapine, the anticonvulsant dosage may need to be increased. However, clozapine should not be used concomitantly with anticonvulsants (e.g., carbamazepine) or other drugs that potentially may cause bone marrow suppression. (See Drug Interactions: Myelosuppressive Agents.)

Extrapyramidal Reactions In contrast to other antipsychotic agents, clozapine has a low potential for causing certain acute extrapyramidal effects (e.g., dystonias). Such effects, when they occur, have been limited principally to tremor, restlessness, rigidity, and akathisia; these manifestations generally are milder and less persistent than those produced by other antipsychotic drugs. In addition, marked or total remission of such manifestations induced by other antipsychotics has occurred during treatment with clozapine in some patients.

Neuroleptic malignant syndrome (NMS), a potentially fatal symptom complex, has been reported in patients receiving phenothiazines or other antipsychotic therapy. NMS attributable to clozapine therapy alone has been reported in a few patients, and there also have been several reports of NMS in patients treated concomitantly with clozapine and lithium or other CNS drugs; some clinicians suggest that NMS may be more likely to occur when clozapine or other antipsychotic agents are used concomitantly with lithium. Manifestations of NMS (e.g., muscle rigidity, hyperpyrexia, tachycardia, increased serum creatine kinase [CK, creatine phosphokinase, CPK], diaphoresis, somnolence), all of which may not occur in all patients with the condition, have occurred in a few patients treated with clozapine alone or combined with lithium or carbamazepine; resolution of the syndrome occurred following discontinuance of clozapine. However, clozapine also has been used successfully and apparently without recurrence of NMS in at least one patient who developed the syndrome while receiving chlorpromazine.

For additional information on NMS, see Extrapyramidal Reactions in Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia A syndrome consisting of potentially irreversible, involuntary, dyskinetic movements may develop in patients treated with antipsychotic agents. However, results of clinical trials in which clozapine was used have demonstrated a virtual absence of acute extrapyramidal reactions (e.g., dystonia), and there reportedly have been no confirmed cases of tardive dyskinesia associated with clozapine therapy alone. Nevertheless, a few cases of tardive dyskinesia have been reported in patients receiving clozapine who had been treated previously with other antipsychotic agents. Although current evidence suggests that clozapine may be less likely than other antipsychotic agents to cause tardive dyskinesia, it cannot yet be concluded, based on current limited experience, that the drug is incapable of causing this syndrome. The possibility of clozapine-induced tardive dyskinesia should be considered in patients receiving long-term therapy with the drug or in those starting clozapine therapy after discontinuance of conventional (typical) antipsychotic agents.

For additional information on tardive dyskinesia, see Tardive Dyskinesia in Cautions: Nervous System Effects in the Phenothiazines General Statement 28:16.08.24.

Other Nervous System Effects Drowsiness and/or sedation occur frequently in patients receiving clozapine. (See Effects on Sleep under Pharmacology: Nervous System Effects.) Somnolence reportedly occurred in 46% of patients receiving clozapine in the International Suicide Prevention Trial (InterSePT) compared with 25% of those receiving olanzapine. The sedative-hypnotic effect of clozapine is most pronounced initially, diminishes after 1–4 weeks, and then generally, but not always, disappears during continued therapy. Daytime sleepiness may be minimized by administration of clozapine at bedtime. (See Dosage and Administration: Dosage.)

Dizziness and vertigo, headache, syncope, disturbed sleep (e.g., insomnia) or nightmares, hypokinesia or akinesia, and agitation have been reported with clozapine therapy. In the International Suicide Prevention Trial (InterSePT), dizziness (excluding vertigo) and insomnia reportedly occurred in 27 and 20% of patients receiving clozapine, respectively, compared with 12 and 33% of those receiving olanzapine, respectively. Clozapine also may cause confusion or delirium, which may be related to central anticholinergic effects, and has been ameliorated in some cases by IV administration of physostigmine. Depression, fatigue, hyperkinesia, weakness or lethargy, and slurred speech also have been reported. Other adverse nervous system effects associated with clozapine therapy include ataxia, epileptiform movements or myoclonic jerks, and anxiety.

Adverse nervous system effects reported in less than 1% of clozapine-treated patients include loss of speech, amentia (deterioration in cognitive function), tics, poor coordination, delusions or hallucinations, stuttering, dysarthria, amnesia, histrionic movements, increased or decreased libido, paranoia, shakiness, parkinsonian syndrome, and irritability. Difficulty in writing, residual daytime effects such as impairment of mental performance, and periodic cataplexy, which is characterized by sudden episodes of dropping objects and may or may not be accompanied by knee buckling, also have been reported infrequently with clozapine therapy. Exacerbation of psychosis, myoclonus, paresthesia, and status epilepticus have been reported in patients receiving clozapine during postmarketing surveillance; however, a causal relationship to the drug has not been established.

Abrupt discontinuance of clozapine (e.g., because of leukopenia or agranulocytosis) may result in recurrence of psychotic symptoms or behavior, including autism, auditory hallucinations, suicide attempts, development of parkinsonian symptoms, anxiety, insomnia, delusions, and violent behavior. It has been suggested that this "rebound psychosis" may result, at least in part, from clozapine-induced supersensitivity of mesolimbic dopamine receptors (see Behavioral Effects in Animals under Pharmacology: Nervous System Effects) and that the essential feature of this phenomenon appears to be recurrence of positive symptoms of schizophrenia. Patients who develop rebound psychosis following discontinuance of clozapine may improve with initiation of other antipsychotic therapy; however, clozapine should *not* be reinstituted in patients in whom severe leukopenia/granulocytopenia or agranulocytosis has occurred. (See Cautions: Hematologic Effects.)

■ **Fever** Fever or transient temperature elevations exceeding 38°C generally have been reported in 5% or more of patients receiving clozapine. The peak incidence of fever occurs within the first 3 weeks of therapy, usually between days 5–20 of treatment. Fever generally is benign and self-limiting and usually diminishes within a few (4–8) days despite continued clozapine therapy; however, it may necessitate discontinuance of the drug. Fever occasionally may be associated with an increase or decrease in leukocyte count, in which case patients should be evaluated for underlying infection or development of agranulocytosis. (See Cautions: Hematologic Effects.) In the presence of high fever, the possibility of neuroleptic malignant syndrome also must be considered. (See Extrapyramidal Reactions under Cautions: Nervous System Effects.)

The mechanism of clozapine-induced fever (other than that occurring secondary to some other factor such as infection) is not yet known. It may result from the drug's pronounced anticholinergic activity (see Anticholinergic Effects under Pharmacology: Nervous System Effects) or a direct effect on the

hypothalamic thermoregulatory center. Clozapine-induced hyperthermia may be a hypersensitivity reaction, a common mechanism underlying drug fevers. It has been suggested that decreasing the dosage of clozapine and then gradually increasing it to the previous level may reverse the hyperthermia and not be accompanied by a recurrence of elevated temperature; however, recurrence is possible despite such dosage adjustment.

■ **Cardiovascular Effects** ***Myocarditis*** Myocarditis (sometimes fatal) has been reported during postmarketing surveillance in patients receiving clozapine. Postmarketing surveillance data from 4 countries employing hematologic monitoring of clozapine-treated patients indicated 30 cases of myocarditis in 205,493 clozapine-treated US patients as of August 2001, 7 cases of myocarditis in 15,600 such Canadian patients as of April 2001, 30 cases of myocarditis in 24,108 such United Kingdom patients as of August 2001, and 15 cases of myocarditis in 8000 such Australian patients as of March 1999, representing an incidence of approximately 5, 16, 43, and 97 cases/100,000 patient-years of clozapine therapy, respectively. Of these 82 cases of myocarditis identified through postmarketing surveillance, 38% resulted in death. Although the overall incidence of myocarditis in patients with schizophrenia receiving antipsychotic agents is unknown, the incidence of myocarditis or fatal myocarditis, respectively, in patients receiving clozapine appears to be 17–322 or 14–161 times greater than the incidence in general population.

These postmarketing surveillance data also suggest that the incidence of myocarditis, including fatal myocarditis, may be highest during the first month of therapy, with 62% of myocarditis cases occurring within the first month of clozapine therapy, 31% of cases occurring after the first month of therapy, and the onset unknown in 7% of cases. Therefore, the possibility of myocarditis should be considered in patients receiving clozapine who present with unexplained fatigue, dyspnea, tachypnea, fever, chest pain, palpitations, other signs or symptoms of heart failure, or ECG findings such as ST-T wave changes or arrhythmias.

It is not known whether eosinophilia is a reliable predictor of myocarditis. However, tachycardia, which has been associated with clozapine therapy, also may be a manifestation of myocarditis. Therefore, tachycardia occurring during the first month of clozapine therapy warrants close monitoring for other manifestations of myocarditis. If myocarditis is suspected, the drug should be discontinued promptly. Because myocarditis recurred in 3 of 5 patients rechallenged with the drug, patients who develop myocarditis while receiving clozapine should *not* be rechallenged with the drug.

Cardiomyopathy Cardiomyopathy has been reported in US patients treated with clozapine at a reporting rate of 8.9 cases/100,000 person-years, which was similar to an estimate of the cardiomyopathy incidence in the US general population derived from the 1999 National Hospital Discharge Survey data (9.7 cases/100,000 person-years). Approximately 80% of clozapine-treated patients in whom cardiomyopathy was reported were younger than 50 years of age; the duration of treatment with clozapine prior to cardiomyopathy diagnosis varied, but exceeded 6 months in 65% of the reports. Dilated cardiomyopathy was most frequently reported, although a large percentage of reports did not specify the type of cardiomyopathy. Signs and symptoms suggestive of cardiomyopathy, particularly exertional dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea, and peripheral edema, should alert the clinician to perform further investigations. If the diagnosis of cardiomyopathy is confirmed, the drug should be discontinued unless the benefit to the patient clearly outweighs the risk.

Thromboembolic Effects Deep-vein thrombosis and pulmonary embolism have been reported in patients receiving clozapine during postmarketing surveillance. As of December 31, 1993, 18 cases of fatal pulmonary embolism were reported in patients 10–54 years of age receiving clozapine therapy. Based on the extent of use observed in the Clozaril National Registry, the mortality rate associated with pulmonary embolism was 1 death per 3450 person-years of use; this incidence is approximately 27.5 times higher than that in the general population. Although a causal relationship between clozapine and these adverse cardiovascular effects has not been established, the possibility of pulmonary embolism should be considered in patients presenting with deep-vein thrombosis or respiratory symptomatology. (See Cautions: Precautions and Contraindications.

Blood Pressure Effects Hypotension and hypertension reportedly occur in less than 10% of patients receiving clozapine. When they occur, changes in blood pressure, principally reductions in systolic pressure, appear soon after initiation of clozapine therapy and may be associated with rapid dosage increases. A decrease in arterial blood pressure below 90 mm Hg was reported in 18% of male patients and 33% of female patients receiving clozapine in one retrospective study. Hypotension may result from clozapine's antiadrenergic effects (see Adrenergic Effects under Pharmacology: Nervous System Effects) and may pose a serious risk for individuals with compromised cardiac function. However, tolerance to the hypotensive effects of clozapine often develops with continued therapy.

Orthostatic hypotension, with or without syncope, has been reported, particularly during initial titration or rapid escalation of clozapine dosage; however, this effect may represent a continuing risk in some patients. Rarely (approximately 1 case per 3000 patients), orthostatic hypotension has been accompanied by profound collapse and respiratory and/or cardiac arrest in patients receiving initial doses as low as 12.5 mg. If clozapine therapy is temporarily discontinued (i.e., for 2 or more days), the manufacturers recommend that the drug be reinitiated at a lower dosage (12.5 mg once or twice daily). In some cases when collapse and cardiac and/or respiratory arrest developed during initial therapy, benzodiazepines or other psychotropic agents were used concomitantly, suggesting a possible adverse interaction between clozapine and these agents. (See Drug Interactions: Benzodiazepines.) Although the clinical importance of this interaction has not been fully established, the manufacturers state that clozapine should be initiated with caution in patients receiving benzodiazepines or other psychotropic agents. Collapse and respiratory and/or cardiac arrest also have been reported in patients receiving initial therapy with clozapine alone. The risk of orthostatic hypotension may be reduced by initiating therapy at lower dosages, followed by only gradual, modest increases as necessary. (See Dosage and Administration: Dosage.) In some cases, withholding the drug for 24 hours and then restarting at a lower dosage has been accomplished without recurrence of orthostatic hypotension.

Tachycardia Tachycardia, which may persist throughout therapy in some cases, reportedly has been observed in 25% of patients receiving clozapine. Patients who experience clozapine-induced tachycardia demonstrate an average increase in pulse rate of 10–15 beats per minute (bpm); with aggressive dosage increases, the mean increase in heart rate ranges from 20–25 bpm. Persistent tachycardia associated with clozapine therapy is not simply a reflex response to hypotension and is present in all positions monitored. Although this effect may lessen once a plateau dosage level is reached, tachycardia may pose a serious risk for individuals with compromised cardiac function.

ECG Effects Some clozapine-treated patients experience ECG repolarization changes, including ST-segment depression, shortening of the PQ interval, and/or flattening, depression, or inversion of T waves. These changes usually normalize after discontinuance of clozapine and are similar to those seen with other antipsychotic agents. The clinical importance of these changes currently is unclear, but some clinicians suggest that they occur infrequently and usually are not serious.

Other Cardiovascular Effects In clinical trials of clozapine, some patients experienced serious cardiovascular events, including ischemic changes, chest pain and angina, hypertension, myocardial infarction, nonfatal arrhythmias, or sudden, unexplained death. Causality assessment was difficult because of serious preexisting cardiac disease in many of the patients and plausible alternative causes.

In addition, postexercise decreases in left ventricular output, which may indicate left ventricular failure, have been reported in patients receiving the drug. Edema, palpitation, phlebitis or thrombophlebitis, cyanosis, ventricular premature complexes, and bradycardia have been reported in less than 1% of clozapine-treated patients. Although a causal relationship has not been established, atrial or ventricular fibrillation, congestive heart failure, pericarditis, and pericardial effusions also have been reported during postmarketing surveillance in patients receiving the drug.

Rare instances of sudden, unexplained death have been reported in psychiatric patients, with or without associated antipsychotic drug treatment, and the relationship between sudden death and antipsychotic drug use is unknown. Some autopsy results have suggested that clozapine-treated patients have died from cardiac arrest and uncompensated cardiac disease, or from other causes such as renal insufficiency or severe alcohol abuse. A causal relationship between clozapine use and sudden death has not been established. (See Cautions: Geriatric Precautions.)

■ **Autonomic Nervous System Effects** Adverse autonomic nervous system effects occur in more than 5% of patients receiving clozapine. Dry mouth occurs frequently, but hypersalivation, an apparently paradoxical effect considering the drug's potent anticholinergic activity, is more common. (See Cautions: GI Effects.)

Other autonomic nervous system effects of clozapine include hyperhidrosis, decreased sweating, visual disturbances, nasal congestion, and pallor. Numbness, polydipsia, hot flushes (flashes), dry throat, and mydriasis have been reported in less than 1% of clozapine-treated patients.

■ **Hepatic Effects** Transient increases in liver function test results, including serum aminotransferases (transaminases), LDH, and alkaline phosphatase, may occur with clozapine therapy, usually with no accompanying physical signs or symptoms. Clozapine-induced changes in liver function test results may be more pronounced than those with other tricyclic antipsychotic agents. Clozapine causes slight liver hyperplasia in rats; hyperplasia was reversible and no histologic changes were detectable. Clozapine occasionally causes slight elevations of bilirubin concentration. Cholestasis, hepatitis, and jaundice have been reported in patients receiving clozapine during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Endocrine and Metabolic Effects** Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents, including clozapine. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., clozapine, olanzapine, quetiapine, risperidone). (See Cautions: Precautions and Contraindications.)

Precise risk estimates for hyperglycemia-related adverse events in patients

treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., clozapine, olanzapine) than with others (e.g., quetiapine, risperidone) in the class, available data are conflicting and insufficient to provide reliuble estimates of relative risk assoeiated with use of the varions atypieal antipsychotics.

Clozapine causes only a brief, transient elevation of prolactin concentration. (See Pharmacology: Neuroendocrine Effects.) Because the drug's effects on prolactin are only minor, prolactin-dependent effects such as galactorrhea and amenorrheu usually are not associated with clozapine therapy. Breast pain or discomfort has been reported in less than 1% of clozapine-treated patients.

Clozapine may cause increased appetite, polyphagia, and weight gain in a substantial proportion (approximately one-third) of patients. Some clinicians suggest that the potential for weight gain with clozapine therapy may be similar to that with other antipsychotic therapy; others state that they have observed greater weight gain with clozapine in some patients. In the 2-year InterSePT trial, weight gain reportedly occurred in 31% of patients receiving clozapine compared with 56% of those receiving olanzapine. Some clozapine-treated patients reportedly have gained up to 1 kg weekly for 6 weeks. Weight gain may result from the drug's serotonergic-, histaminergic-, and adrenergic-blocking properties. Weight gain has been reported to be a problem for some patients during long-term therapy with clozapine and may be a major cause of outpatient noncompliance. Some clinicians suggest using exercise and active measures (e.g., dietary counseling) to control dietary intake in clozapine-treated patients.

Hyperuricemia, hyponatremia, weight loss, and decreased serum cholesterol concentrations also have been reported in patients receiving clozapine, although a causal relationship to the drug has not been established. In addition, hypercholesterolemia and hypertriglyceridemia have been reported very rarely during postmarketing experience with the drug.

Small decreases in protein-bound iodine or thyroxine concentrations have heen reported in some patients receiving clozapine, but these values remained within normal limits.

■ **GI Effects** Increased salivation may occur in approximately one-third of patients receiving clozapine; in some studies, hypersalivation was reported in up to 75–85% of clozapine-treated patients. In the InterSePT trial, increased salivation reportedly occurred in 48% of patients receiving clozapine compared with 6% of those receiving olanzapine. Salivation may be profuse, very fluid, and particularly troublesome during sleep because of decreased swallowing. Since clozapine exhibits intrinsic anticholinergic properties, hypersalivation is an unexpected paradoxieal effect. A muscle-relaxant effect of the drug may contribute to hypersalivation, but the cause has not been fully elucidated. Difficulty in swallowing has been reported in a few clozapine-treated patients, and it has been suggested that the drug may cause esophageal dysfunction, which may contribute to or exacerbate the nocturnal hypersalivation associated with clozapine therapy. Some clozapine-treated patients develop tolerance to increased salivation within a few weeks. Occasionally, hypersalivation may be ameliorated by reduction of clnzapine dosage or cautious use of a peripherally acting anticholinergic drug; however, some clinicians generally advise against the use of anticholinergic therapy for this adverse effect because of possible potentiation of clozapine's anticholinergic activity.

Other GI effeets associated with clozapine therapy include constipation, diarrhea, nausea and vomiting, dyspepsia or heartburn, abdominal discomfort, and anorexia; some of these effects have been reported in more than 5% of patients. Constipation, nausea, vomiting, and dyspepsia reportedly occurred in 14–25% of patients receiving clozapine in the InterSePT trial compared with 8–10% of those receiving olanzapine. Although some clinicians advocate the use of metoclopramide (e.g., in doses less than 30 mg daily) for the treatment of clozapine-induced nausea, nther clinicians suggest that metoclopramide or other dopamine antagonists not be used or be used with extreme caution for the treatment of clozapine-induced nausea because of their potential for causing parkinsonian manifestations and tardive dyskinesia.

Abdominal distention, gastroenteritis, rectal bleeding, nervous stomach, abnormal stools, hematemesis, gastric ulcer, bitter taste, and eructation have been reported in less than 1% of patients receiving clozapine. Although a causal relationship to the drug has not been established, salivary gland swelling and paralytic ileus also have been reported in patients receiving clozapine.

■ **Genitourinary Effects** Genitourinary effects reported with clozapine therapy include polyuria, incontinence, urinary urgency or frequency, urinary retention, or other urinary abnormalities; enuresis; impotence; abnormal ejaculation; dysmenorrhea; and vaginal itch or infection. Priapism and acute interstitial nephritis also have been reported with clozapine therapy, although a causal relationship to the drug has not been established.

■ **Respiratory Effects** Clozapine-induced respiratory effects include throat discomfort, dyspneu or shortness of breath, coughing, pneumonia or pneumonia-like symptoms, rhinorrhea, hyperventilation, wheezing, bronchitis, laryngitis, and sneezing. Although a causal relationship to the drug has not been established, aspiration and pleural effusion also have been reported with clozapine therapy during postmarketing surveillance.

Respiratory depression or failure, including arrest requiring resuscitation, also has been reported in patients receiving clozapine, usually at initiation of therapy and particularly in patients receiving concomitant benzodiazepine therapy or in those with a history of recent benzodiazepine use. Some evidence indicates that the incidence of respiratory arrest and vascular collapse is about 1–2% of patients receiving clozapine concomitantly with a benzodiazepine. For additional precautionary information about this potential effect, see Benzodiazepines under Drug Interactions: CNS Depressants.

■ **Dermatologic and Sensitivity Reactions** Rash has been reported in 2% of patients receiving clozapine. Pruritus, eczema, erythema, bruising, dermatitis, petechiae, and urticaria have occurred in less than 1% of patients.

Hypersensitivity reactions, including photosensitivity, vasculitis, erythema multiforme, and Stevens-Johnson syndrome, have been reported with clozapine during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Musculoskeletal Effects** Adverse musculoskeletal effects reported in 1% of clozapine-treated patients include muscular weakness (myasthenic syndrome); back, neck, and leg pain; and muscle ache or spasm. Muscle twitching and joint pain have been reported less frequently. Rhabdomyolysis has been reported with clozapine during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Other Adverse Effects** Numb or sore tongue, chills (with or without fever), malaise, ear or eyelid disorder, ocular hyperemia, epistaxis, and nystagmus have been reported in 1% or less of patients receiving clozapine. Periorbital edema and narrow angle glaucoma also have been reported in clozapine-treated patients, although a causal relationship to the drug has not been established.

■ **Precautions and Contraindications** Clozapine shares many of the toxic potentials of other antipsychotic agents (e.g., phenothiazines), and the usual precautions associated with therapy with these agents should be observed. (See Cautions, in the Phenothiazines General Statement 28:16.08.24.)

Sedative Effects Because of initial sedative effects of the drug, patients should be cautioned that clozapine may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle), especially during the first few days of therapy. The recommendation for gradual dosage escalation should be closely followed. (See Dosage and Administration.)

Febrile Reactions During clozapine therapy, patients also may experience transient temperature elevations exceeding 38°C, with the peak incidence within the first 3 weeks of therapy. (See Cautions: Fever.) While this fever generally is benign and self-limiting, it may necessitate discontinuance of therapy. Occasionally, there may be an associated increase or decrease in leukocyte count and patients with fever should be carefully monitored to rule out the possibility of infection or the development of agranulocytosis. In the presence of high fever, the possibility of neuroleptio malignant syndrome also must be considered. (See Extrapyramidal Reactions under Cautions: Nervous System Effects.)

Anticholinergic Effects and Paralytic Ileus Clinical experience with clozapine in patients with concomitant systemic diseases is limited. However, clozapine has potent anticholinergic activity and should therefore be used with caution in individuals whose condition may be aggravated by anticholinergic effects (e.g., patients with prostatic hyperplasia, urinary retention, angle-closure [obstructive, narrow-angle] glaucoma). Clozapine therapy has been associated with varying degrees of impairment of intestinal peristalsis, ranging from constipation to intestinal obstruction, fecal impaction, and paralytic ileus, that rarely have been fatal. The manufacturers state that constipation may be treated initially by maintaining adequate hydration and by using bulk-forming laxatives. Consultation with a gastroenterologist may be necessary in more severe cases. Clozapine is contraindicated in patients with paralytic ileus.

Hepatic Dysfunction Because there have been reports of hepatie dysfunction, including hepatitis, in patients reeeiving clozapine, the drug should be used with caution in patients with preexisting liver disease. Liver function tests should be performed immediately in patients who develop nausea, vomiting, and/or anorexia during clozapine therapy. The manufacturers state that clozapine therapy should be discontinued in patients with marked elevations in serum aminotransferase concentrations or in those presenting with manifestations of jaundice.

Individuals with Phenylketonuria Individuals with phenylketonuria (i.e., homozygous genetic deficiency of phenylalanine hydroxylase) and other individuals who must restrict their intake of phenylalanine should be warned that clozapine 25- or 100-mg orally disintegrating tablets contain aspartame, which is metabolized in the GI tract to provide about 1.74 or 6.96 mg of phenylalanine, respectively, following oral administration.

Hyperglycemia and Diabetes Mellitus Because severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents, including clozapine, the manufacturers state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia (e.g., polydipsia, polyphagia, polyuria, weakness) during treatment with an atypieal antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetie treatment despite discontinuance of the suspect drug; in other cases hyperglycemia resolved with discontinuance of the antipsychotic.

Various experts have developed additional recommendations for the management of diabetes risks in patients receiving atypical antipsychotics; these include initial screening measures and regular monitoring (e.g., determination of diabetes risk factors; BMI determination using weight and height; waist circumference; blood pressure; fasting blood glucose; hemoglobin A_{1c} [HbA_{1c}]; fasting lipid profile), as well as provision of patient education and referral to clinicians experienced in the treatment of diabetes, when appropriate. Although some clinicians state that a switch from one atypical antipsychotic agent to another that has not been associated with substantial weight gain or diabetes should be considered in patients who experience weight gain (equal to or exceeding 5% of baseline body weight) or develop worsening glycemia or dyslipidemia at any time during therapy, such recommendations are controversial because differences in risk of developing diabetes associated with use of the different atypical antipsychotics remain to be fully established. Many clinicians consider antipsychotic efficacy the most important factor when making treatment decisions and suggest that detrimental effects of switching from a beneficial treatment regimen also should be considered in addition to any potential for exacerbation or development of medical conditions (e.g., diabetes). Decisions to alter drug therapy should be made on an individual basis, weighing the potential risks and benefits of the particular drug in each patient.

Cardiovascular Effects Clozapine should be used with caution in patients with cardiovascular and/or pulmonary disease because the drug may cause tachycardia, hypotension, and cardiac and/or respiratory arrest. In such patients, the recommendation for gradual dosage titration following a low initial dose should be observed carefully. (See Dosage and Administration: Dosage.)

Analyses of postmarketing surveillance data suggest that clozapine is associated with an increased risk of potentially fatal myocarditis, particularly during the first month of therapy. Immediate discontinuance of the drug is recommended in cases of suspected myocarditis. (See Myocarditis under Cautions: Cardiovascular Effects.)

Fatal pulmonary embolism has been reported with clozapine therapy. The possibility of pulmonary embolism should be considered in patients presenting with deep-vein thrombosis, acute dyspnea, chest pain, or other respiratory signs and symptoms.

Because cardiomyopathy has been reported in patients treated with clozapine, signs and symptoms suggestive of cardiomyopathy, particularly exertional dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea, and peripheral edema, should alert the clinician to perform further investigations. If the diagnosis of cardiomyopathy is confirmed, the drug should be discontinued unless the benefit to the patient clearly outweighs the risk.

Orthostatic hypotension with and without syncope can occur with clozapine therapy and may represent a continuing risk in some patients. Orthostatic hypotension is more likely to occur during initial titration of the drug in association with rapid dose escalation, but may even occur with the first dose at clozapine doses as low as 12.5 mg. Rarely, severe hypotension or orthostatic collapse can be profound and be accompanied by respiratory and/or cardiac arrest. Such adverse cardiovascular effects have occurred during initial treatment with the drug alone or in combination with benzodiazepines or other psychotropic agents. (See Drug Interactions: CNS Depressants.) Temporary reduction in dose or interruption of clozapine therapy may be required. Severe hypotensive effects also may be alleviated with standard measures (e.g., IV fluids, placing patient in Trendelenburg's position) and, if required, by the administration of norepinephrine or phenylephrine; epinephrine should *not* be used since a further lowering of blood pressure may occur. (See Drug Interactions: Hypotensive Agents.) Patients should be informed of the risk of orthostatic hypotension associated with use of clozapine, especially during the period of initial dosage titration. In addition, if clozapine therapy has been discontinued for more than 2 days, patients should be advised to contact their clinician for dosing instructions. (See Reinitiation of Therapy under Dosage: Psychotic Disorders, in Dosage and Administration.)

Seizures Clozapine is contraindicated in patients with uncontrolled seizure disorders.

Generalized tonic-clonic (grand mal) seizures have occurred in patients receiving clozapine, particularly in patients receiving high dosages (greater than 600 mg daily) and/or in whom plasma clozapine concentrations were elevated. (See Seizures under Cautions: Nervous System Effects.) Clozapine should be administered with extreme caution to patients having a history of seizure disorder or other factors possibly predisposing to seizure (e.g., abnormal EEG without a history of epilepsy, preexisting CNS pathology, history of electroconvulsive therapy or of perinatal or birth difficulties, family history of seizure or febrile convulsion). Because of the substantial risk of seizures associated with clozapine use, patients should be advised not to engage in any activity where sudden loss of consciousness could cause serious risk to themselves or others (e.g., operating heavy machinery, driving an automobile, swimming, climbing). In addition, the manufacturers recommend that general anesthesia be administered with caution in patients receiving clozapine therapy because of this and other adverse CNS effects associated with the drug. An anesthesiologist should be consulted regarding continuation of clozapine therapy in patients undergoing surgery involving general anesthesia.

Hematotoxicity Because of the substantial risk of agranulocytosis, a potentially life-threatening adverse event, clozapine therapy should be reserved for use in the treatment of severely ill schizophrenic patients who fail to respond to adequate courses of standard antipsychotic therapy or for suicide risk reduction in patients with schizophrenia or schizoaffective disorder who are judged to be at risk for recurrent suicidal behavior. Patients should be warned of this risk and informed that clozapine is available only through distribution systems that ensure baseline and periodic monitoring of leukocyte counts according to a prescribed schedule prior to delivery of the next supply of medication. (See Cautions: Hematologic Effects.) In addition, patients should be advised to report immediately the development of lethargy, malaise, weakness, fever, sore throat, mucous membrane ulceration, or any other potential manifestation of infection. Particular attention should be paid to any flu-like symptoms or other complaints that might suggest infection. Patients who develop agranulocytosis or severe leukopenia/granulocytopenia (leukocyte less than 2000/mm^3 and ANC less than 1000/mm^3) while receiving clozapine should *not* be rechallenged with the drug. Although it is not known whether the risk of agranulocytosis is increased, clozapine generally should be avoided or used with caution in patients with a history of agranulocytosis induced by other drugs.

Clozapine is contraindicated in patients with myeloproliferative disorders, preexisting bone marrow depression, or a history of clozapine-induced agranulocytosis or severe granulocytopenia. The drug also is contraindicated in patients receiving other agents that may cause agranulocytosis or suppress bone marrow function and in those with severe CNS depression or comatose states from any cause. Although the manufacturers do not mention it as a specific contraindication to clozapine therapy, the American Psychiatric Association recommends that clozapine therapy be avoided in schizophrenic patients who are unable or unwilling to comply with the close monitoring that is necessary to detect possible adverse hematologic effects associated with the drug.

Other Precautions and Contraindications Clozapine is contraindicated in patients with a history of hypersensitivity to the drug or any ingredient in the formulation.

■ **Pediatric Precautions** Safety and efficacy of clozapine in children and adolescents younger than 16 years of age have not been established. However, clozapine has been used in a limited number of children and adolescents with treatment-refractory schizophrenia (see Pediatric Considerations under Psychotic Disorders: Schizophrenia, in Uses) and results of at least one randomized, double-blind clinical study indicate that adverse hematologic effects were a major concern for children and adolescents receiving clozapine†. Although no cases of agranulocytosis occurred in this study, 24% of these children and adolescents experienced mild‡ to moderate neutropenia during 2 years of follow-up; compared with an estimated cumulative risk of 1.5–2% of developing neutropenia in adults. The precise mechanism by which clozapine induces agranulocytosis is not known, but a higher concentration of the metabolite norclozapine, which has been associated with hematopoietic toxicity in children and adolescents receiving clozapine, has been suggested as a possible reason for the increased risk in this age group.

In addition to adverse hematologic effects, clinically important seizure activity (e.g., epileptiform spikes, myoclonus, tonic-clonic seizures) also has been reported in children and adolescents with no previous history of epilepsy who received clozapine. In some cases, EEG abnormalities were associated with clinical deterioration (i.e., increased aggression, psychosis, irritability). Because some children and adolescents responded behaviorally to reduced dosages of clozapine and the addition of an anticonvulsant (e.g., valproate), it has been suggested that the EEG may be a sensitive indicator of clozapine toxicity in children as well as in adults.

■ **Geriatric Precautions** Clinical studies of clozapine did not include sufficient numbers of patients 65 years of age and older to determine whether geriatric patients respond differently than younger patients. Because geriatric patients may be at increased risk for certain cardiovascular (e.g., orthostatic hypotension, tachycardia) and anticholinergic effects of the drug (e.g., constipation, urinary retention in the presence of prostatic hypertrophy), clozapine should be used cautiously in this age group. In addition, geriatric patients generally are more sensitive than younger patients to drugs that affect the CNS; data from clinical studies indicate that the incidence of tardive dyskinesia appears to be highest among geriatric patients, especially women. In general, dosage should be titrated carefully in geriatric patients, usually initiating therapy at the low end of the dosage range; the greater frequency of decreased hepatic, renal, and/or cardiac function and of concomitant disease and drug therapy observed in the elderly also should be considered.

Geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs appear to be at an increased risk of death compared with that among patients receiving placebo. Analyses of 17 placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6- to 1.7- fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., aripiprazole, olanzapine, quetiapine, risperidone) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. Clozapine is not approved for the treatment of dementia-related psychosis.

■ **Mutagenicity and Carcinogenicity** Clozapine did not exhibit carcinogenic potential in long-term studies in mice and rats receiving dosages approximately 7 times (on a mg/kg basis) the usual human dosage. Clozapine also did not exhibit genotoxic or mutagenic effects when assayed in appropriate bacterial and mammalian tests.

■ **Pregnancy, Fertility, and Lactation** Reproduction studies in rats and rabbits using clozapine dosages approximately 2–4 times the usual human dosage have not revealed evidence of harm to the fetus. There are no adequate and controlled studies to date using clozapine in pregnant women, and the drug should be used during pregnancy only when clearly needed. Patients receiving clozapine should notify their physician if they become or plan to become pregnant during therapy.

Reproduction studies in rats and rabbits using clozapine dosages approximately 2–4 times the usual human dosage have not revealed impaired fertility.

Studies in animals suggest that clozapine may be distributed into milk. Because of the potential for serious adverse reactions to clozapine in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Drug Interactions

The manufacturers state that the potential risks of using clozapine in combination with other drugs have not been evaluated systematically. However, clinical experience and/or theoretical considerations indicate that certain potential drug interactions exist.

■ **Myelosuppressive Agents** The mechanism of clozapine-induced agranulocytosis is unknown; however, the possibility that causative factors may interact synergistically to increase the risk and/or severity of bone marrow suppression warrants consideration. (See Cautions: Hematologic Effects.) Therefore, clozapine should not be used with other agents having a well-known potential to suppress bone marrow function. That clozapine may be directly myelotoxic has been suggested by in vitro study of the serum and bone marrow of a patient who died during multidrug therapy that included clozapine and carbamazepine.

■ **Drugs Affecting the Seizure Threshold** Clozapine may lower the seizure threshold and has caused seizures in some patients (see Seizures under Cautions: Nervous System Effects); therefore, concomitant therapy with other agents that lower the seizure threshold generally should be avoided if possible. If such combined therapy is required, caution should be exercised (e.g., using low initial dosages of clozapine with slow upward titration) and the possible need for anticonvulsant therapy considered.

■ **CNS Depressants** ***Benzodiazepines*** Severe hypotension (including absence of measurable blood pressure), respiratory or cardiac arrest, and loss of consciousness have been reported in several patients who received clozapine concomitantly with or following benzodiazepine (i.e., flurazepam, lorazepam, diazepam) therapy. Such effects occurred following administration of 12.5–150 mg of clozapine concurrently with or within 24 hours of the benzodiazepine, but patients generally have recovered within a few minutes to hours, usually spontaneously; the reactions usually developed on the first or second day of clozapine therapy. Although a causal relationship has not definitely been established and such effects also have been observed in clozapine-treated patients who were not receiving a benzodiazepine concomitantly (see Cautions: Cardiovascular Effects), death resulting from respiratory arrest reportedly has occurred in at least one patient receiving clozapine concomitantly with a benzodiazepine. An increased incidence of dizziness and sedation and greater increases in liver enzyme test results also have been reported with this drug combination.

The manufacturers of clozapine recommend caution when the drug is initiated in patients receiving benzodiazepine therapy. However, some clinicians advise that, pending further accumulation of data, greater precaution should be exercised. These clinicians recommend that since initial titration of clozapine may cause respiratory arrest requiring resuscitation, which may be potentiated by recent benzodiazepine therapy, these latter drugs should be discontinued for at least 1 week prior to initiating clozapine therapy. In addition, these clinicians recommend that clozapine therapy be initiated in a setting where facilities for resuscitation are immediately available for the first few hours after administration of the first dose. Other clinicians, however, state that institutional initiation of clozapine therapy may not be necessary or practical, although they recommend slow and cautious initiation of the drug at low dosages.

Other CNS Depressants Clozapine may be additive with, or may potentiate the action of, other CNS depressants such as opiates or other analgesics, barbiturates or other sedative/hypnotics, general anesthetics, or alcohol. When clozapine is used concomitantly with other CNS-depressant drugs, caution should be exercised to avoid excessive sedation.

■ **Other CNS-active Agents** Although a causal relationship has not been established, at least one death has been reported with concomitant clozapine and haloperidol therapy. A 31-year-old woman with schizophrenia developed respiratory arrest, became comatose, and died 4 days after receiving 10 mg of haloperidol orally and a single 100-mg dose of clozapine IM. The patient had been maintained on oral clozapine 200 mg daily for 2 years and also had received smaller doses of haloperidol concomitantly with clozapine therapy without unusual adverse effect.

Neuroleptic malignant syndrome has been reported rarely with clozapine therapy alone and during concomitant therapy with clozapine and carbamazepine, lithium, or other CNS-active agents. (See Extrapyramidal Reactions under Cautions: Nervous System Effects.)

Concomitant use of clozapine and lithium may also increase the risk of seizures.

Orthostatic hypotension, sometimes accompanied by profound collapse and respiratory and/or cardiac arrest, has been reported rarely with clozapine therapy alone and during concomitant therapy with other psychotropic agents. Although the clinical importance of this interaction has not been fully established, the manufacturers of clozapine state that the drug should be initiated with caution in patients receiving other psychotropic agents.

■ **Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes** Clozapine is a substrate for many cytochrome P-450 (CYP) isoenzymes, in particular 1A2, 2D6, and 3A4. The risk of metabolic interactions caused by an effect on an individual isoform is therefore minimized. However, concomitant use of clozapine with drugs that inhibit the CYP enzyme system (e.g., caffeine, cimetidine, erythromycin, quinidine, certain antidepressants, phenothiazines, type IC antiarrhythmics [e.g., propafenone, flecainide, encainide]) may result in increased plasma concentrations of clozapine. Conversely, concomitant use of clozapine with drugs that induce the CYP enzyme system (e.g., carbamazepine, nicotine, phenytoin, rifampin) may result in decreased plasma concentrations of clozapine. Caution should be observed if clozapine is used concomitantly with these drugs. Dosage adjustments of clozapine and/or other drugs may be necessary in patients receiving concomitant therapy with drugs that inhibit or induce the CYP enzyme system.

Phenytoin Substantial reductions in plasma clozapine concentrations and exacerbation of psychosis have been reported in patients receiving concomitant therapy with clozapine and phenytoin, and an increase in clozapine dosage may be required to reestablish antipsychotic efficacy in patients receiving such combined therapy. In 2 patients stabilized for 1–2 weeks on a given dosage of clozapine, addition of phenytoin for prevention of clozapine-induced seizures resulted in a 65–85% decrease in steady-state plasma clozapine concentrations. Control of psychotic manifestations was regained in both patients by gradually increasing clozapine dosage. Although the mechanism of this potential interaction has not been established, it has been suggested that phenytoin may increase clozapine metabolism via stimulation of the hepatic cytochrome P-450 (microsomal) enzyme system and/or displacement of clozapine from protein binding sites, or that phenytoin may decrease absorption of clozapine from the GI tract. Pending further study, clozapine-treated patients in whom phenytoin therapy is initiated should be monitored carefully for reemergence of psychotic manifestations and clozapine dosage adjusted accordingly.

Carbamazepine Concomitant use of clozapine and carbamazepine has been shown to decrease clozapine concentrations by about 40–50%. In addition, neuroleptic malignant syndrome has been reported rarely with clozapine therapy alone and during concomitant therapy with carbamazepine. (See Extrapyramidal Reactions under Cautions: Nervous System Effects.) Therefore, the manufacturers of clozapine state that concomitant use of these agents generally is not recommended. However, if clozapine and carbamazepine are used concomitantly, it should be considered that discontinuance of carbamazepine may result in increased plasma concentrations of clozapine.

Selective Serotonin-reuptake Inhibitors Concomitant use of clozapine with certain selective serotonin-reuptake inhibitors (SSRIs), including citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline, can increase plasma concentrations of clozapine and enhance clozapine's pharmacologic effects secondary to suspected inhibition of clozapine metabolism by SSRIs. Modest (less than twofold) elevations in plasma clozapine concentrations have been reported in patients receiving clozapine concomitantly with certain SSRIs (i.e., fluoxetine, paroxetine, sertraline), although substantial (threefold) increases in trough plasma clozapine concentrations have occurred in patients receiving concomitant therapy with clozapine and fluvoxamine. The manufacturers of clozapine state that caution should be exercised and patients should be closely monitored when clozapine is used in patients receiving SSRIs, and a reduction in clozapine dosage should be considered.

■ **Drugs with Anticholinergic Activity** Clozapine has potent anticholinergic effects and may potentiate the actions of other drugs possessing such activity (e.g., antimuscarinics).

■ **Hypotensive Agents** Clozapine may be additive with or potentiate the actions of hypotensive agents. In addition, the administration of epinephrine should be avoided in the treatment of clozapine-induced hypotension because of a possible reversal of epinephrine's vasopressor effects and subsequent further lowering of blood pressure.

■ **Smoking** Some evidence indicates that cigarette smoking may substantially reduce plasma clozapine concentrations. Limited data indicate that average plasma clozapine concentrations following a given dose in smokers average 60–82% of those in nonsmokers. Changes in liver enzyme activity and/or the GI tract induced by nicotine or other substances present in cigarette smoke may explain these reduced concentrations. These effects should be considered when adjusting clozapine dosage in patients who smoke cigarettes.

Acute Toxicity

■ **Pathogenesis** Acute toxicity studies in animals revealed that the LD_{50}s for clozapine administered orally, IV, or intraperitoneally are approximately 145–325, 58–61, and 90 mg/kg, respectively.

Although the acute lethal dose of clozapine in humans remains to be established, fatal overdoses with the drug generally have been associated with doses exceeding 2.5 g. However, there also have been reports of patients surviving overdoses that substantially exceeded 4 g of the drug.

■ **Manifestations** In general, overdosage of clozapine may be expected to produce effects that are extensions of pharmacologic and adverse effects. The most commonly reported signs and symptoms of clozapine overdosage have been altered states of consciousness and CNS depression (e.g., drowsiness, delirium, coma), tachycardia, cardiac arrhythmias, hypotension, respiratory depression or failure, aspiration, pneumonia, and hypersalivation. Seizures have occurred with overdosage in some patients. (See Seizures under Cautions: Nervous System Effects.)

A 24-year-old woman who ingested 2 g in excess of her prescribed daily dosage (i.e., total ingestion approximately 3 g within a 24-hour period) had a tonic-clonic (grand mal) seizure; her plasma clozapine concentration 1 hour after the seizure (1313 ng/mL) was 500 ng/mL higher than usual, but she recovered uneventfully. In a 50-year-old woman who ingested 1 g of clozapine, the only manifestations were confusion and hallucinations lasting about 48 hours. A 26-year-old man who ingested approximately 3 g of clozapine became drowsy, agitated, and disoriented; he also had visual hallucinations, dysarthria, tachycardia, and hypersalivation. The patient was treated with gastric lavage and also received diazepam, digitalis, and anti-infectives, but continued to exhibit manifestations of severe central anticholinergic toxicity. Administration of physostigmine salicylate 2 mg by slow IV injection resulted in improvement in the patient's mental status within minutes; however, symptoms recurred after approximately 1 hour. Symptoms finally remitted 18–24 hours later with no further treatment.

■ **Treatment** Treatment of clozapine overdosage generally requires symptomatic and supportive care, including monitoring of cardiac and vital signs. There is no specific antidote for the management of clozapine overdosage.

The manufacturers recommend establishing and maintaining an airway and ensuring adequate ventilation and oxygenation. Activated charcoal, which may be used with sorbitol, may be as or more effective than emesis or gastric lavage and should be considered in the treatment of clozapine overdosage. Electrolyte and acid-base balance should be monitored and adjusted accordingly. Peritoneal dialysis or hemodialysis is of limited value in the treatment of clozapine overdosage because the drug is almost totally bound to serum protein. Forced diuresis, hemoperfusion, and exchange transfusion also are unlikely to be of benefit. While physostigmine salicylate may be useful as adjunctive treatment if severe anticholinergic toxicity is present, the drug should *not* be used routinely because of its potential adverse effects.

Epinephrine should *not* be used for treating clozapine-induced hypotension, since clozapine can reverse epinephrine's vasopressor effects and cause a further lowering of blood pressure. Because of potential additive anticholinergic effects, quinidine or procainamide should be avoided when treating clozapine-induced arrhythmias. Surveillance of the patient should be continued for several days following overdosage because of the risk of delayed effects. In managing clozapine overdosage, the clinician should consider the possibility of multiple drug involvement.

Chronic Toxicity

Physical and/or psychological dependence have not been reported in patients receiving clozapine.

Chronic toxicity studies in mice, rats, dogs, and monkeys have revealed no specific organ toxicity. After 1 year of treatment with clozapine, a brown discoloration caused by increased lipopigment was observed in various organs in rats; this change normally appears with increasing age. Discoloration was noted in the thyroid, brain, liver, kidney, heart, spleen, and skeletal muscle of rats, but such increased pigmentation was not associated with deleterious changes. The liver did show slight, dose-dependent changes, including centrolobular vacuolation, hepatocyte swelling, and increased weight.

Pharmacology

Clozapine is a dibenzodiazepine-derivative antipsychotic agent. While clozapine shares some of the pharmacologic actions of other antipsychotic agents, the drug has been described as an atypical or second-generation antipsychotic agent since many of its CNS effects differ from those of typical agents (e.g., butyrophenones, phenothiazines). In fact, these apparent differences in actions on neostriatal dopaminergic receptors have led some investigators to question the importance of the dopaminergic system in mediating the therapeutic effects of neuroleptic drugs. The exact mechanism of antipsychotic action of clozapine has not been fully elucidated but appears to be more complex than that of conventional (typical) antipsychotic agents and may involve serotonergic, adrenergic, and cholinergic neurotransmitter systems in addition to more selective, regionally specific effects on the mesolimbic dopaminergic system. Because of differences in the neurologic effects of clozapine, the drug is not considered a classic neuroleptic agent.

■ **Nervous System Effects** Although the precise mechanism of action of antipsychotic drugs has not been fully elucidated, current data suggest that the therapeutic effects of these agents involve antagonism of dopaminergic systems in the CNS. In animals, classic neuroleptic agents increase muscle tone or induce postural abnormalities (catalepsy), antagonize stereotyped behaviors induced by the dopamine agonists apomorphine and amphetamine, accelerate dopamine turnover in various areas of the brain, increase serum prolactin concentrations, and produce dopamine receptor hypersensitivity on repeated administration. These effects, many of which have been attributed to blockade of dopamine receptors in the neostriatum, form the basis for the hypothesis that idiopathic psychoses result from overactivity of dopamine in neostriatal and mesolimbic systems.

Unlike typical antipsychotic agents, clozapine exerts relatively weak antidopaminergic action within the neostriatum and has a low propensity to produce extrapyramidal effects or stimulate prolactin secretion. While some studies have demonstrated that relatively high doses of clozapine suppress the conditioned avoidance response in animals, which is a characteristic of typical antipsychotic agents, this response is not completely blocked by clozapine, and tolerance to this effect develops rapidly with repeated dosing, suggesting that it is not specifically related to clozapine's antipsychotic action. Further research is needed to elucidate fully clozapine's antipsychotic action in terms of the drug's serotonergic, adrenergic, muscarinic, and peptidergic effects and their influences on functional alterations in dopamine receptor systems.

Antidopaminergic Effects The therapeutic effects of antipsychotic drugs are thought to be mediated by dopaminergic blockade in the mesolimbic and mesocortical areas of the CNS, while antidopaminergic effects in the neostriatum appear to be associated with extrapyramidal effects. Several (at least 5) different types or subtypes of dopamine receptors have been identified in animals and humans. The relative densities of these receptors and their distribution and function vary for different neuroanatomical regions, and clozapine's unique effects may be secondary to regionally specific receptor interactions and/or other effects on dopaminergic neurons. Results obtained from receptor binding, behavioral, metabolic, and electrophysiologic studies of clozapine as well as the apparently low incidence of extrapyramidal effects associated with clozapine therapy suggest that the drug is more active in the mesolimbic than the neostriatal dopaminergic system. Results of some studies suggest that clozapine is more effective in increasing dopamine turnover and release in the nucleus accumbens or olfactory tubercle than in the neostriatum with acute administration and that it reduces dopamine release in the accumbens but not in the neostriatum during prolonged administration, which suggests preferential effects on dopaminergic function in the limbic system. However, conflicting data (i.e., no preferential limbic effects) also have been reported with both acute and repeated administration of the drug, which may reflect differences in analytical techniques, regional differences in drug distribution or receptor affinity, or other variables.

Some evidence suggests that the effects of clozapine on dopamine metabolism in the neostriatum are dose related; unlike typical antipsychotic drugs, clozapine appears to increase striatal dopamine turnover only at suprathera-peutic doses. Single high doses (80 mg/kg intraperitoneally) of clozapine in rats interfere with dopaminergic transmission by blocking postsynaptic dopamine receptors and causing a compensatory increase in dopaminergic neuronal firing, while lower doses retard dopamine release. Clozapine appears to increase striatal dopamine content when given either in single high doses or repeated low doses, and low doses of the drug reportedly decrease the degradation of dopamine to 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid, HVA) in the neostriatum. In a rodent model of tardive dyskinesia, single low doses (up to 1.2 mg/kg intraperitoneally) of clozapine suppressed ketamine-induced linguopharyngeal movements, which resemble symptoms of tardive dyskinesia (e.g., tongue protrusions, retrusions, and swallows), by 15–75% compared with baseline measures. At clozapine doses of 4.8 mg/kg or higher, clozapine caused total suppression of these movements, and duration of suppression became dose dependent. Since suppression of abnormal linguopharyngeal movements occurred at doses substantially lower than those reported to alter dopamine turnover, it has been suggested that doses of the drug lower than those required for antipsychotic activity may be useful for treating antipsychotic-induced tardive dyskinesia.

Current evidence suggests that the clinical potency and antipsychotic efficacy of both typical and atypical antipsychotic drugs generally are related to their affinity for and blockade of central dopamine D_2 receptors; however, antagonism at D_2 receptors does not appear to account fully for the antipsychotic effects of clozapine.

In in vitro studies, clozapine is a comparatively weak antagonist at D_2 receptors. Clozapine's affinity for the D_2 receptor on a weight basis reportedly is approximately one-third (33%) that of loxapine, one-tenth (10%) that of chlorpromazine, and one-fiftieth (2%) that of haloperidol. In oral dosages of 300 mg daily, clozapine produces a 40–65% occupancy of D_1 and D_2 receptors. During long-term clozapine therapy, the relative occupancy of D_1 receptors may become greater than that of D_2 receptors, or the long-term effects of the drug on D_2 receptors may be antagonized by its nondopaminergic properties. Although the in vitro affinity of clozapine for D_1 and D_2 receptors in brain tissue of animals appears to be similar, the drug's in vivo effects in many animals resemble those of D_1 receptor-specific antagonists. Compared with typical antipsychotic agents, clozapine shows greater affinity for and appears to produce greater blockade of neostriatal dopamine D_1 receptors; other data suggest that clozapine preferentially but not selectively antagonizes D_1 receptor-mediated functions. At clinically effective dosages, however, the drug produces comparable blockade of D_1 and D_2 receptors and less D_2 blockade than typical antipsychotic drugs. Long-term administration of clozapine leads to a 35–50% "up-regulation" of D_1 receptors, which is comparable to that observed with administration of selective D_1 antagonists; however, the number of D_2 receptors is not changed, possibly because the proportion of occupied receptors required to elicit a response is less for D_1 than for D_2 receptors. Limited evidence suggests that D_1 receptors may exist either coupled to adenylate cyclase or in uncoupled form. Clozapine appears to be a potent, competitive inhibitor of

dopamine-stimulated adenylate cyclase in vitro, and the adenylate cyclase-coupled state of the D_1 receptor binds clozapine with high affinity; in contrast, typical antipsychotic agents bind preferentially to the uncoupled D_1 receptor.

Although their role in eliciting the pharmacologic effects of antipsychotic agents remains to be fully elucidated, dopamine D_3, D_4, and D_5 receptors also have been identified; clozapine appears to have a much higher affinity for the D_4 receptor than for D_2 or D_3 receptors. Current information on D_3-receptor affinity for antipsychotic drugs suggests that most antipsychotics probably bind to both D_2 and D_3 receptors, although with higher affinity to D_2 receptors; however, the magnitude of the difference in D_3- versus D_2-receptor binding is much less with atypical antipsychotics such as clozapine, suggesting that effects on D_3 receptors may play a more important role in the pharmacologic actions of atypical versus typical antipsychotic drugs. The high affinity of the D_4 receptor for clozapine and its preferential distribution in cortical and limbic areas in animals may explain, in part, the relative lack of tardive dyskinesia and extrapyramidal effects during clozapine therapy. The cloning of a gene for a neuron-specific dopamine D_5 receptor, which binds antipsychotic drugs with similar affinity as the D_1 receptor but has a tenfold higher affinity for dopamine, also has been reported.

Clozapine's clinical potency appears to be twice that of chlorpromazine on a weight basis, although the drug demonstrates considerably weaker D_2-receptor binding affinity than chlorpromazine and appears to be much less potent in elevating dopamine metabolite concentrations in the brain. Clozapine produces a more potent blockade of central serotonergic, adrenergic, histamine H_1, and muscarinic receptors than typical antipsychotic agents; also, long-term administration of clozapine enhances striatal D_1-receptor function in animals and results in "down-regulation" of cortical, type 2 serotonergic (5-HT_2) receptors, suggesting that an interaction between these central neurotransmitter systems may be important for the drug's antipsychotic efficacy. Antagonism at cholinergic and α_1-adrenergic receptors in the mesolimbic system, compensating for dopaminergic blockade in the neostriatum, may explain the apparent selectivity and low incidence of extrapyramidal effects seen with clozapine. The amygdala also may be a site of action for clozapine, since repeated administration of the drug selectively induces supersensitivity to locally applied dopamine in the amygdala, and amygdaloid neurons are excited by clozapine but generally unresponsive to other antipsychotic agents (e.g., haloperidol).

Further studies are needed to elucidate the mechanism of clozapine's antipsychotic effects in various areas of the CNS.

Neurophysiologic Effects In vitro and in vivo electrophysiologic studies in animals demonstrate different sensitivities of various brain areas to clozapine-mediated postsynaptic receptor blockade. While clozapine increases firing rates of both nigrostriatal (A9 pathway) and mesolimbic (A10 pathway) dopaminergic neurons after acute administration, only mesolimbic dopaminergic neurons exhibit prolonged depolarization blockade following repeated exposure to the drug. Repeated administration of typical antipsychotic agents (e.g., haloperidol) concomitantly with an anticholinergic agent (trihexyphenidyl) or an α_1-adrenergic blocking drug (prazosin) mimicked these selective effects of clozapine on mesolimbic versus nigrostriatal dopaminergic neurons, suggesting that α_1-adrenergic blocking and/or anticholinergic effects may be responsible, in part, for the differential effects of clozapine in these midbrain areas. Some evidence suggests that the nucleus accumbens has greater sensitivity for clozapine than do other regions, which may explain why the drug appears to produce depolarization blockade of dopaminergic neurons only in the mesolimbic area. However, some studies have shown that neurons in the neostriatum also may be responsive to clozapine. Clozapine reportedly produces an increase in dopamine metabolites in the neostriatum comparable to or even greater than that in the nucleus accumbens. Demonstrable dopamine-receptor supersensitivity in both striatal and limbic forebrain regions also has been reported with prolonged clozapine administration. Therefore, it has been suggested that there may be a dissociation between the effects of clozapine on synthesis and metabolism of dopamine within nigrostriatal neurons and the drug's effects on neuronal firing rate and dopamine release.

Adrenergic Effects Clozapine has adrenergic-blocking activity, which may be partially responsible for the sedation, muscle relaxation, and cardiac effects observed in patients receiving the drug. (See Cautions: Cardiovascular Effects.) Although the drug appears to have relatively weak α-adrenergic blocking effects compared with typical antipsychotic drugs such as chlorpromazine, clozapine's in vitro affinity (relative to dopamine D_2-receptor affinity) for α_1- and α_2-adrenergic receptors is much higher than that of other antipsychotics, including chlorpromazine, haloperidol, loxapine, and thioridazine. Clozapine increases the number and sensitivity of α_1-adrenergic, but not dopamine D_2, receptors. The turnover rate of epinephrine and norepinephrine also may be increased by clozapine, but to a lesser extent than that of dopamine. Substantial increases in plasma norepinephrine concentrations, which decreased following discontinuance of the drug but remained above basal levels, have been noted in both schizophrenic and healthy individuals receiving clozapine; such increases may be the result of feedback mechanisms activated by adrenergic blockade.

Clozapine's central α_1-adrenergic blocking activity also may be responsible for the dose-related hypothermia observed in mice given the drug. Clozapine also induces ataxia and blocks amphetamine-induced hyperactivity in mice, although repeated administration of the drug results in almost complete tolerance to these effects. It has been suggested that clozapine's α_1-adrenergic blocking properties may, in part, mediate its differential effects on midbrain dopamine receptors and be responsible for its relative lack of extrapyramidal effects. However, the clinical importance of the drug's α_1-adrenergic effects has not been fully elucidated.

Anticholinergic Effects Clozapine possesses potent anticholinergic activity in vitro; the drug's affinity for muscarinic receptors substantially exceeds that of other antipsychotic agents (e.g., 39–50 times greater than that of chlorpromazine and 100 times that of loxapine) and may be similar to that of tricyclic antidepressants and antimuscarinic antiparkinsonian agents (e.g., benztropine, trihexyphenidyl). It has been suggested that clozapine's anticholinergic effects may be more potent centrally than peripherally and that adverse anticholinergic effects generally are not dose limiting; however, peripheral anticholinergic effects such as dry mouth are common and may be troublesome. Clozapine-induced delirium, which reportedly has occurred with rapid dosage escalation, has been reversed by physostigmine; this suggests that clozapine has central antimuscarinic activity. Some evidence also suggests that clozapine's anticholinergic properties may counteract the effects of dopamine receptor blockade in the neostriatum and thus prevent extrapyramidal reactions. Limited data suggest that the propensity of antipsychotic drugs to cause extrapyramidal effects varies inversely with anticholinergic potency and antimuscarinic activity; however, the relatively potent anticholinergic activity of clozapine does not appear to account adequately for its atypical actions.

Serotonergic Effects It has been suggested that schizophrenia may involve a dysregulation of serotonin- and dopamine-mediated neurotransmission, and clozapine may at least partially restore a normal balance of neurotransmitter function, possibly through serotonergic regulation of dopaminergic tone. Clozapine blocks central type 2 serotonergic (5-HT_2) receptors; the drug also antagonizes central and peripheral type 3 serotonergic (5-HT_3) receptors. Long-term and acute administration of clozapine has produced down-regulation of 5-HT_2 receptors in the frontal cortex and neostriatum of male rats; single or repeated daily injections of clozapine also reduced the number of cortical 5-HT_2 receptors but did not change receptor affinity. In contrast to effects caused by typical antipsychotic agents, an increase in brain tryptophan, serotonin, and 5-hydroxyindoleacetic acid (5-HIAA) concentrations generally has been reported with clozapine administration in animals. It has been suggested that these effects might contribute to the pronounced sedative effects of clozapine, although increases in blood serotonin concentrations occurring during clozapine treatment in humans have been inconsistent and variable. (See Effects on Sleep under Pharmacology: Nervous System Effects.) Clozapine's serotonergic effects also reportedly may contribute to the drug's efficacy against negative symptoms of schizophrenia and to the weight gain observed during clozapine therapy. (See Cautions: Endocrine and Metabolic Effects.)

Effects on Other Central Neurotransmitters Clozapine appears to have important activity on the metabolism of γ-aminobutyric acid (GABA), which has inhibitory effects on dopaminergic neurons. In contrast to the effects of typical antipsychotic drugs, clozapine apparently augments GABA turnover in both the neostriatum and nucleus accumbens. Increases in neostriatal GABA turnover and release may attenuate extrapyramidal reactions, while a similar action in the nucleus accumbens may be related to antipsychotic efficacy.

Clozapine appears to have central histamine H_1-receptor blocking activity; such activity reportedly may be associated with sedation, hypotension, and weight gain. The drug's affinity (relative to dopamine D_2-receptor affinity) for histamine H_1-receptors is approximately 30 times that of chlorpromazine and 4 times that of loxapine.

Behavioral Effects in Animals Studies of the effects of clozapine on animal behavior routinely used to detect antipsychotic activity support its classification as an atypical antipsychotic drug. Such studies suggest that the neostriatum is relatively unresponsive to clozapine. Since the drug does not induce catalepsy or inhibit apomorphine-induced stereotypy, which are thought to be mediated principally by the nigrostriatal dopamine system, clozapine's antipsychotic activity appears to result from the drug's activity in other areas. Clozapine also does not block amphetamine-induced hyperactivity or apomorphine-induced emesis in animals as the typical antipsychotic agents do. Long-term administration of clozapine causes supersensitization of behaviors mediated by mesolimbic dopaminergic pathways (e.g., dopamine-induced locomotion) but not those mediated via neostriatal systems (e.g., dopamine-induced stereotypy). Long-term administration of clozapine in male rats caused a marked supersensitivity (of the same magnitude and duration as that of haloperidol) in the mesolimbic but not the nigrostriatal system. It has been suggested that supersensitivity of mesolimbic dopamine receptors may be associated with the apparent rebound psychosis that has been reported following clozapine therapy. (See Cautions: Other Nervous System Effects.)

EEG Effects Clozapine may produce dose-related changes in the EEG, including increased discharge patterns similar to those associated with seizure disorders, and may lower the seizure threshold; seizures have occurred in patients receiving the drug, particularly with high dosages (greater than 600 mg daily), rapid dosage increases, and/or in the presence of high plasma concentrations. (See Seizures in Cautions: Nervous System Effects.) Some EEG changes associated with clozapine administration are atypical of those generally seen with other antipsychotic agents, resembling more closely those produced by antidepressants. Like other drugs with antipsychotic activity, clozapine increases beta-, delta-, and theta-band amplitudes and slows dominant alpha frequencies in clinical EEG studies. However, in patients with severe, treatment-resistant schizophrenia, increases in delta and theta band frequencies are more pronounced with clozapine than with haloperidol or chlorpromazine therapy, a

finding that appears to parallel the drugs' relative antiserotonergic, antihistaminic, and anticholinergic activities. Enhanced EEG synchronization, paroxysmal sharp-wave activity, and spike and wave complexes also may develop during clozapine therapy. Clozapine-induced EEG changes generally appear soon after initiation of the drug and return to baseline upon cessation of therapy. In one study, the EEG showed slight general changes or slight diffuse slowing in 75% of patients receiving clozapine; in another study, clozapine caused marked EEG changes, including a slowing of basal activity, in 5% of patients.

Effects on Sleep Clozapine causes a shift in the sleep-wake pattern toward dozing in animals, with marked reductions in both slow-wave and paradoxical sleep times. However, tolerance to the drug's sedative effect usually occurs, although slowly in some patients, during continuous administration of clozapine. In a controlled study of short-term (3-day) administration in healthy young men, clozapine in dosages of 25 mg nightly substantially increased total sleep time on the first night of administration, but the duration of sleep returned to baseline by the third night. Clozapine did not substantially affect the time spent in stage 1, 2, 3, or slow-wave sleep, nor did it affect latency to the rapid eye movement (REM) period or the percentage of time spent in REM sleep. However, the percentage of time spent in stage 4 sleep was reduced substantially on the second and third nights of drug administration, while a variety of REM indices were increased on the third night of the study.

In a few patients receiving clozapine dosages of 150–800 mg daily, REM sleep increased to 85–100% of total sleep time after several days of drug therapy, with the onset of REM sleep occurring almost immediately after patients fell asleep. Intensification of dream activity also has been reported during clozapine therapy. Some clinicians have suggested that a correlation may exist between increases in body temperature and REM sleep and clozapine-induced improvement in psychosis. Cataplexy has been reported in some patients receiving clozapine.

■ **Neuroendocrine Effects** In contrast to typical antipsychotic drugs, clozapine therapy in usual dosages generally produces little or no elevation of prolactin concentration in humans. Administration of clozapine to rats has produced a transient, dose-related increase in prolactin concentrations that is of much shorter duration than that caused by other antipsychotic agents. Prolactin normally is inhibited by dopamine released from tuberoinfundibular (TIDA) neurons into the pituitary portal circulation. In rats, clozapine acutely increases the activity of TIDA neurons, which inhibit the release of prolactin; activation of TIDA neurons may be mediated by an enhanced release of neurotensin. Clozapine's effect on prolactin appears to be transient, possibly because the drug appears to dissociate from dopamine receptors more rapidly than typical antipsychotic agents and is therefore eliminated from the brain more rapidly.

Clozapine has an effect on corticotropin (ACTH) and corticosterone, possibly through its effects on dopamine metabolism in the hypothalamus. Short-term administration of clozapine (cumulative dose: 200 mg) to a few patients with schizophrenia resulted in marked inhibition of apomorphine-induced somatotropin (growth hormone) response, suggesting that clozapine may block the dopamine receptors responsible for eliciting this response. In contrast to typical antipsychotic agents, clozapine decreases or has no effect on basal cortisol levels. Clozapine markedly increases corticosterone concentrations in a dose-dependent fashion; other antipsychotic agents appear to increase corticosterone concentrations only at doses producing substantial D_2-receptor blockade. Clozapine-induced stimulation of corticosterone secretion may result from stimulation, rather than blockade, of dopamine receptors, but the exact mechanism has not been fully elucidated.

■ **Other Effects** Clozapine produced a dose-dependent delay in initiation of copulation in male rats, which may be related to blockade of mesolimbic dopamine receptors; however, the drug had no effect on copulatory behavior once the behavior had started. Fertility in male and female rats reportedly is not adversely affected by clozapine. (See Cautions: Pregnancy, Fertility, and Lactation.)

In animals, even small oral doses of clozapine cause ptosis, relaxation, and a reduction in spontaneous activity, effects that are consistent with the drug's sedative activity. Inhibition of locomotor activity induced by clozapine diminishes with repeated administration. With increasing doses of the drug, reactions to acoustic and tactile stimuli decline, and disturbances in equilibrium have been reported. Clozapine also inhibits isolation-induced aggression in mice at doses lower than those affecting motor function, suggesting a specific antiaggressive effect.

Studies in animals suggest that clozapine has a weak and variable diuretic effect; the clinical importance of this effect has not been established. In both rats and dogs, low doses of clozapine tend to increase the elimination of water and electrolytes, while higher doses are associated with increases in potassium excretion and sodium retention.

Pharmacokinetics

■ **Absorption** Clozapine is rapidly and almost completely absorbed following oral administration. However, because of extensive hepatic first-pass metabolism, only about 27–50% of an orally administered dose reaches systemic circulation unchanged. Some, but not all, evidence suggests that clozapine may exhibit nonlinear, dose-dependent pharmacokinetics, with oral bioavailability being approximately 30% less following a single 75-mg dose than at steady state following multiple dosing. GI absorption appears to occur principally in the small intestine and is approximately 90–95% complete within 3.5 hours after an oral dose. Food does not appear to affect the rate or extent of GI absorption of the drug. The relative oral bioavailability of clozapine has been shown to be equivalent following administration of commercially available 25-mg and 100-mg conventional tablets, conventional tablets and capsules, and conventional and orally disintegrating tablets of the drug in several studies.

Following oral administration of a single 25- or 100-mg oral dose of clozapine as tablets in healthy adults, the drug is detectable in plasma within 25 minutes, and peak plasma clozapine concentrations occur at about 1.5 hours. Peak plasma concentrations may be delayed with higher single doses and with multiple dosing of the drug. In one multiple-dose study, peak plasma clozapine concentrations at steady state averaged 319 ng/mL (range: 102–771 ng/mL) and occurred on average at 2.5 hours (range: 1–6 hours) after a dose with 100 mg twice daily as conventional tablets in healthy adults; minimum plasma concentrations at steady state averaged 122 ng/mL (range: 41–343 ng/mL). Steady-state plasma concentrations ranging from 200–600 ng/mL generally are achieved with oral dosages of 300 mg daily, and steady-state peak plasma concentrations generally occur within 2–4 hours after a dose. Steady-state plasma concentrations of clozapine are achieved after 7–10 days of continuous dosing.

Following multiple-dose administration of clozapine orally disintegrating tablets at a dosage of 100 mg twice daily in adults, peak plasma clozapine concentrations at steady state averaged 413 ng/mL (range: 132–854 ng/mL) and occurred on average at 2.3 hours (range: 1–6 hours). Minimum plasma concentrations at steady state in this study averaged 168 ng/mL (range: 45–574 ng/mL).

Considerable interindividual variation in plasma clozapine concentrations has been observed in patients receiving the drug, and some patients may exhibit either extremely high or extremely low plasma concentrations with a given dosage. Such variability may be particularly likely at relatively high dosages (e.g., 400 mg daily) of the drug. In one study, a sixfold interindividual variation in steady-state plasma clozapine concentration was observed in patients receiving such dosages. In addition, considerable intraindividual variation, particularly from week to week, may occur in some patients. However, substantial intraindividual variations in pharmacokinetic parameters typically are not observed from day to day. Although the interindividual variability in plasma clozapine concentrations is consistent with that reported for other antipsychotic drugs and may be secondary to differences in absorption, distribution, metabolism, or clearance of the drug, further study is needed to clarify whether such variation results principally from variable pharmacokinetics or other variables.

There is some evidence that interindividual differences in pharmacokinetic parameters for clozapine may result, at least in part, from nonlinear, dose-dependent pharmacokinetics of the drug. However, a linear dose-concentration relationship also has been reported. Results of a study in patients with chronic schizophrenia revealed a correlation between oral clozapine dosages of 100–800 mg daily and steady-state plasma concentrations of the drug. In addition, linearly dose-proportional changes in area under the plasma concentration-time curve (AUC) and in peak and trough plasma concentrations have been observed with oral dosages of 37.5, 75, and 150 mg twice daily in other studies.

Smokers appear to achieve plasma clozapine concentrations that are approximately 60–80% of those achieved by nonsmokers following oral administration of the drug, possibly because of alterations in hepatic metabolism and/or GI absorption of the drug caused by nicotine or other substances (e.g., polycyclic aromatic hydrocarbons) present in cigarette smoke. (See Drug Interactions: Smoking.) There also is limited evidence that gender may affect plasma clozapine concentrations, with concentrations being somewhat reduced, perhaps by as much as 20–30%, in males compared with females. In addition, smoking has a greater effect on clozapine plasma concentrations in men than in women, although this difference could result simply from gender differences in smoking behavior. Plasma concentrations may be increased in geriatric individuals compared with relatively young (e.g., 18–35 years old) individuals, possibly secondary to age-related decreases in hepatic elimination of clozapine.

Pharmacologic effects of clozapine (e.g., sedation) reportedly are apparent within 15 minutes and become clinically important within 1–6 hours. The duration of action of clozapine reportedly ranges from 4–12 hours following a single oral dose. In one study in patients with schizophrenia, the sedative effect was apparent within hours of the first dose of the drug and was maximal within 7 days. (See Effects on Sleep under Pharmacology: Nervous System Effects.) However, antipsychotic activity generally is delayed for one to several weeks after initiation of clozapine therapy, and maximal activity may require several months of therapy with the drug.

Correlations between steady-state plasma concentrations of clozapine and therapeutic efficacy have not been established, and some evidence suggests that the degree of clinical improvement is independent of plasma concentrations ranging from 100–800 ng/mL. However, it also has been suggested that serum clozapine concentrations less than 600 ng/mL may be adequate for therapeutic effect in most patients. Results of one study of 29 patients treated with clozapine 400 mg daily for 4 weeks showed that patients were most likely to respond to therapy when their plasma clozapine concentrations were at least 350 ng/mL and/or when plasma concentrations of clozapine plus norclozapine (an active metabolite) totaled at least 450 ng/mL. Further study is needed to determine whether nonresponding patients with plasma clozapine concentrations less than 350 ng/mL will benefit from increasing their dosage in an attempt to achieve higher concentrations.

Although a relationship between clozapine plasma concentrations and the risk of seizures has been suggested (see Seizures under Cautions: Nervous

System Effects), most clinicians believe that a relationship between plasma concentrations of the drug and the risk of adverse effects has not been established.

■ **Distribution** Distribution of clozapine into human body tissues is rapid and extensive; distribution of metabolites of the drug also appears to be extensive. In mice and rats, clozapine distributes principally into the lung, spleen, liver, kidney, gallbladder, and brain, achieving concentrations in these tissues up to 50 times those in blood. At 8 hours after IV injection, clozapine was still detectable in these organs but not in blood. There is limited evidence in animals that clozapine and its metabolites may be preferentially retained in the lungs by an energy-dependent, carrier-mediated process and by cellular binding. Evidence in animals also suggests that competition between clozapine and other drugs (e.g., chlorpromazine, imipramine, certain tetracycline antibiotics) for pulmonary binding sites may potentially affect plasma and tissue concentrations of clozapine, but the clinical importance, if any, of such an effect has not been established.

The volume of distribution of clozapine has been reported to be approximately 4.65 L/kg. In one study, the volume of distribution at steady state averaged 1.6 L/kg (range: 0.4–3.6 L/kg) in schizophrenic patients. Because the volume of distribution of clozapine is smaller than that of other antipsychotic agents, it has been suggested that clozapine is less sequestered in tissues than the other drugs. Clozapine is approximately 97% bound to serum proteins.

Results of receptor-binding studies in monkeys indicate that clozapine rapidly crosses the blood-brain barrier following IV injection. The highest brain uptake of the drug was in the striatum in these animals; lesser concentrations were achieved in the thalamus and mesencephalon, although they exceeded those in the cerebellum. The pharmacokinetic characteristics of the drug in the CNS paralleled those in plasma in these monkeys, with an elimination half-life from CNS of about 5 hours. Evidence from other animal studies indicates that CNS concentrations of the drug exceed those in blood. Distribution of the drug into the CNS in humans has not been characterized.

Clozapine reportedly is present in low concentrations in the placenta in animals; information on placental transfer of the drug in humans currently is unavailable. Results of animal studies indicate that clozapine distributes into milk. (See Cautions: Pregnancy, Fertility, and Lactation.)

■ **Elimination** The decline of plasma clozapine concentrations in humans is biphasic. The elimination half-life of clozapine following a single 75-mg oral dose reportedly averages 8 hours (range: 4–12 hours); that after a 100-mg oral dose appears to be similar. The elimination half-life of clozapine at steady state following administration of 100 mg twice daily reportedly averages 12 hours (range: 4–66 hours). The rapid elimination phase may represent redistribution and is followed by a slower apparent mean terminal elimination half-life of 10.3–38 hours. Although a study comparing single and multiple dosing of clozapine demonstrated an increase in elimination half-life with multiple dosing, other evidence suggests this finding is not attributable to concentration-dependent pharmacokinetics.

Clozapine is metabolized in the liver prior to excretion. Clozapine may undergo *N*-demethylation, *N*-oxidation, 3′-carbon oxidation, epoxidation of the chlorine-containing aromatic ring, substitution of chlorine by hydroxyl or thiomethyl groups, and sulfur oxidation. A glucuronide metabolite, tentatively identified as a quaternary ammonium *N*-glucuronide of clozapine, also has been identified. Metabolism of clozapine may occur by one or more of these routes.

The rate of formation and biologic activity of clozapine metabolites have not been fully elucidated. The desmethyl metabolite of clozapine (norclozapine) has limited activity while the hydroxylated and *N*-oxide derivatives are inactive. The *N*-oxide and desmethyl derivatives are found in urine and plasma of humans in a proportion of 2:1.

Approximately 32% of a single oral dose of clozapine is found in plasma as the parent compound after 3 hours, 20% in 8 hours, and 10% up to 48 hours following the dose. Only limited amounts (approximately 2–5%) of unchanged drug are detected in urine and feces. Approximately 50% of an administered dose is excreted in urine and 30% in feces; maximum fecal excretion has been estimated at 38%. Approximately 46% of an oral dose of clozapine is excreted in urine within 120 hours.

Total plasma and blood clearance of clozapine reportedly average 217 and 250 mL/minute, respectively, but show considerable interindividual variation.

Chemistry and Stability

■ **Chemistry** Clozapine is a dibenzodiazepine-derivative antipsychotic agent. The drug is a piperazine-substituted tricyclic antipsychotic agent that is structurally similar to loxapine but that differs pharmacologically from this and other currently available antipsychotic agents (e.g., phenothiazines, butyrophenones). Because of these pharmacologic differences, clozapine is considered an atypical or second-generation antipsychotic agent.

While the structure-activity relationships of phenothiazine antipsychotic agents have been well described, these relationships for heterocyclic antipsychotic agents, including clozapine, have not been as fully characterized. Generally, the unsubstituted benzene ring seems to be important for interactions at dopamine receptors, while the chloro-substituted benzene ring seems more important for action at muscarinic receptors. In addition, an open carbon side chain replacing the piperazine moiety of clozapine generally leads to loss of activity.

Clozapine differs structurally from most currently available antipsychotic agents by the presence of a seven- rather than a six-membered central ring and the spatial relationship between the piperazine moiety and the chloro-substituted benzene ring. The core tricyclic ring system of clozapine is nonplanar and allows the piperazine moiety limited freedom of rotation.

Clozapine differs structurally from loxapine by the presence of a diazepine rather than an oxazepine central ring in the tricyclic nucleus and by the presence of a chlorine atom at position 8 rather than 2 of the tricyclic nucleus. The presence of a chlorine atom at position 8 of the tricyclic nucleus of clozapine appears to be associated with its distinct pharmacologic profile and may be responsible for the drug's antimuscarinic activity.

Clozapine occurs as a yellow, crystalline powder and is very slightly soluble in water.

■ **Stability** Commercially available conventional clozapine tablets should be stored in tight containers at a temperature not exceeding 30°C. Clozapine orally disintegrating tablets should be stored in their original sealed blister at a controlled room temperature of 25°C, but may be exposed to temperatures ranging from 15–30°C. The orally disintegrating tablets should be protected from moisture.

Preparations

Clozapine is available only through distribution systems that ensure baseline and periodic testing of white blood cell counts and absolute neutrophil counts as a condition of provision of the patient's next supply of drug. The individual manufacturers should be contacted for additional information on current mechanisms for obtaining the drug.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Olanzapine

■ Olanzapine is considered an atypical or second-generation antipsychotic agent.

Uses

Olanzapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). In addition, olanzapine is used alone or in conjunction with lithium or divalproex sodium for the management of acute mixed or manic episodes associated with bipolar I disorder; the drug also is used for longer-term maintenance monotherapy in patients with this disorder. Olanzapine also is used for the management of acute agitation in patients with bipolar disorder or schizophrenia.

■ **Psychotic Disorders** Olanzapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia Olanzapine is used orally for the management of schizophrenia. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation; while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and

Methylphenidate Hydrochloride

Methylphenidylacetate Hydrochloride

■ Methylphenidate is a piperidine-derivative CNS stimulant that has pharmacologic actions that are qualitatively similar to those of amphetamines.

Uses

Methylphenidate is used alone or combined with behavioral treatment as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD). Methylphenidate also is used in the symptomatic treatment of narcolepsy.

■ **Attention Deficit Hyperactivity Disorder** Methylphenidate is used alone or combined with behavioral treatment as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in carefully selected children 6 years of age and older, adolescents, and adults. Although long thought of as a childhood disorder, ADHD is now known to persist into adolescence and/or adulthood in some patients, and adults are increasingly being treated for ADHD. Adults maintaining only some of the manifestations of ADHD are considered by DSM-IV to have ADHD in partial remission. ADHD in adults also has been referred to as simply attention deficit disorder (ADD). Most evidence and experience on the treatment of ADHD has been in children. Almost all studies comparing behavioral therapy versus stimulants alone for ADHD have shown a much stronger therapeutic effect from stimulants than from behavioral therapy.

Diagnostic Considerations ADHD is one of the most commonly diagnosed neurobehavioral disorders of childhood, generally estimated as occurring in 3–12% of US school-age children, although wider ranges of prevalence have been reported. Within this range, reported prevalence rates generally are at the higher end for community samples versus school samples. ADHD also is one of the most prevalent chronic health conditions in school-aged children. Although ADHD has been reported more frequently in boys than in girls (ratio of boys versus girls varies between 3:1 to 9:1), this difference may be artifactual and decrease with age, being skewed in part to boys because of referral bias related to disruptive behavior since boys generally exhibit more hyperactive/impulsive symptoms and more conduct and oppositional symptoms than girls. In addition, when DSM-IV rather than earlier criteria are used, more females have been diagnosed with the predominantly inattentive type.

The diagnosis of ADHD should be made using well-tested diagnostic interview methods; neuropsychologic and/or biologic tests are not recommended for routine clinical use, although they may be useful to researchers investigating links between symptoms and underlying attentional processes and brain functions. To help ensure an accurate diagnosis and decrease the variation in how the diagnosis is made, clinicians should employ DSM-IV criteria in the context of their clinical assessment to diagnose ADHD. However, given the lack of methods to confirm the diagnosis of ADHD through other means, clinicians must recognize the limitations of the DSM-IV definitions (e.g., most of the development and testing of DSM-IV occurred in children evaluated in psychiatric settings, there are no clear empiric data supporting the number of items required for the diagnosis, current criteria do not take into account gender differences nor developmental differences in behavior, behavioral characteristics remain subjective and may be interpreted differently). According to DSM-IV criteria, there are 3 subtypes of ADHD: the principally inattentive type (ADHD/I), the principally hyperactive-impulsive type (ADHD/HI), and the combined inattentive and hyperactive-impulsive type (ADHD/C).

There currently are *no* data establishing that ADHD results from brain malfunction. ADHD is a clinical diagnosis; while the diagnosis can be made reliably using interview methods, there currently is no independent valid test for ADHD nor have laboratory tests, physical examination findings, or general medical conditions been established as aiding in the clinical assessment of this disorder. Diagnostic methods employed in the clinical setting have been variable, and the frequency of diagnosis of ADHD varies widely among type of practitioner (primary care and developmental pediatricians, family physicians, child neurologists, psychologists, and psychiatrists). Pediatricians, family physicians, and psychiatrists tend to rely on parent rather than teacher input, and there is a general disconnect between developmental or educational (school-based) assessments and health-related (medical practice-based) services, including poor communication between diagnosticians and those who implement and monitor treatment in schools, and follow-up may be inadequate and fragmented. School-based clinics with a team approach that includes parents, teachers, school psychologists, and other mental health specialists may improve barriers to appropriate identification, evaluation, and intervention as well as access to assessment and treatment. Current formal diagnostic criteria for ADHD were designed principally for diagnosing this disorder in young children. However, the American Psychiatric Association (APA) and others (e.g., American Academy of Child and Adolescent Psychiatry [AACAP]) have developed diagnostic criteria (e.g., DSM-IV) for ADHD to ages extending through adulthood.

ADHD usually is characterized by developmentally inappropriate symptoms (e.g., moderate to severe distractibility, short attention span, hyperactivity, emotional lability, impulsivity, carelessness, accident-proneness, irresponsibility, failure to complete tasks). The essential feature of ADHD is a persistent pattern of inattention and/or hyperactivity/impulsivity that is more frequent and severe than is observed in individuals with a comparable developmental level, and core symptoms include developmentally inappropriate levels of attention and concentration, activity, distractability, and impulsivity. Some hyperactive/impulsive or inattentive symptoms are present before 7 years of age, although many individuals are diagnosed after the symptoms have been present for many years. In most cases, ADHD becomes apparent (and thus comes to medical attention) during the first few years of grammar (grade) school. Some impairment from symptoms is present in at least 2 settings (e.g., at home, school, or work), and there is clear evidence of interference with developmentally appropriate social, academic, and/or occupational functioning. The final diagnosis of this disorder should not be made if these symptoms are of only comparatively recent origin. Nonlocalizing (soft) neurologic signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of CNS dysfunction may or may not be warranted.

Children with ADHD usually exhibit pronounced difficulties and impairment resulting from the disorder across multiple settings (at school, at home, with peers) as well as resultant long-term adverse effects on later academic, vocational, social-emotional, and psychiatric outcomes. Such children exhibit higher accident rates, and later in life, those with ADHD that is combined with conduct disorders exhibit drug abuse, antisocial behavior, and accidents of all sorts; for many individuals, the long-term effects of ADHD continue into adulthood. Individuals with a history of ADHD consume a disproportionate share of resources and attention from health-care services, the criminal justice system, schools, and other social services, and ADHD, often combined with coexisting conduct disorders, contributes to societal problems including violent crime and teenage pregnancy. Parents of children with ADHD, as with other behavioral disorders and chronic diseases, experience increased levels of parental frustration, marital discord, divorce, and costs for medical care that may not be covered by health insurance. Up to 80% of diagnosed hyperactive children continue to exhibit features of ADHD into adolescence and up to 65% into adulthood, and most experts consider it a chronic disorder that often seems to require ongoing treatment. As a result, ADHD represents a major public health problem with profound impact on individuals, families, schools, and society; however, because there currently are no established means for preventing this disorder, current efforts must be aimed at effectively identifying, diagnosing, and treating ADHD. Comorbid conditions are present in up to two-thirds of clinically referred children with ADHD, including high rates for oppositional defiant disorder, conduct disorder, mood disorders (e.g., depression), and anxiety disorders. Tourette's syndrome and chronic tic disorder also often are present, and speech and language delays are common.

Although some patients continue to experience the full range of ADHD symptoms into adulthood, the occurrence of adult-onset ADHD is unlikely; however, unrecognized cases of ADHD may not be diagnosed until adulthood. A clinical diagnosis of ADHD in adults, according to DSM-IV criteria, requires evidence of symptom onset before 7 years of age, persisting from childhood until the time of evaluation, and with distress and/or impairment in functioning occurring in more than one setting (e.g., home, work). Some symptoms of disinhibition may present differently in adults than children; the physical symptoms of hyperactivity in children may be replaced in adults with fidgetiness or an inner feeling of restlessness, difficulty relaxing, and a feeling of being chronically "on edge". The DMS-IV criteria also state that a diagnosis of ADHD in partial remission may be used for adults who no longer meet the full range of diagnostic criteria that was present in childhood, but still retain some of the manifestations that cause functional impairment. Confirmation of ADHD in previously undiagnosed adults may present challenges such as difficulty in obtaining a longitudinal history, poor insight and underestimation of the severity of symptoms and resulting impairment, and differentiation from other psychiatric conditions (e.g., bipolar disorder, depression, axis II personality disorders, learning disabilities, narcolepsy, undiagnosed borderline intellectual functioning). Rating scales such as the Wender Utah Rating Scale, Brown Attention-Deficit Disorder Scale for Adults, and the Conners Adult ADHD Rating Scale may be useful adjuncts to clinical assessment in confirming the diagnosis of ADHD in adults.

Therapeutic Considerations **Considerations In Choosing a Therapy.** The choice of therapeutic intervention(s) for ADHD will depend on comorbid conditions, specific target symptoms, and the strengths and weaknesses of the patient, family, school, and community. Parents, school personnel, and patients should be included in discussions of treatment options. A wide variety of treatments have been employed for the management of ADHD, including drug therapy with amphetamines and similar stimulants (e.g., methylphenidate, pemoline [no longer commercially available in the US]), psychotropic drugs (e.g., antidepressants such as desipramine or imipramine), and other drugs (e.g., atomoxetine, clonidine); psychosocial treatment; dietary management; herbal and homeopathic treatments; biofeedback; meditation; and perceptual stimulation/training. Drug therapy and psychosocial interventions have been the focus of research to date, and efficacy studies have focused principally on the combined-type of ADHD; meeting criteria for inattention and hyperactivity/impulsivity; most randomized trials have been of short duration (usually not exceeding 3 months), although a large, multicenter study with a treatment duration of 14 months recently was reported. Current evidence from these studies supports the efficacy of stimulants and psychosocial treatment; however, there are no well-designed, long-term studies employing these treatments beyond 14 months nor is there information on long-term outcomes of drug therapy on educational and occupational achievements, involvement with police, or other areas of social functioning. Results of 3 double-blind clinical studies in 416 children 6–

12 years old with ADHD indicate that therapy with methylphenidate hydrochloride extended-release trilayer core tablets (Concerta®) was more effective than placebo in decreasing hyperactive-impulsive or inattentive symptoms based on evaluation by community school teachers using the Inattention/Overactivity with Aggression (IOWA) Conners scale. Stimulant drug therapy generally appears to be more effective than psychosocial therapy overall, including behavioral treatment that includes parent training, intensive child-focused treatment, and school-based interventions.

Drug therapy is not indicated in all children with ADHD, and such therapy should be considered only after a complete evaluation including medical history has been performed. The decision to use stimulants should depend on the age of the child and the physician's assessment of the severity and duration of symptoms and should not depend solely on one or more behavioral characteristics. The decision to initiate drug therapy is based on the diagnostic evidence of ADHD and persistent target symptoms that are sufficiently severe to cause functional impairment at school; functional impairment usually also is evident at home and with peers. The risks of drug therapy must be weighed carefully with the risks of the untreated disorder, and the expected benefits of drug therapy must be weighed relative to other treatment options. Drug therapy should *not* be used as a substitute for appropriate educational curricula, student-to-teacher ratios, or other environmental accommodations. When severe impulsivity, noncompliance, or aggression is present, the need to initiate drug therapy may be more urgent.

Stimulants. Stimulants (e.g., methylphenidate, amphetamines) remain the drugs of choice for the management of ADHD. Methylphenidate is the most extensively studied and frequently prescribed drug for the treatment of ADHD. Few, if any, differences have been found between methylphenidate, dextroamphetamine, or pemoline (no longer commercially available in the US) or various dosage forms (short-, intermediate, or long-acting formulations) of the drugs in short-term clinical studies in children with ADHD, and the choice of stimulant therapy should be individualized. However, because hepatic toxicities have been associated with pemoline, some experts recommended its use *only* in patients who failed to respond to adequate trials of methylphenidate *and* an amphetamine as well as adequate trials of second-line therapies (e.g., tricyclic antidepressants, bupropion). In 2005, the US Food and Drug Administration (FDA) determined that the risk of hepatic toxicity associated with the drug outweighs its benefits.

Short-term and longer-term (up to 14 months' duration) studies have shown unequivocal beneficial effects of the stimulants on the defining core symptoms of ADHD (attention and concentration, activity, distractability, impulsivity) and associated aggressiveness during continued therapy with the drugs. The response rate for any single stimulant drug in ADHD is about 70%, and at least 80% of children will respond to a single stimulant without major adverse effect if therapy is titrated carefully. Children who fail to show positive therapeutic effects or who experience intolerable adverse effects with one stimulant should be tried on an alternative stimulant since most such children will exhibit a positive response to alternative stimulants and current evidence from crossover studies supports the efficacy of different stimulants in the same child; likewise, children who fail an adequate trial of 2 stimulants, should be tried on a third type or formulation of stimulant. Another consideration for trials with alternative stimulants before resorting to a trial with an alternative therapeutic class is the fact that there currently is greater evidence for the safety and efficacy of stimulants in children with ADHD. However, stimulants usually do not normalize the entire spectrum of behavioral problems, and many children effectively treated with these drugs still manifest a higher level of some behavioral problems than children without ADHD or other behavior disturbances. In addition, titration of therapy may result in improvement in one area of functioning while eliciting no or even a detrimental effect in another area. Although stimulants have been shown to remain effective over many years, long-term benefits remain to be established.

Effects on attentional, academic, behavioral, and social domains exhibit substantial interindividual and intraindividual variation, and the principal disappointment with stimulant drug therapy has been the finding that despite improvement in core symptoms of ADHD, there is little consistent improvement in academic or social skills. Stimulants appear to be as effective in patients with ADHD and associated aggression as in those with pure ADHD. It currently is unclear whether patients with comorbid anxiety disorders respond as well to stimulants as other patients with ADHD; however, some evidence suggests that the emphasis for patients with comorbid anxiety should be on increased reliance on psychosocial interventions. For patients whose symptoms are not severe outside the school setting, drug holidays may be attempted for all or part of the summer to assess continuing efficacy and need for such therapy as well as to minimize adverse effects.

Although the abuse potential of stimulants such as amphetamines and methylphenidate is well established, there currently is no evidence that drug abuse is a major problem with properly monitored stimulant therapy for ADHD. In addition, while it has been suggested that the substantial increase in stimulant prescriptions for ADHD in recent years may pose societal risks, the thresbold of drug availability that can lead to oversupply and resultant illicit use is unknown, and there is little evidence that current levels of stimulant production in the US have had a substantial effect on abuse. Drug abuse and cigarette smoking are associated with childhood ADHD, but there has been controversy whether therapy with stimulants increases or decreases the risk of abuse. Some evidence, including a pooled analysis of available prospective and retrospective studies that included information on stimulant use in children, adolescents, and adults with ADHD, indicates that stimulant use does not lead to an increased risk of substance experimentation, use, dependence, or abuse, and effective ADHD stimulant therapy actually may reduce the risk for subsequent drug and alcohol use disorders. Caution in prescribing stimulants may be indicated in patients with comorbid conduct disorder, preexisting dependency, or a chaotic family. If the risk of drug abuse by the patient or their peers or family is considered high, a nonstimulant drug may be preferable to methylphenidate or an amphetamine (e.g., dextroamphetamine).

Multimodal Therapy. Although multimodal therapy, integrating drug therapy with environmental, educational, psychotherapeutic, and school-based approaches, seems intuitively powerful and some studies and clinicians have suggested the superiority of such an approach versus drug therapy or psychosocial interventions, there currently is little evidence from well-designed studies substantiating this assertion, particularly outside a research setting. In addition, data from a large, well-designed study indicates that drug therapy employing systematic intensive monitoring methods over a period of about 1 year is superior to an intensive set of behavioral treatments on core ADHD symptoms; combined behavioral and drug therapy added little benefit overall but did result in greater improvements in social skills and was judged more favorably by parents and teachers. While it remains to be determined, however, whether the addition of behavioral therapy can improve functioning at reduced stimulant dosages, evidence from this study indicates significantly lower total daily dosages of methylphenidate during combined therapy compared with drug therapy alone.

Alternatives to Stimulants. For patients who are intolerant of or unresponsive to stimulants, various other drugs (e.g., tricyclic antidepressants, atomoxetine, bupropion, selective serotonin-reuptake inhibitors, clonidine, guanfacine) have proven useful in clinical practice. However, experience with such alternative drug therapy is far less extensive than with stimulants, and conclusions regarding relative efficacy currently cannot be made.

Most experts recommend use of a tricyclic antidepressant or bupropion for the treatment of ADHD in children who are nonresponsive or partial responders to adequate trials with at least 2 different stimulants. There currently are no data establishing that one of these alternative drugs is more efficacious than the other in the treatment of ADHD. Tricyclic antidepressants generally have been shown to be effective in the management of ADHD in children and adolescents, but are associated with a narrower margin of safety. In addition, although a causal relationship has not been established, several recent cases of sudden death in children receiving desipramine have raised concerns about the use of this tricyclic. (See Cautions: Pediatric Precautions in Desipramine 28:16.04.28.) Therefore, some experts no longer recommend use of desipramine for the treatment of ADHD in children. Tricyclic antidepressants appear to be less effective than stimulants in improving attentional and cognitive symptoms, but may be useful for impulsive or hyperactive behavior. Tricyclic antidepressant therapy may be indicated as second-line therapy in patients who do not respond to stimulants or who develop clinically important depression or otherwise do not tolerate the drugs; these antidepressants also may be useful for patients with tics or Tourette's disorder or in whom these conditions are exacerbated or not adequately controlled during stimulant therapy. Regardless of which tricyclic antidepressant is considered for use in the management of ADHD, the drugs should be used only if clearly indicated and with careful monitoring, including baseline and subsequent determinations of ECG and other parameters.

Atomoxetine, a selective norepinephrine-reuptake inhibitor, is used in the treatment of ADHD in children 6 years of age and older, adolescents, and adults. Efficacy of atomoxetine for this indication was established in short-term controlled clinical studies in children and adolescents 6–18 years of age and in adults who met DSM-IV criteria for ADHD; efficacy also was established in one longer-term (12 months) controlled clinical study in children and adolescents 6–15 years of age. In one of the short-term studies, atomoxetine and methylphenidate produced comparable results in the reduction of ADHD symptoms in children and adolescents; however, further evaluation in placebo-controlled clinical studies are needed to determine comparative efficacy and tolerance of atomoxetine and other therapies in the treatment of ADHD.

Therapeutic Considerations for Patients with Comorbid Conditions. Alternative drug therapies also may be used alone or in combination with stimulants in patients with ADHD and comorbid conditions (e.g., aggression, anxiety, depression, tic disorders) that are unresponsive to stimulants alone. For the management of anxiety or depression in children with ADHD, selective serotonin-reuptake inhibitors (SSRIs) are considered by some experts the drugs of choice usually to be used in combination with a stimulant. In one clinical study, combined use of methylphenidate and fluoxetine in 32 children with ADHD and a comorbid mood or conduct disorder resulted in marked improvement in school grades and behavior as rated by parents, with no serious adverse effects reported. However, some experts recommend a conservative approach to such combined use of these drugs because of suggestions of rare but potentially serious drug interactions between SSRIs and stimulants. (See Drug Interactions: Antidepressants.)

Some experts state that in the absence of contraindications, α-adrenergic agents (e.g., clonidine) are considered the drugs of choice for the treatment of tic disorders in children with ADHD who were intolerant of stimulants. Clonidine's use has been documented principally in children with ADHD and comorbid conditions, especially sleep disturbances. Antipsychotic agents (e.g., haloperidol, pimozide, risperidone) are recommended by some experts as alternative therapies.

For the management of comorbid intermittent explosive disorder in children with ADHD, mood stabilizing agents (e.g., lithium or valproic acid) are recommended as adjuncts to stimulant therapy. Clonidine, an α-adrenergic agonist, also has been used in the management of comorbid aggressive symptoms as an adjunct to methylphenidate therapy; however, this use is controversial and further study is needed to evaluate efficacy of such concomitant therapy and the potential risk of development of serious cardiovascular effects. Although carbamazepine has been widely used for the treatment of aggression in adults, its efficacy in children remains to be established. In one controlled study, use of the drug failed to reduce aggression in children. Further studies are needed to evaluate the relative role of carbamazepine in the treatment of intermittent explosive disorder in children with ADHD. In addition, some experts no longer recommend use of typical antipsychotic (neuroleptic) agents because of the possible risk of withdrawal and tardive dyskinesia. However, use of risperidone (an atypical antipsychotic agent) may be considered in severely aggressive children with ADHD in whom other treatments have failed.

Adolescents and Adults. Stimulants have been used effectively in the management of ADHD in adolescents and adults, but experience is far less extensive than in children and potential age-related differences in response remain to be elucidated. Children and adults appear to share a similar treatment-responsive, underlying disorder. Although reported rates of stimulant efficacy have varied widely in adults, this variation may have resulted from use of inadequate dosages, diagnostic differences, and/or high rates of comorbid disorders. Stimulants should be used cautiously in adults with comorbid substance abuse disorders.

■ **Narcolepsy** Methylphenidate is used in the symptomatic treatment of narcolepsy. Methylphenidate has been used with equivocal results in the treatment of apathetic or withdrawn senile behavior and mild depression, but the drug should not be used in the treatment of endogenous depression or agitated depressive states since anxiety may be aggravated.

Dosage and Administration

■ **Administration** Methylphenidate hydrochloride is administered orally. Methylphenidate is administered percutaneously by topical application of a transdermal system.

Oral Administration To avoid insomnia, the last daily dose of conventional (immediate-release) preparations should be given several hours before retiring.

Methylphenidate hydrochloride chewable tablets should be administered with a full glass (i.e., at least 240 mL [8 ounces]) of water or other fluid to avoid choking. (See Precautions Associated with Specific Methylphenidate Formulations under Cautions: Precautions and Contraindications.)

The extended-release tablets and extended-release trilayer core tablets of methylphenidate hydrochloride should be swallowed intact and should *not* be crushed or chewed. The extended-release capsules (Metadate® CD, Ritalin® LA) may be swallowed intact or the entire contents of a capsule(s) may be sprinkled onto a small amount (e.g., one tablespoonful) of applesauce immediately prior to administration. The manufacturer of Ritalin® LA states that the capsule contents should not be mixed with warm applesauce because the release properties of the formulation could be affected. The sprinkle/applesauce mixture should be taken immediately; the sprinkle/applesauce mixture must not be stored for use at a later time. One manufacturer suggests that the patient should drink fluids immediately after swallowing the intact capsule or sprinkle/applesauce mixture. Subdividing the contents of a capsule is not recommended, and crushing or chewing of the extended-release capsule or the capsule contents should be avoided.

Patients receiving methylphenidate hydrochloride extended-release trilayer core tablets (Concerta®) should be instructed *not* to become concerned if they notice a tablet-like substance in their stools; this is normal since the tablet containing the drug is designed to remain intact and slowly release the drug from a nonabsorbable shell during passage through the GI tract. The manufacturer states that it is possible that the extended-release trilayer core tablets may be visible on abdominal radiographs under certain circumstances, particularly when digital enhancing techniques are utilized.

Transdermal Administration Patients receiving transdermal methylphenidate should be carefully instructed in the proper use and disposal of the transdermal system.

The methylphenidate transdermal system should be applied once daily in the morning, 2 hours before an effect is needed, and should be removed 9 hours after application. The system should be applied immediately after opening the package and removing the protective liner; the system should not be used if the package seal is broken. The adhesive side of the transdermal system should be placed on a clean, dry area of the hip that is not oily, damaged, or irritated; application of the transdermal system to the waistline or to areas under tight clothing should be avoided, since clothing may cause the system to rub off. The system should be pressed firmly in place with the palm of the hand for approximately 30 seconds, making sure that there is good contact with the skin, particularly around the edges of the system. Application sites should be alternated daily (e.g., opposite hip) if possible.

Following proper application of the transdermal system, bathing, swimming, or showering has not been shown to affect adherence to the skin. If a system becomes dislodged during the intended period of use, it should be replaced with a new system applied at a different site, but the total wear time should not exceed 9 hours per day.

After removal, used systems should be folded so that the adhesive side adheres to itself and then should be flushed down the toilet or disposed of in an appropriate lidded container. Any unused systems that are no longer needed should be removed from their packaging, separated from the protective liner, folded so that the adhesive side adheres to itself, and then flushed down the toilet or disposed of in an appropriate lidded container.

The manufacturer encourages parents to record on the administration chart included with each carton the time that each transdermal system was applied and removed. If a system was removed without the parent's or caregiver's knowledge, or if a system is missing from the tray, the parent or caregiver should be encouraged to ask the child when and how the system was removed.

■ **Dosage** Dosage of methylphenidate hydrochloride must be carefully adjusted according to individual requirements and response. The extended-release tablets should not be used for initiating therapy nor until the daily dosage is titrated using the conventional tablets; the extended-release tablets may be used and given at 8-hour intervals when the 8-hour dosage of the extended-release preparation corresponds to the titrated 8-hour dosage of the conventional tablets. Alternatively, dosage may be initiated with the methylphenidate hydrochloride extended-release capsules or the extended-release trilayer core tablets for patients who are not currently taking methylphenidate starting with the lowest daily dose and increasing at approximately weekly intervals.

Patients receiving intermediate- or long-acting preparations also may require supplemental therapy with methylphenidate conventional tablets to increase the efficacy, particularly in the morning, or to extend the duration of therapeutic effects later in the day.

Attention Deficit Hyperactivity Disorder Methylphenidate hydrochloride dosage for the treatment of attention deficit hyperactivity disorder (ADHD) should be individualized based on patient response and tolerance. The first dosage that produces an observable response may not be the optimum dosage to improve function, and titration to higher dosages should continue in an attempt to achieve a better response. Such a strategy may require subsequent lowering of dosage when higher dosages produce adverse effects or no further clinical improvement. The best dosage for a given patient is the one that provides optimum therapeutic effects with minimal adverse effects. Dosing schedules also may vary, although there currently are no consistent controlled studies comparing alternative dosing schedules. Patients who require relief only during school may respond adequately to a 5-day (i.e., school day) regimen while those requiring relief at home and school may need a daily regimen throughout the week.

The optimum duration of treatment with methylphenidate has not been established; however, pharmacologic treatment may be required for extended periods. The long-term usefulness of the drug should be reevaluated periodically in patients receiving methylphenidate for extended periods. In patients who have responded to methylphenidate therapy, the drug should be discontinued periodically to assess the patient's condition; improvement may be maintained temporarily or permanently after the drug is discontinued.

Immediate-release Oral Preparations. As an adjunct in the treatment of ADHD in children 6 years of age and older, the usual initial dosage of methylphenidate hydrochloride as conventional (immediate-release) preparations is 5 mg before breakfast and lunch. Dosage may be increased by 5–10 mg daily at weekly intervals and can be administered in twice- or thrice-daily regimens. Although some clinicians have recommended weight-based dosing in children, dosage of methylphenidate, unlike most drugs, generally can be adjusted without regard to the child's weight. When weight-based dosing was employed, an initial dosage of 0.25 mg/kg daily was used. If adverse effects were not observed, the daily dose could be doubled each week until the optimum dosage of 2 mg/kg daily is reached.

Oral dosage in children generally ranges from 5–20 mg 2 or 3 times daily and should not exceed 60 mg daily. Although dosages for older adolescents and adults are similar to those for children, total daily dosages may be increased up to 65 mg since more doses are required to medicate these patients throughout a longer active day. Some clinicians have employed a regimen that included systematic intensive monitoring (referred to as "medical management") in the treatment of ADHD, and such a regimen was shown to be more effective than less intensively titrated and monitored regimens (referred to as "community management"). In the medical management regimen, methylphenidate dosage was titrated over a 28-day period via daily-switch titration involving 5 randomly ordered repeats each of placebo and 5-, 10-, 15-, or 20-mg (higher for children weighing more than 25 kg) daily dosages; each dose was repeated at breakfast and lunch, with a half dose (rounded to nearest 5 mg) given in the afternoon. Based on clinical assessment of response, a best dose was chosen for initial maintenance. In addition to the systematic dosage titration, patients underwent 30-minute monthly drug therapy assessment visits during maintenance. Pharmacotherapists could increase or decrease therapy during such visits by 10 mg daily. In general, patients received higher than typical dosages of the drug when this titration and monitoring method was employed. Dosage at the end of a 14-month study period averaged 37.7 mg daily administered in 3 unequally divided doses daily as noted above.

Children whose dosage is excessive or who are overly sensitive to the drug may become overfocused or appear dull or overly restricted; a dosage reduction may obviate such effects. Rarely, some children may experience psychotic reactions, mood disturbances, or hallucinations at relatively high dosages. If a beneficial effect is not attained after appropriate dosage adjustment over a one-month period, methylphenidate therapy should be discontinued.

Intermediate-acting Oral Preparations. Methylphenidate hydrochloride extended-release tablets (Metadate® ER, Methylin® ER, Ritalin-SR®) may be used as an adjunct in the treatment of ADHD in children 6 years of age and older in patients whose ADHD symptoms are controlled with conventional methylphenidate hydrochloride tablets. The manufacturers suggest that extended-release methylphenidate hydrochloride tablets can be substituted for the conventional tablets at the nearest equivalent total daily dosage. For example, patients receiving 10 mg of conventional tablets in the morning and at noon can be switched to 20 mg of methylphenidate hydrochloride extended-release tablets administered once daily in the morning. In some patients, supplemental doses of a short-acting (conventional) preparation may be needed. The usual dosage of methylphenidate hydrochloride administered as an intermediate-acting oral preparation is 20–40 mg once daily or 40 mg in the morning and 20 mg in the early afternoon.

Long-acting Oral Preparations. Methylphenidate hydrochloride extended-release capsules (Metadate® CD, Ritalin® LA) also may be used as an adjunct in the treatment of ADHD in children 6 years of age and older. The initial dosage of methylphenidate hydrochloride extended-release capsules is 20 mg once daily in the morning. Alternatively, when a lower initial daily dosage is appropriate, therapy with Ritalin® LA may be initiated at a dosage of 10 mg once daily. The manufacturer states that Metadate® CD extended-release capsules should be administered before breakfast. Dosage of Metadate® CD may be increased by 10–20 mg daily at weekly intervals, until an optimum response is achieved or adverse effects are observed. Dosage of Ritalin® LA may be increased by 10 mg daily at weekly intervals. Dosages of methylphenidate hydrochloride extended-release capsules exceeding 60 mg daily are not recommended.

Alternatively, as an adjunct in the treatment of ADHD, methylphenidate hydrochloride extended-release trilayer core tablets (Concerta®) may be used. The usual initial dosage of the drug as extended-release trilayer core tablets is 18 mg once daily, in the morning. If adequate response does not occur, dosage may be increased at approximately weekly intervals. The maximum dosage of Concerta® recommended by the manufacturer is 54 mg daily for children 6–12 years of age or 72 mg daily (not to exceed 2 mg/kg daily) for adolescents 13–17 years of age; however, some clinicians state that dosage in children 6–12 years of age may be increased to a maximum dosage of 72 mg daily.

Some clinicians state that patients currently receiving methylphenidate hydrochloride conventional tablets may be switched to Metadate® CD extended-release capsules. Patients being transferred from methylphenidate therapy using conventional tablets at a dosage of 10 mg twice daily can be switched to a dosage of 20 mg every morning as Metadate® CD extended-release capsules. Patients receiving methylphenidate hydrochloride therapy using conventional tablets at a dosage of 20 mg twice daily can be switched to a dosage of 40 mg every morning as Metadate® CD extended-release capsules.

The manufacturer of Ritalin® LA extended-release capsules states that patients receiving conventional or extended-release methylphenidate hydrochloride tablets may be switched to Ritalin® LA extended-release capsules. Patients being transferred from methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 5 mg twice daily can be switched to a dosage of 10 mg every morning as Ritalin® LA extended-release capsules. Patients receiving methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 10 mg twice daily or a 20-mg dosage of an extended-release tablet can be switched to a dosage of 20 mg every morning as Ritalin® LA extended-release capsules. Patients being transferred from methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 15 mg twice daily can be switched to a dosage of 30 mg every morning as Ritalin® LA extended-release capsules. Patients receiving methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 20 mg twice daily or a 40-mg dosage of an extended-release tablet can be switched to a dosage of 40 mg every morning as Ritalin® LA extended-release capsules. Patients being transferred from methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 30 mg twice daily or a 60-mg dosage of an extended-release tablet can be switched to a dosage of 60 mg every morning as Ritalin® LA extended-release capsules. For other conventional or extended-release tablet regimens, the nearest daily dosage can be substituted based on clinical judgment.

The manufacturer of Concerta® extended-release methylphenidate hydrochloride trilayer core tablets states that patients receiving conventional methylphenidate hydrochloride tablets may be switched to Concerta® extended-release trilayer core tablets. Patients being transferred from methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 5 mg 2 or 3 times daily can be switched to a dosage of 18 mg every morning as the extended-release trilayer core tablets. Patients receiving methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 10 mg 2 or 3 times daily can be switched to 36 mg every morning of the methylphenidate hydrochloride extended-release trilayer core tablets. Patients receiving methylphenidate hydrochloride therapy using a conventional tablet at a dosage of 15 mg 2 or 3 times daily can be switched to 54 mg every morning as the extended-release trilayer core tablets. The initial dosage of methylphenidate hydrochloride as extended-release trilayer core tablets in patients being switched from conventional tablets should not exceed 54 mg daily. A 27-mg extended-release trilayer core tablet also is available for patients who require a more gradual titration or who can not tolerate a dosage of 36 mg daily. For other conventional or extended-release tablet regimens, the nearest equivalent daily dosage can be substituted based on clinical judgment. Subsequent titration to higher or lower dosages may be necessary and should occur at approximately weekly intervals, guided by the patient's clinical response and tolerance; however, the manufacturer states that daily dosages exceeding 72 mg are not recommended.

In some patients receiving long-acting methylphenidate preparations, supplemental doses of a short-acting (conventional) preparation may be needed.

Transdermal System. Dosage titration, final dosage, and wear time of the transdermal system should be individualized according to the needs and response of the patient.

The recommended initial dosage of methylphenidate in patients who are receiving the transdermal formulation as their initial methylphenidate regimen is 1 system delivering 10 mg/9 hours applied once daily. If adequate response is not achieved, dosage may be increased at weekly intervals by advancing to the next larger dosage system (i.e., a dosage system delivering 15 mg/9 hours applied once daily during week 2, followed by a dosage system delivering 20 mg/9 hours applied once daily during week 3, and then a dosage system delivering 30 mg/9 hours applied once daily during week 4).

Because differences in bioavailability exist between the methylphenidate transdermal system and other methylphenidate formulations, patients being transferred from therapy with other methylphenidate formulations to transdermal therapy with the drug should receive the same initial transdermal dosage and follow the same dosage titration schedule recommended for patients receiving transdermal methylphenidate as their initial methylphenidate regimen.

The methylphenidate transdermal system may be removed earlier than 9 hours if a shorter duration of effect is desired or if late-day adverse effects occur. If aggravation of symptoms or other adverse events occur, the dosage or wear time should be reduced, or, if necessary, the drug should be discontinued.

Narcolepsy In the treatment of narcolepsy, the usual oral adult dosage of methylphenidate hydrochloride is 10 mg 2 or 3 times daily, given 30–45 minutes before meals. Some patients may require 40–60 mg daily; in others, 10–15 mg daily may be adequate.

Cautions

Methylphenidate generally is well tolerated. Common adverse effects of the drug include nervous system (insomnia, delayed sleep onset, headache, nervousness, jitteriness, social withdrawal) and GI (anorexia) effects. Most adverse effects of methylphenidate can be managed successfully by adjustment in dosage and/or schedule. About 15–30% of children with ADHD experience tics while receiving stimulants such as methylphenidate, but such tics usually are transient. About half of children with ADHD have underlying Tourette's syndrome, and the effects of stimulants on tics are unpredictable; the presence or emergence of tics is not an absolute contraindication to stimulant therapy and some evidence indicates that the incidence of tics is not increased with such therapy.

Discontinuance of methylphenidate therapy, because of sadness and an increase in tics, respectively, was required in 0.9% of patients receiving extended-release trilayer core tablets and 1% of patients receiving placebo in a 4-week controlled study in children. In a 2-week controlled study in adolescents, discontinuance of methylphenidate therapy (because of increased mood irritability) was required in 0% of patients receiving extended-release trilayer core tablets and 1.1 % of patients receiving placebo. In uncontrolled clinical trials, adverse effects requiring discontinuance of methylphenidate therapy occurred in 6.7% of patients receiving the extended-release trilayer core tablets. The principal reasons for discontinuance were insomnia in 1.5% of patients, twitching in 1% of patients, and nervousness, emotional lability, abdominal pain, and anorexia each in 0.7% of patients. Discontinuance of methylphenidate therapy also occurred in 2 patients (1%) receiving extended-release capsules (Metadate® CD) in controlled clinical trials, principally because of rash and pruritus in one patient and headache, abdominal pain, and dizziness in the other patient. In addition, discontinuance of methylphenidate therapy because of depression occurred in a child with ADHD (1.5%) receiving extended-release capsules (Ritalin® LA) in a double-blind controlled clinical trial. Discontinuance also occurred in 6 patients (3.7%) receiving the drug in this trial during the initial single-blind titration period; the reasons for discontinuance were anger (2 patients), hypomania, anxiety, depressed mood, fatigue, migraine, and lethargy. In a 7-week controlled trial in children, adverse effects requiring discontinuance of therapy occurred in 7.1% of patients receiving transdermal methylphenidate and 1.2% of those receiving placebo; reasons for discontinuance of transdermal methylphenidate therapy included erythema or other reactions at the application site, confusional state, crying, headache, irritability, tics, viral infection, or infectious mononucleosis.

Loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently in children than in adults receiving methylphenidate.

■ **Nervous System Effects** The most frequent adverse effects of methylphenidate appear to be dose related and include nervousness and insomnia. Insomnia has been reported in 4–5% of children and adolescents with ADHD receiving methylphenidate hydrochloride extended-release trilayer core tablets, in 5% of children with ADHD receiving Metadate® CD extended-release capsules, in about 3% of children with ADHD receiving Ritalin® LA extended-release capsules, and in 13% of children with ADHD receiving the drug as a transdermal system in clinical trials. Nervousness and insomnia usually can be controlled by reducing dosage and not administering the drug in the afternoon or evening. Headache has been reported in 9–14% of children and adolescents with ADHD receiving methylphenidate hydrochloride extended-release trilayer

core tablets and in 12% of children with ADHD receiving extended-release capsules of the drug in clinical trials. Affect lability (including emotionality and emotional sensitivity, instability, and lability) has been reported in 6% of children with ADHD receiving methylphenidate as a transdermal system in clinical trials. Dizziness was reported in 2% of children with ADHD receiving extended-release trilayer core tablets in clinical trials. In 2 uncontrolled studies, the cumulative incidence of new-onset tics in children receiving methylphenidate hydrochloride extended-release trilayer core tablets was reported to be 9% after 27 months of treatment (first study) and 1% after up to 9 months of treatment (second study). Ties were reported in 7% of children with ADHD receiving methylphenidate as a transdermal system in clinical trials.

Toxic psychosis and Tourette's syndrome have been reported rarely in patients receiving methylphenidate. Neuroleptic malignant syndrome (NMS) also has been reported rarely in patients receiving methylphenidate; most of these patients also were receiving other drugs that have been associated with NMS. An NMS-like syndrome developed in one 10-year old boy (who had been receiving methylphenidate for about 18 months) 45 minutes after ingesting the first dose of venlafaxine. It is not known if such a reaction was associated with administration of either drug alone or if it represented a drug interaction between methylphenidate and venlafaxine or, alternatively, if the reaction was of unknown etiology.

Other adverse effects of methylphenidate include akathisia, dyskinesia, drowsiness, and aggressive behavior. Depression, anxiety, abnormal behavior, irritability, and suicidal behavior (including completed suicide) have been reported in patients receiving methylphenidate, but a causal relationship to the drug has not been definitely established.

■ **GI and Growth Effects** Abdominal pain and anorexia have been reported in 7 and 2–4%, respectively, of children and adolescents with ADHD receiving methylphenidate hydrochloride extended-release trilayer core tablets in clinical trials and in 7 and 9%, respectively, of children with ADHD receiving methylphenidate extended-release capsules (Metadate® CD) in clinical trials. Anorexia also has been reported in about 3% of children with ADHD receiving extended-release capsules (Ritalin® LA) and in 5% of children with ADHD receiving methylphenidate as a transdermal system in controlled clinical trials. Although appetite suppression and weight loss are common with stimulant therapy, there is no apparent difference in their occurrence between methylphenidate or amphetamine (e.g., dextroamphetamine) therapy in children. Results of one study suggest that prolonged methylphenidate hydrochloride therapy (30–40 mg daily) may cause suppression of normal weight gain in children. Results of an analysis of weight and height patterns in children 7–13 years of age suggested that treatment with methylphenidate for up to 3 years was associated with a temporary slowing in growth rate (on average, height gain was suppressed by about 2 cm and weight gain was suppressed by 2.7 kg over 3 years), without evidence of growth rebound during this period of development. Published data are inadequate to determine whether long-term use of amphetamines may cause similar suppression of growth; however, it is anticipated that amphetamines, like methylphenidate, also cause temporary growth suppression. Therefore, the manufacturers of stimulant preparations state that growth should be monitored during therapy with stimulants, and children who are not growing or gaining height or weight as expected may require temporary discontinuance of therapy. Although concerns about potential dose-related growth delays in children have been raised, a prospective follow-up study into adulthood found no significant impairment in height achieved. In general, studies of stimulants in children have found little or no decrease in expected height, with any decrease in growth early in treatment being compensated for later on. Although drug holidays during summers have been suggested to minimize weight loss and other potential adverse effects, there currently are no data from controlled studies establishing whether such holidays are beneficial or associated with risks.

Vomiting was reported in 3–4% and diarrhea was reported in 2% of children and adolescents with ADHD receiving methylphenidate hydrochloride extended-release trilayer core tablets in clinical trials. Nausea and vomiting were reported in 12 and 10%, respectively, of children with ADHD receiving methylphenidate as a transdermal system in clinical trials. Other adverse GI effects of methylphenidate include weight loss during prolonged therapy and dryness of the throat.

■ **Hepatic Effects** Abnormal liver function, ranging from serum aminotransferase (transaminase) elevations to hepatic coma, has been reported in patients receiving methylphenidate, although a definite causal relationship has not been established. Hepatotoxicity was associated with methylphenidate therapy in at least one patient.

■ **Dermatologic and Sensitivity Reactions** Hypersensitivity reactions including rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathologic findings of necrotizing vasculitis, and thrombocytopenic purpura may occur in patients receiving methylphenidate. Stevens-Johnson syndrome has been reported rarely. Fixed drug eruption has been reported in patients receiving methylphenidate, although a definite causal relationship has not been established. Erythema occurs in a majority of patients receiving methylphenidate as the transdermal system but generally causes minimal or no discomfort.

In a study evaluating the potential for methylphenidate transdermal system to cause contact sensitization, continuous exposure of the same skin site to transdermal methylphenidate for 3 weeks resulted in contact sensitization; contact sensitization was confirmed by rechallenge in some individuals. Contact sensitization has not been reported in patients who used the transdermal system as prescribed (i.e., alternating application sites on the hip). However, because sensitization was not specifically assessed in efficacy studies, the incidence of contact sensitization associated with appropriate use of the transdermal system is currently not known. (See Precautions Associated with Specific Methylphenidate Formulations under Cautions: Precautions and Contraindications.)

■ **Hematologic Effects** Thrombocytopenia and/or easy bruisability, epistaxis, and gingival bleeding; leukopenia; anemia; and eosinophilia have been reported rarely in patients receiving methylphenidate, but a causal relationship to the drug has not been definitely established. (See Other Precautions and Contraindications under Cautions: Precautions and Contraindications.)

■ **Cardiovascular Effects** Sudden death, stroke, myocardial infarction, angina, tachycardia, cardiac arrhythmias, palpitation, and increase or decrease in blood pressure and pulse rate may occur in patients receiving stimulants, including methylphenidate. (See Cardiovascular Precautions under Cautions: Precautions and Contraindications.) Isolated cases of cerebral arteritis and/or occlusion have been reported in patients receiving methylphenidate. Cardiac arrest, Raynaud's phenomenon, peripheral coldness, and reversible ischemic neurologic deficit have been reported in patients receiving methylphenidate, although a definite causal relationship has not been established.

■ **Ocular Effects** Blurred vision and difficulty with accommodation have been reported in patients receiving methylphenidate.

■ **Respiratory Effects** Upper respiratory tract infection, increased cough, pharyngitis, sinusitis, and rhinitis were reported in 8, 4, 2–4, 3, and 3%, respectively, of children and adolescents receiving methylphenidate hydrochloride extended-release trilayer core tablets in clinical trials. Nasal congestion and nasopharyngitis were reported in 6 and 5%, respectively, of children receiving methylphenidate as a transdermal system in clinical trials.

■ **Other Adverse Effects** Pulmonary talc granulomata, superficial abscesses, other foreign body reactions, and eosinophilia have been reported in drug abusers who have dissolved methylphenidate hydrochloride tablets in water and injected the resulting solution.

Scalp hair loss has been reported rarely in patients receiving methylphenidate, but a causal relationship to the drug has not been definitely established.

Dysmenorrhea has been reported in adolescents receiving methylphenidate hydrochloride extended-release trilayer core tablets.

■ **Precautions and Contraindications** ***Psychiatric Precautions*** Aggressive behavior and hostility frequently are observed in children and adolescents with ADHD and have been reported in patients receiving drug therapy for the disorder. Although a causal relationship to stimulants has not been established, patients beginning treatment for ADHD should be monitored for the onset or worsening of aggressive behavior or hostility.

Psychotic or manic symptoms (e.g., hallucinations, delusional thinking, mania) have been reported in children and adolescents without prior history of psychotic illness or mania who received usual dosages of stimulants. In a pooled analysis of multiple short-term, placebo-controlled studies, such symptoms occurred in about 0.1% of patients receiving usual dosages of stimulants (i.e., methylphenidate, amphetamine) compared with 0% of those receiving placebo. If psychotic or manic symptoms occur during stimulant therapy, a causal relationship to stimulants should be considered, and discontinuance of therapy may be appropriate.

Stimulants should be used with caution in the management of ADHD in patients with comorbid bipolar disorder because of the potential for precipitation of mixed or manic episodes in such patients. Prior to initiating stimulant therapy, patients with ADHD and comorbid depressive symptoms should be carefully screened to determine if they are at risk for bipolar disorder; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, or depression).

Stimulants may exacerbate symptoms of behavior disturbance and thought disorder in patients with a preexisting psychotic disorder.

Each time methylphenidate is dispensed, a medication guide should be provided to the patient or caregiver, alerting them to the risks associated with stimulant therapy (e.g., adverse psychiatric effects, possible cardiovascular risks) and advising them of necessary precautions. (See Other Precautions and Contraindications under Cautions: Precautions and Contraindications.) Patients or caregivers should be instructed to inform clinicians of preexisting illnesses or conditions, including suicidal ideation or behaviors of mental or psychiatric disorders. They also should be instructed to inform clinicians immediately if adverse psychiatric effects (e.g., hallucinations, delusional thinking, mania) occur during stimulant therapy.

Cardiovascular Precautions Stimulants, including methylphenidate, cause modest increases in average blood pressure (i.e., by about 2–4 mm Hg) and heart rate (i.e., by about 3–6 beats/minute); larger increases may occur in some patients. Although modest increases would not be expected to have short-term sequelae, all patients should be monitored for larger changes in blood pressure and heart rate. Caution is advised in patients with underlying medical conditions that might be affected by increases in blood pressure or heart rate (e.g., hypertension, heart failure, recent myocardial infarction, ventricular arrhythmia).

Although a causal relationship to stimulants has not been established, sudden unexplained death, stroke, and myocardial infarction have been reported in adults receiving usual dosages of stimulants for the treatment of ADHD.

Sudden unexplained death also has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of CNS stimulants. Results of one retrospective, case-control epidemiologic study showed that there may be an association between use of stimulant medications (e.g., methylphenidate) and sudden unexplained death in healthy children and adolescents. (See Cautions: Pediatric Precautions.) Given the study limitations, the US Food and Drug Administration (FDA) is unable to conclude that these data affect the overall risk and benefit profile of stimulant medications used to treat ADHD in children and adolescents. Amphetamines or other stimulants should not be discontinued by parents of children or patients receiving these medications for ADHD before consulting with their clinician. Because of postmarketing reports and the results of this and other epidemiologic studies, FDA is conducting an ongoing review of the safety of amphetamines and other stimulants to evaluate a possible link between use of these agents and sudden death in children. To determine whether there is a direct causal relationship between use of stimulants and serious adverse cardiovascular events, the Agency for Healthcare Research and Quality (AHRQ) and FDA announced in 2007 that they are collaborating on a large study evaluating clinical data on approximately 500,000 adults and children who received these drugs for management of ADHD during a 7-year period ending in 2005; data collection for the study is expected to be completed in 2009.

Children, adolescents, and adults who are being considered for stimulant therapy should undergo a thorough medical history review (including evaluation for a family history of sudden death or ventricular arrhythmia) and physical examination to detect the presence of cardiac disease, and should receive further cardiac evaluation (e.g., ECG, echocardiogram) if initial findings suggest such disease. Although some serious cardiac conditions are independently associated with an increased risk of sudden death, CNS stimulants generally should *not* be used in children, adolescents, or adults with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious cardiac conditions. Patients who develop exertional chest pain, unexplained syncope, or other manifestations suggestive of cardiac disease during stimulant therapy should undergo prompt cardiac evaluation.

Each time methylphenidate is dispensed, a medication guide should be provided to the patient or caregiver, alerting them to the risks associated with stimulant therapy (e.g., possible cardiovascular risks, adverse psychiatric effects) and advising them of necessary precautions. (See Other Precautions and Contraindications under Cautions: Precautions and Contraindications.) Patients or caregivers should be instructed to inform clinicians of preexisting illnesses or conditions, including cardiac or cardiovascular disease. They also should be instructed to inform clinicians immediately if adverse cardiovascular effects (e.g., chest pain, shortness of breath, fainting) occur during stimulant therapy.

For further information on screening for cardiac conditions, selecting appropriate candidates for stimulant therapy, and monitoring for treatment-emergent cardiac conditions, see Cardiovascular Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.

Precautions Associated with Specific Methylphenidate Formulations Administration of methylphenidate hydrochloride chewable tablets without adequate fluid may cause tablet contents to swell, resulting in blockage of the throat or esophagus and, possibly, choking. Therefore, chewable tablets should be taken with a full glass (i.e., at least 240 mL [8 ounces]) of water or other fluid and should *not* be administered in patients with difficulty swallowing. Patients should be advised to immediately seek medical attention if they experience chest pain, vomiting, or difficulty in swallowing or breathing following administration of the chewable tablets.

Individuals with phenylketonuria (i.e., homozygous genetic deficiency of phenylalanine hydroxylase) and other individuals who must restrict their intake of phenylalanine should be warned that each 2.5-, 5-, or 10-mg chewable tablet contains aspartame (NutraSweet®), which is metabolized in the GI tract to provide about 0.42, 0.84, or 1.68 mg, respectively, of phenylalanine following oral administration.

Methylphenidate hydrochloride extended-release capsules (Metadate® CD) contain sucrose and should not be used in patients with hereditary fructose intolerance, glucose-galactose malabsorption, or sucrase-isomaltase insufficiency.

Methylphenidate hydrochloride extended-release trilayer core tablets generally should not be used in patients with preexisting severe GI narrowing since obstruction may occur.

Patients receiving the methylphenidate transdermal system should be advised to avoid exposing the application site to direct external heat sources (e.g., heating pads, electric blankets, heated water beds) while wearing the transdermal system. Release of methylphenidate from the transdermal system is temperature dependent; release may increase more than twofold when the system is exposed to heat. (See Pharmacokinetics: Absorption.)

Use of the methylphenidate transdermal system may result in contact sensitization. Transdermal methylphenidate should be discontinued if contact sensitization is suspected (i.e., if erythema develops and is accompanied by evidence of a more intense local reaction [e.g., edema, papules, vesicles] that does not improve substantially within 48 hours or that spreads beyond the application site). Diagnosis of allergic contact dermatitis should be confirmed by appropriate diagnostic testing. Patients sensitized from use of the methylphenidate transdermal system may develop systemic sensitization or other systemic reactions if methylphenidate-containing products are administered via other routes (e.g., orally). Manifestations of systemic sensitization may include a flare-up of previous dermatitis or of prior positive patch test sites, or generalized skin eruptions in previously unaffected skin. Other systemic reactions may include headache, fever, malaise, arthralgia, diarrhea, or vomiting. Patients who develop contact sensitization to the methylphenidate transdermal system should be under close medical supervision if oral methylphenidate therapy is initiated. Some patients sensitized to methylphenidate by exposure to the methylphenidate transdermal system may not be able to receive methylphenidate in any form.

Other Precautions and Contraindications The manufacturer's patient information (medication guide) should be provided to the patient or caregiver each time methylphenidate is dispensed, and the clinician should discuss and answer questions about its contents (e.g., benefits and risks of stimulant therapy, appropriate use) as needed. The patient or caregiver also should be instructed to read and understand the contents of the medication guide before initiating therapy and each time the prescription is refilled.

Patients or caregivers should be instructed to inform clinicians of preexisting illnesses or conditions (e.g., cardiac or cardiovascular disease, thyroid disease, glaucoma, suicidal ideation or behaviors, mental or psychiatric disorder, seizures, history of substance abuse).

The manufacturers recommend that laboratory tests, including periodic complete blood cell (with differential) and platelet counts, be performed periodically during prolonged methylphenidate hydrochloride therapy. However, the clinical rationale for this precaution has been questioned by some clinicians since adverse hematologic effects have occurred only rarely in patients receiving methylphenidate and a causal relationship to the drug has not been conclusively established in these cases. Most clinicians consider routine hematologic monitoring unnecessary in the absence of clinical signs (e.g., fever, sore throat, unusual bleeding or bruising) suggestive of possible hematologic toxicity, although some clinicians suggest annual hematologic monitoring in any patient receiving prolonged therapy with the drug. In addition, the American Academy of Pediatrics (AAP) states that routine hematologic, serologic, or ECG monitoring is *not* necessary during methylphenidate therapy.

If paradoxical aggravation of symptoms occurs during methylphenidate therapy, dosage should be reduced or the drug discontinued.

Tolerance and psychological dependence with varying degrees of abnormal behavior have been reported in patients chronically taking large doses of methylphenidate. Frank psychotic episodes including hallucinosis can occur, particularly with parenteral abuse. The possibility of psychological or physical dependence should be considered, particularly when methylphenidate is administered to alcoholics, emotionally unstable patients, or those known to have been addicted to other drugs. The drug should be administered with caution to persons with a history of drug or alcohol dependence since such patients may increase dosage on their own initiative.

Abrupt withdrawal of methylphenidate following prolonged administration may unmask severe depression as well as the effects of chronic overactivity; paranoid and suicidal ideation, dysphoric mood (e.g., depression, irritability, anxiety), fatigue, insomnia or hypersomnia, psychomotor agitation, and disturbed sleep also may occur. Therefore, patients should be carefully supervised during withdrawal of the drug; long-term follow-up may be required since some manifestations (e.g., depression) may persist for prolonged periods.

Visual disturbances (difficulty with accommodation, blurred vision) have been reported in patients receiving stimulants, including methylphenidate.

Methylphenidate should be used with caution in patients with a history of seizures and/or EEG abnormalities. There is some clinical evidence that stimulants, including methylphenidate, may lower the seizure threshold in patients with a history of seizures, in those with prior EEG abnormalities in the absence of seizures, and, very rarely, in those without a history of seizures and no prior evidence of EEG abnormalities. Although safe concomitant use of methylphenidate and anticonvulsants has not been established, studies of methylphenidate use have not shown an increase in seizure frequency or severity when the stimulant was used in patients receiving appropriate anticonvulsant therapy. If seizures occur in patients receiving methylphenidate, the drug should be discontinued.

Therapy with CNS stimulants may be associated with at least a temporary suppression of growth in children. (See Cautions: GI and Growth Effects.)

Methylphenidate is contraindicated in patients with a history of marked anxiety, tension, and agitation, since the drug may aggravate these symptoms. Methylphenidate is also contraindicated in patients with glaucoma, in patients with motor tics or a family history or diagnosis of Tourette's syndrome, and in those known to be hypersensitive to the drug. However, AAP states that the presence of tics before or during medical management of ADHD is *not* an absolute contraindication to stimulant drug use. (See the opening discussion in Cautions.) Methylphenidate also is contraindicated during or within 14 days of administration of monoamine oxidase (MAO) inhibitors since hypertensive crisis could result. (See Drug Interactions: Antidepressants.)

■ **Pediatric Precautions** Although safety and efficacy of methylphenidate in children younger than 6 years of age have not been established, the drug has been used in several controlled clinical studies in preschool-aged children up to 6 years of age. Some studies reported higher rates of adverse effects, particularly with higher dosages, than had previously been reported in children 6 years of age and older and the adverse effects reported in preschool-aged children may be different than those reported in older children with

ADHD. Some of the adverse behavioral effects reported in clinical studies in preschool-aged children receiving methylphenidate also were reported in those receiving placebo; some of these behaviors may actually improve in preschool-aged children receiving methylphenidate therapy. Other issues involved with the use of stimulants in children younger than 6 years of age are the lack of established dosage recommendations for this population. Additional study and experience are required to elucidate further the safety and efficacy of the drug in this age group.

Long-term administration of CNS stimulants has been associated with at least a temporary suppression of normal weight and/or height patterns in children; patients requiring long-term therapy with methylphenidate should be carefully monitored and the drug should be discontinued temporarily in children in whom suppression of normal growth or weight gain is observed. However, AAP states that studies of stimulants in children generally have found little or no decrease in expected height, with any decrease in growth early in treatment being compensated for later on. (See Cautions: GI and Growth Effects.)

Sudden death has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of CNS stimulants. Results of one retrospective, case-control epidemiologic study suggested a possible association between use of stimulant medications and sudden unexplained death in healthy children and adolescents. (See Cardiovascular Precautions under Cautions: Precautions and Contraindications.)

■ **Pregnancy and Lactation** Although there are no adequate and controlled studies to date in humans, methylphenidate hydrochloride has been shown to have teratogenic effects in rabbits when given at dosages 100 and 40 times the recommended human dosage on a mg/kg or mg/m² basis, respectively. Methylphenidate hydrochloride should be used during pregnancy only when the potential benefits justify the possible risks to the fetus.

It is not known whether methylphenidate is distributed into human milk. Because many drugs are distributed into human milk, caution should be exercised if methylphenidate is administered to a nursing woman.

Drug Interactions

■ **Antidepressants** Because monoamine oxidase (MAO) inhibitors potentiate the pressor effects of sympathomimetic drugs, methylphenidate is contraindicated in patients currently receiving, or having recently received (i.e., within 2 weeks), MAO inhibitor therapy. The metabolism of tricyclic antidepressants (e.g., imipramine, clomipramine, desipramine) has been reported to be inhibited when these drugs are used in patients receiving methylphenidate. Some manufacturers state that the metabolism of selective serotonin-reuptake inhibitors (SSRIs) may be inhibited when methylphenidate is used concomitantly. Dosage reduction of tricyclic antidepressants and SSRIs may be required in patients receiving concomitant methylphenidate therapy.

■ **Cardiovascular Agents** Methylphenidate should be used with caution in patients receiving pressor agents. Methylphenidate may antagonize the effects of antihypertensive agents (e.g., guanethidine [no longer commercially available in the US]) or bretylium. Rare cases of serious adverse cardiovascular effects, including death, have occurred in patients receiving methylphenidate and clonidine concomitantly, although due to the presence of possibly confounding risk factors and lack of systematic evaluation, causality has not been established.

■ **Other Drugs** The metabolism of coumarin anticoagulants and anticonvulsants (e.g., phenobarbital, phenytoin, primidone) has been reported to be inhibited when these drugs are administered in patients receiving methylphenidate. Although additional studies did not confirm the reported inhibition of metabolism of anticonvulsants and coumarin anticoagulants, the possibility that methylphenidate may raise the serum concentrations of these drugs to toxic concentrations necessitating a decrease in dosage should be considered. Additionally, metabolism of phenylbutazone (no longer commercially available in the US) has been reported to be inhibited when administered in patients receiving methylphenidate hydrochloride conventional or extended-release tablets. Dosage reduction of coumarin anticoagulants, anticonvulsants, or phenylbutazone may be required in patients receiving concomitant methylphenidate therapy. It may be necessary to monitor plasma drug concentrations (or, in the case of coumarin anticoagulants, prothrombin time [PT]) when methylphenidate is initiated or discontinued.

Studies to evaluate the effects of changes in gastric pH on the absorption of methylphenidate hydrochloride administered as extended-release capsules (Ritalin® LA) have not been performed to date; the manufacturer states that concurrent use of drugs that increase gastric pH (e.g., antacids, H_2-receptor antagonists) could potentially alter the release characteristics of the formulation.

Acute Toxicity

■ **Manifestations** Acute toxicity due to methylphenidate overdosage results in symptoms similar to those of acute amphetamine intoxication and may be manifested by cardiovascular symptoms including flushing, palpitation, hypertension, cardiac arrhythmias, and tachycardia. Mental disturbances such as confusion, delirium, euphoria, hallucinations, and toxic psychosis may also occur. Other symptoms of overdosage include agitation, headache, vomiting, dryness of mucous membranes, mydriasis, hyperpyrexia, sweating, tremors, hyperreflexia, muscle twitching, and seizures which may be followed by coma.

■ **Treatment** In the treatment of methylphenidate overdosage, general physiologic supportive measures, including maintenance of adequate circulation and respiratory exchange should be immediately instituted. The patient should be protected against self-injury and should be isolated to avoid possible external stimuli. In cases of overdosage involving transdermal methylphenidate, all transdermal systems of the drug should be removed immediately and the skin cleansed of any remaining adhesive; the potential for continued absorption of residual drug in the skin following system removal should be considered. If signs and symptoms of acute toxicity are not too severe and the patient is conscious, gastric contents may be evacuated following ingestion of oral dosage forms by induction of emesis or gastric lavage. In patients with severe intoxication, administration of a carefully titrated dose of a short-acting barbiturate may be required before beginning gastric lavage. External cooling procedures may be required for the treatment of hyperpyrexia. Effectiveness of peritoneal dialysis or extracorporeal hemodialysis for the treatment of methylphenidate overdosage has not been established.

Pharmacology

The pharmacologic actions of methylphenidate are qualitatively similar to those of the amphetamines and include CNS and respiratory stimulation and weak sympathomimetic activity. The mechanism of action involved in the central effect of methylphenidate has not been determined. The main sites of CNS action appear to be the cerebral cortex and subcortical structures including the thalamus; stimulation by methylphenidate causes an increase in motor activity, mental alertness, diminished sense of fatigue, brighter spirits, and mild euphoria. Methylphenidate apparently produces an anorexigenic effect. In usual therapeutic oral dosage, methylphenidate exhibits only moderate effects on the peripheral circulatory system.

Pharmacokinetics

■ **Absorption** Methylphenidate hydrochloride appears to be well absorbed from the GI tract; however, oral bioavailability of the drug is low (about 30%; range: 10–52%), which suggests substantial first-pass metabolism. Following oral administration of methylphenidate hydrochloride as conventional tablets, oral solution, or chewable tablets, peak plasma concentrations were attained at approximately 1–2 hours. Methylphenidate hydrochloride oral solution and chewable tablets are bioequivalent to methylphenidate hydrochloride conventional tablets.

Extended-release methylphenidate hydrochloride tablets are absorbed more slowly but to the same extent as the conventional tablets. Following oral administration of methylphenidate hydrochloride extended-release tablets (Methylin® ER, Ritalin-SR®) in children, peak plasma concentrations were attained at 4.7 hours.

After oral administration of methylphenidate hydrochloride 20 or 40 mg as extended-release capsules (Metadate® CD) in children, peak plasma concentrations were attained at 1.5 hours and again at 4.5 hours after a dose. In children, the mean peak plasma concentration and mean area under the plasma concentration-time curve (AUC) for methylphenidate were slightly lower following administration of 20 mg of the drug once daily as Metadate® CD extended-release capsules than following administration of 10 mg twice daily as conventional tablets. In children and adults, the relative bioavailability of Ritalin® LA extended-release capsules administered once daily is comparable to that of the conventional tablets administered twice daily 4 hours apart. The initial rate of absorption of methylphenidate hydrochloride and the time to first and second peak plasma concentrations were similar following administration of 40 mg of the drug once daily as Ritalin® LA extended-release capsules or 20 mg twice daily (given 4 hours apart) as conventional tablets, but greater interindividual variability and a smaller difference between peak and trough plasma concentrations (resulting from a lower second peak concentration and a higher minimum concentration between the 2 peak concentrations) were observed with the extended-release capsules. In adults, the relative bioavailability of the extended-release trilayer core tablets of methylphenidate hydrochloride (Concerta®) administered once daily is comparable to that of the conventional tablets administered 3 times daily. Following oral administration of the extended-release trilayer core tablets of methylphenidate hydrochloride in healthy adults, an initial peak plasma concentration is attained within 1 hour while peak plasma concentrations of about 3.7 ng/mL are achieved within approximately 6–10 hours.

Following application of a single transdermal system (Daytrana®), peak plasma methylphenidate concentrations are attained within 7.5–10.5 hours. Application of the transdermal system to inflamed skin results in shorter time to peak plasma concentration (4 hours) and a threefold increase in peak plasma concentration and AUC compared with application to intact skin. When heat is applied to the transdermal system after application, time to peak plasma concentration occurs 0.5 hour earlier, and median peak plasma concentration and AUC are twofold and 2.5-fold higher, respectively, than those observed following application without heat. Application sites other than the hip can have different absorption characteristics and have not been adequately studied. Some data suggest that transdermal absorption of methylphenidate may be increased with chronic administration.

Effects persist for 3–6 hours after oral administration of conventional tablets, about 3–8 hours after oral administration of certain extended-release tablets (e.g., Metadate® ER, Methylin® ER, Ritalin-SR®), and about 8–12 hours after oral administration of extended-release trilayer core tablets (Concerta®) or extended-release capsules (e.g., Metadate® CD, Ritalin® LA).

Because of substantially greater first-pass metabolism following oral compared with transdermal administration, a lower transdermal dose of methylphenidate may result in greater systemic exposure to *d*-methylphenidate (the more pharmacologically active isomer) than a higher (on a mg/kg basis) oral dose of the drug. Following repeated transdermal administration of methylphenidate, *l*-methylphenidate is systemically available; on average, systemic exposure to *l*-methylphenidate is 27–45% less than exposure to *d*-methylphenidate. Little, if any, *l*-methylphenidate is systemically available following oral administration of the drug.

In adults, administration of methylphenidate hydrochloride 20 mg as an oral solution with a high-fat meal delayed the peak plasma concentration by approximately 1 hour and increased the average peak plasma concentration and AUC for methylphenidate by 13 and 25%, respectively; the magnitude of increase in peak plasma concentration and AUC is similar between methylphenidate hydrochloride oral solution and conventional tablets. Administration of methylphenidate hydrochloride 20 mg as chewable tablets with a high-fat meal in adults delayed the time to peak plasma concentration by approximately 1 hour and increased the AUC by about 20%; the magnitude of food effect is comparable to that observed with conventional tablets. Administration of methylphenidate hydrochloride 40 mg as extended-release capsules (Metadate® CD) with a high-fat meal in adults delayed the first peak plasma concentration by approximately 1 hour and increased the average peak plasma concentration and AUC for methylphenidate by 30 and 17%, respectively. In a single-dose study in healthy adults, administration of Ritalin® LA extended-release capsules with a high-fat breakfast delayed the first and second peak plasma concentrations and decreased the second mean peak plasma concentration by 25% compared with administration in the fasting state. However, the bioavailability of the extended-release capsules (i.e., Metadate® CD, Ritalin® LA) was not affected by opening the capsules and sprinkling the contents onto applesauce.

■ **Distribution** The extent of methylphenidate distribution in humans is unknown.

■ **Elimination** Methylphenidate is metabolized primarily by de-esterification to form α-phenylpiperidine acetic acid (ritalinic acid), which has little or no pharmacologic activity. Some data indicate that clearance of methylphenidate increases with increasing weight, suggesting that patients with higher body weight may have lower exposures to total methylphenidate at similar doses.

Following oral administration of methylphenidate hydrochloride conventional tablets in adults or children, the mean terminal elimination half-life was reported to be 3.5 or 2.5 hours, respectively. The mean terminal elimination half-life following oral administration of methylphenidate hydrochloride as an oral solution in adults is similar to that following administration of conventional tablets. The mean terminal half-life following oral administration of methylphenidate hydrochloride 20 mg as chewable tablets in adults is 3 hours, which is comparable to that following administration of conventional tablets. Following oral administration of methylphenidate hydrochloride conventional (5 mg 3 times daily) or extended-release trilayer core tablets (Concerta®) (18 mg once daily) in adults, the plasma elimination half-life reportedly is 3 or 3.5 hours, respectively. Following oral administration of a single 20-mg dose of methylphenidate hydrochloride as extended-release capsules (Metadate® CD) in adults, the mean terminal half-life of the drug was reported to be 6.8 hours. The mean elimination half-life of methylphenidate following removal of the transdermal system in children 6–12 years was approximately 3–4 hours for *d*-methylphenidate and 1.4–2.9 hours for *l*-methylphenidate.

Following oral administration of 20 mg of radiolabeled methylphenidate hydrochloride as conventional tablets, approximately 50, 80, and 95% of the dose was recovered as metabolites in urine within 6, 24, and 90 hours, respectively.

Chemistry and Stability

■ **Chemistry** Methylphenidate hydrochloride is a piperidine-derivative stimulant. The drug occurs as a fine, white, odorless, crystalline powder and is freely soluble in water and soluble in alcohol. Methylphenidate hydrochloride is commercially available as conventional tablets, chewable tablets, and an oral solution formulated for immediate release of the drug; extended-release tablets (e.g., Metadate® ER, Methylin® ER, Ritalin-SR®) with an intermediate duration of action; and extended-release capsules (e.g., Metadate® CD, Ritalin® LA) and extended-release tablets (e.g., Concerta®) with a longer duration of action. Methylphenidate is commercially available as a transdermal system.

The commercially available methylphenidate hydrochloride extended-release capsules (Metadate® CD) contain 30% of the dose in immediate-release pellets and 70% of the dose in extended-release pellets that slowly release methylphenidate. The commercially available methylphenidate hydrochloride extended-release capsules (Ritalin® LA) contain the drug in equal amounts in immediate- and extended-release pellets.

The commercially available extended-release tablets of methylphenidate hydrochloride (Concerta®) contain the drug in an oral osmotic delivery system formulation. The osmotic delivery system consists of an osmotically active trilayer core (comprised of two layers containing the drug and a push layer containing osmotically active components) surrounded by a semipermeable membrane with an immediate-release drug overcoat and a laser-drilled delivery orifice. When exposed to water in the GI tract, the drug overcoat is solubilized providing an initial dose of methylphenidate; as water enters the formulation, the osmotic layer expands and the drug is pushed out the delivery orifice of the membrane into the GI tract at a controlled rate. The rate of methylphenidate delivery in the GI tract is independent of GI pH or the presence of food in the GI tract. The inert tablet ingredients remain intact and are eliminated in feces.

The commercially available transdermal system of methylphenidate consists of a laminate film backing layer, an adhesive layer containing the drug, and a protective liner attached to the adhesive surface. The methylphenidate dosage delivered is dependent on the size of the transdermal system and the length of time the system is worn.

■ **Stability** Methylphenidate hydrochloride tablets, extended-release tablets, extended-release trilayer core tablets (Concerta®), and extended-release capsules (Metadate® CD, Ritalin® LA) and methylphenidate transdermal systems should be stored at a controlled room temperature of 25°C, but may be exposed to temperatures ranging from 15–30°C. Methylphenidate hydrochloride oral solution and chewable tablets should be stored at 20–25°C.

Preparations

Methylphenidate hydrochloride is subject to control under the Federal Controlled Substances Act of 1970 as a schedule II (C-II) drug.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Methylphenidate

Topical		
Transdermal System	10 mg/9 hours (27.5 mg/12.5 cm²)	**Daytrana®** (C-II), Shire

Modafinil

■ Modafinil is a CNS stimulant that is structurally and pharmacologically distinct from other currently available CNS stimulants.

Uses

Modafinil is used to improve wakefulness in adults with excessive sleepiness associated with narcolepsy, obstructive sleep apnea/hypopnea syndrome (OSAHS), and shift work sleep disorder (SWSD). Careful attention to the diagnosis and treatment of the underlying sleep disorder is essential whenever modafinil is used in patients with these conditions. (See Diagnosis of Sleep Disorders under Warnings/Precautions: General Precautions, in Cautions.)

■ **Narcolepsy** Modafinil is used in the symptomatic treatment of narcolepsy to improve wakefulness in adults with excessive daytime sleepiness (EDS). Narcolepsy is a CNS disorder characterized by somnolence, often accompanied by sudden attacks of weakness (cataplexy) while awake and disrupted nocturnal sleep, and occasionally by hypnagogic hallucinations and/or sleep paralysis before falling asleep or awakening. The disorder involves dysregulation of wakefulness and sleep.

Efficacy of modafinil has been established in the US in 2 double-blind, multicenter, placebo-controlled clinical trials of 9 weeks' duration. In these and other clinical studies, modafinil 200 or 400 mg daily increased daytime wakefulness and alertness and decreased the number of daytime sleep episodes as determined by several objective (e.g., the Multiple Sleep Latency Test [MSLT], the Maintenance of Wakefulness Test [MWT], the Steer Clear Performance Test [SCPT]) and subjective (e.g., the Epworth Sleepiness Scale [ESS]) measures of sleepiness. Patients showed an enhanced ability to remain awake with both dosages relative to placebo at 3, 6, and 9 weeks, and at study end point (last post-baseline assessment while the patient was in the study) and also greater global improvement in overall disease status (measured by the Clinical Global Impression of Change [CGI-C]). However, despite the clinical improvement, mean objective and subjective measures of sleepiness did not completely normalize with modafinil therapy, with a degree of clinically important physiologic sleepiness persisting despite therapy. The percentage of patients exhibiting any degree of improvement in overall disease status on the CGI-C in the two 9-week studies establishing efficacy in the US was 60–72, 58–64, or 37–38% for the 400-mg regimen, 200-mg regimen, or placebo, respectively. The efficacy of the 2 modafinil dosage regimens was not shown to differ significantly in these studies.

Although the long-term efficacy of modafinil has not been established systematically beyond 9 weeks, improvements in overall disease status on the CGI-C and in subjective measures of sleepiness on the ESS were maintained in a 40-week open-label extension of one of the trials. In this open-label extension, the percentage of patients exhibiting improvement on the CGI-C ranged from 84% after 2 weeks of extension therapy to 91% after 40 weeks. The drug also was well tolerated for up to 40 weeks of therapy, with 11% of patients discontinuing modafinil because of adverse effects and 14% because of inadequate therapeutic effect. Although most patients enrolled in the 2 clinical trials establishing efficacy in the US had histories of cataplexy, those requiring anticataplectic therapy generally were excluded from enrollment. Therefore, current evidence of efficacy for modafinil is limited principally to effects on excessive daytime sleepiness. In one study in a limited number of patients, cataplexy was not affected by modafinil therapy.

Modafinil did not affect the initiation, maintenance, quality, or quantity of nighttime sleep and did not affect the ability to voluntarily sleep (nap) during the daytime. Like other CNS stimulants modafinil can alter mood, perception, thinking, and feelings and can cause psychoactive and euphoric effects. However, in clinical trials, there was no clinically important association between modafinil and the incidence of agitation in patients. In animals, modafinil is reinforcing; however, the somatic effects of the drug were comparable to those of caffeine and differed from those of amphetamine. Although there currently does not appear to be evidence of problems with modafinil abuse, caution is recommended in patients with a history of drug or stimulant abuse. Withdrawal of modafinil has not been associated with any manifestations of dependency.

■ **Obstructive Sleep Apnea/Hypopnea Syndrome** Modafinil is used in the symptomatic treatment of OSAHS to improve wakefulness in adults with excessive sleepiness. The drug should be used as an adjunct to standard treatment(s) for the underlying obstruction (e.g., nasal continuous positive airway pressure [CPAP]). If CPAP is considered the treatment of choice for a patient with OSAHS, every effort should be made to optimize CPAP treatment for an adequate period of time prior to initiating modafinil therapy. When modafinil is used adjunctively with CPAP treatment, the encouragement of and periodic assessment of CPAP compliance is necessary.

Efficacy of modafinil in reducing excessive daytime sleepiness in patients with OSAHS was established principally in 2 multicenter, placebo-controlled clinical trials. In both of these studies, enrolled patients met the International Classification of Sleep Disorders (ICSD) criteria for OSAHS, which also are consistent with DSM-IV criteria. These criteria include either excessive sleepiness or insomnia with frequent episodes of impaired breathing during sleep and associated features (e.g., loud snoring, morning headaches, dry mouth upon awakening) or polysomnography demonstrating more than 5 obstructive apneas (each greater than 10 seconds in duration) per hour of sleep and one or more of the following: frequent arousals from sleep associated with the apneas; bradytachycardia; and arterial oxygen desaturation in association with the apneas. In addition, all patients enrolled in these studies had excessive daytime sleepiness as demonstrated by a score of 10 or higher on the Epworth Sleepiness Scale (ESS) despite treatment with CPAP. Evidence that CPAP was effective in reducing the episodes of apnea/hypopnea also was required along with documentation of CPAP use.

In the first multicenter, placebo-controlled study, which was of 12 weeks' duration, patients were randomized to receive modafinil 200 mg daily, modafinil 400 mg daily, or placebo. The majority of patients (80%) in this study were fully compliant with CPAP (defined as CPAP use for more than 4 hours per night on more than 70% of nights); the remainder of patients were partially CPAP compliant (defined as CPAP use for less than 4 hours per night on more than 30% of nights). Efficacy of modafinil was principally evaluated by measurement of sleep latency as assessed by the Maintenance of Wakefulness Test (MWT) and change in the patient's overall disease status as measured by the Clinical Global Impression of Change (CGI-C) at week 12 or at the final visit. The modafinil-treated patients demonstrated a significant improvement in their ability to remain awake as measured by the MWT at the study end point and in their clinical condition as measured by the CGI-C compared with those receiving placebo. The 200- and 400-mg daily doses produced similar clinical efficacy in this study.

In the second multicenter, placebo-controlled study, which was of 4 weeks' duration, patients were randomized to receive either modafinil 400 mg daily or placebo. Documentation of regular CPAP use (for at least 4 hours each night on 70% of nights) was required for all patients. Efficacy in reducing daytime sleepiness was principally assessed by the change from baseline on the ESS at week 4 or the final visit. Patients who received modafinil demonstrated a significant reduction in their ESS score from baseline (mean scores reduced by 4.6) compared with patients receiving placebo (mean scores reduced by 2). In addition, the percentage of patients with normalized daytime sleepiness (ESS score less than 10) was significantly higher for the modafinil group than for those receiving placebo (51 and 27%, respectively). Nighttime sleep as measured by polysomnography was not affected by modafinil administration in these 2 studies.

The manufacturer states that the long-term efficacy (e.g., longer than 12 weeks) of modafinil in OSAHS has not been systematically evaluated in placebo-controlled studies to date. However, a 12-month, noncomparative extension phase of the 12-week, placebo-controlled trial in which patients received modafinil 200, 300, or 400 mg daily demonstrated substantial reductions in ESS scores compared with baseline following 3, 6, 9, and 12 months of therapy. When modafinil is used for extended periods, the need for continued therapy should be reassessed periodically.

■ **Shift Work Sleep Disorder** Modafinil is used in the symptomatic treatment of SWSD to improve wakefulness in adults with excessive sleepiness. Criteria of the International Classification of Sleep Disorders (ICSD-10) for chronic SWSD (which are consistent with DSM-IV criteria for circadian rhythm sleep disorder: shift work type) require a primary complaint of excessive sleepiness or insomnia that is temporally associated with a work period

ommends avoiding concomitant alcohol consumption during desvenlafaxine therapy.

■ **Electroconvulsive Therapy** The risks and/or benefits of combined use of electroconvulsive therapy and desvenlafaxine have not been evaluated.

Description

Desvenlafaxine succinate, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is an antidepressant. Desvenlafaxine is the principal active metabolite of venlafaxine and is pharmacologically related to duloxetine, another SNRI.

The exact mechanism of antidepressant action of desvenlafaxine has not been fully elucidated but appears to be associated with the drug's potentiation of serotonergic and noradrenergic activity in the CNS. Like venlafaxine and duloxetine, desvenlafaxine is a potent inhibitor of neuronal serotonin and norepinephrine reuptake; however, inhibition of dopamine reuptake at concentrations that inhibit serotonin and norepinephrine reuptake appears unlikely in most patients. The drug does not inhibit monoamine oxidase (MAO) and has not demonstrated significant affinity for muscarinic cholinergic, H_1-histaminergic, α_1-adrenergic, dopaminergic, γ-aminobutyric acid (GABA), glutamate, and opiate receptors in vitro.

Desvenlafaxine is principally metabolized via conjugation by uridine diphosphoglucuronosyltransferase (UGT) isoenzymes and, to a lesser extent, through oxidation (by the cytochrome P-450 [CYP] 3A4 isoenzyme). The drug minimally inhibits the CYP2D6 isoenzyme and does not inhibit the CYP 1A2, 2A6, 2C8, 2C9, or 2C19 isoenzymes. Desvenlafaxine is not an inhibitor of CYP3A4, nor is it an inducer of CYP3A4. The drug exhibits a low degree of protein binding (30%) and has a mean elimination half-life of approximately 11 hours. Approximately 45% of a single oral dose of desvenlafaxine is eliminated unchanged in the urine at 72 hours, approximately 19% of the dose is excreted as the glucuronide metabolite, and less than 5% is excreted as the oxidative metabolite (N,O-didesmethylvenlafaxine).

Advice to Patients

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.) FDA recommends providing written patient information (medication guide) explaining risks of suicidality each time the drug is dispensed. Importance of advising patients about importance of reading the patient information before taking desvenlafaxine and each time the prescription is refilled.

Importance of informing patients of potential risk of serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions, particularly with concurrent use of desvenlafaxine and 5-HT_1 receptor agonists (also called triptans), tramadol, tryptophan, other serotonergic agents, or antipsychotic agents. Importance of immediately contacting clinician if signs and symptoms of these syndromes develop (e.g., restlessness, hallucinations, loss of coordination, fast heart beat, increased body temperature, muscle stiffness, increased blood pressure, diarrhea, coma, nausea, vomiting, confusion).

Importance of advising patients not to concurrently take other products containing desvenlafaxine or venlafaxine.

Importance of instructing patients not to take desvenlafaxine with a monoamine oxidase (MAO) inhibitor or within 14 days of stopping the drug, and to allow 7 days after stopping desvenlafaxine before starting therapy with an MAO inhibitor.

Importance of advising patients that they should have regular monitoring of blood pressure while taking desvenlafaxine.

Importance of advising patients with raised intraocular pressure or those at risk of acute narrow-angle glaucoma (angle-closure glaucoma) that mydriasis has been reported with desvenlafaxine and that they should be monitored.

Importance of advising patients, their families, and caregivers to observe desvenlafaxine-treated patients for signs of activation of mania/hypomania.

Importance of advising patients that elevations in total cholesterol, LDL, and triglycerides may occur and that measurement of lipid levels may be considered during therapy.

Importance of advising patients to notify their clinician if they develop any allergic signs or symptoms during therapy (e.g., rash, hives, swelling, difficulty breathing).

Risk of cognitive and motor impairment; importance of exercising caution while operating hazardous machinery, including automobile driving, until patients are reasonably certain that desvenlafaxine therapy does not adversely affect their ability to engage in such activities.

Importance of avoiding alcohol during desvenlafaxine therapy.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs or herbal supplements, as well as any concomitant illnesses (e.g., cardiovascular, cerebrovascular, or lipid metabolism disorders; glaucoma) or personal or family history of suicidality or bipolar disorder. Importance of advising patients about the risk of bleeding associated with concomitant use of desvenlafaxine with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of advising patients that it usually takes several weeks of antidepressant therapy before they will start to feel better. Advise patients not to stop taking the drug if they do not feel the results right away.

Importance of advising patients not to stop taking desvenlafaxine without first talking with their clinician. Importance of patients being aware that discontinuance effects may occur when stopping the drug.

Importance of informing patients to swallow desvenlafaxine extended-release tablets whole, and not to crush, cut, chew, or dissolve the tablets.

Importance of informing patients that they may notice an inert matrix tablet passing in the stool or via colostomy, and that the active medication has already been absorbed by the time the patient sees the inert matrix tablet.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview* (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Desvenlafaxine Succinate

Oral		
Tablet, extended-release, film-coated	50 mg (of desvenlafaxine)	**Pristiq**†, Wyeth
	100 mg (of desvenlafaxine)	**Pristiq**†, Wyeth

†Use is not currently included in the labeling approved by the US Food and Drug Administration.

Duloxetine Hydrochloride

■ Duloxetine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is an antidepressant and anxiolytic agent.

Uses

■ **Major Depressive Disorder** Duloxetine hydrochloride is used for the acute and maintenance treatment of major depressive disorder in adults.

Efficacy of duloxetine for the acute treatment of major depression has principally been established by 4 double-blind, placebo-controlled studies of 8–9 weeks' duration in outpatient settings in adults. In these studies, patients receiving duloxetine (40–120 mg daily) had greater improvements in the 17-item Hamilton depression rating scale (HAMD-17) total score than did patients receiving placebo. No age-, race-, or gender-related differences in efficacy were noted in these studies.

Efficacy of duloxetine for the maintenance treatment of major depressive disorder has been established in a randomized, placebo-controlled relapse prevention study in which 533 adult outpatients who met DSM-IV criteria for major depressive disorder initially received duloxetine 60 mg once daily in a 12-week, open-label acute phase. Patients who responded to treatment during the acute phase were then randomized to continue receiving duloxetine at the same dosage or to receive placebo for 26 weeks in the continuation phase. The duloxetine-treated patients experienced a longer time to relapse of depression compared with the placebo recipients. In addition, more placebo recipients relapsed compared with patients receiving duloxetine (approximately 29% and 17%, respectively).

The manufacturer states that if duloxetine is used for extended periods, the need for continued therapy should be reassessed periodically.

Antidepressant efficacy of duloxetine in hospital settings has not been adequately studied to date.

For further information on treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidal risk, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in Fluoxetine Hydrochloride 28:16.04.20.

■ **Generalized Anxiety Disorder** Duloxetine hydrochloride is used for the acute management of generalized anxiety disorder in adults. Efficacy of duloxetine for this indication has been established by 3 placebo-controlled trials of 9–10 weeks' duration in outpatient settings in adults who met DSM-IV criteria for generalized anxiety disorder. In these studies, patients receiving duloxetine (60–120 mg daily) had greater improvements in the Hamilton anxiety scale (HAM-A) total score and the Sheehan Disability Scale (SDS) global functional impairment score than did patients receiving placebo. No age- or gender-related differences in efficacy were noted in these studies.

The manufacturer states that the anxiolytic efficacy of duloxetine for long-term use (i.e., exceeding 10 weeks) has not been established by controlled studies to date. If duloxetine is used for extended periods, the need for continued therapy should be reassessed periodically.

■ **Neuropathic Pain** Duloxetine hydrochloride is used for the management of neuropathic pain associated with diabetic peripheral neuropathy in

adults. Efficacy of duloxetine for this indication has been established by 2 controlled studies of 12 weeks' duration in adults with type 1 or 2 diabetes mellitus and a diagnosis of painful distal symmetrical sensorimotor polyneuropathy for at least 6 months. Patients were excluded from the studies if they met DSM-IV-TR criteria for major depressive disorder and dysthymia. In these studies, 51% of patients receiving duloxetine (60–120 mg daily) and up to 4 g of acetaminophen daily (as needed) reported at least a 30% sustained reduction in pain compared with 31% of those receiving placebo plus acetaminophen (as needed). Some patients in the study experienced a decrease in pain as early as week 1, which persisted throughout the study.

■ **Fibromyalgia** Duloxetine hydrochloride is used for the management of fibromyalgia in adults. Efficacy of duloxetine for this indication has been established by 2 randomized, double-blind, placebo-controlled, fixed-dose studies in adults with a diagnosis of fibromyalgia based on the American College of Rheumatology (ACR) criteria (i.e., history of widespread pain for 3 months and pain present in 11 or more of the 18 specific tender point sites). The first study was of 3 months' duration and enrolled female patients only while the second study was of 6 months' duration and enrolled both male and female patients. Approximately 25% of the patients had concurrent major depressive disorder. Both of these studies compared duloxetine 60 mg once daily or 120 mg daily (given in divided doses in study 1 and as a single daily dose in study 2) with placebo. In addition, Study 2 compared duloxetine 20 mg daily with placebo during the initial 3 months of the 6-month study; after 3 months, the duloxetine dosage was titrated up to 60 mg once daily for the remainder of the study. In these studies, duloxetine therapy in dosages of 60 or 120 mg daily significantly improved the endpoint mean pain scores from baseline and increased the number of patients who had at least a 50% reduction in pain score compared with baseline. Although pain reduction was observed in patients both with and without major depressive disorder, the degree of pain reduction may be greater in patients with major depressive disorder. Some patients experienced a reduction in pain as early as week 1, which persisted throughout the study. Improvement also was noted on measures of function as well as on the Patient Global Impression of Improvement (PGI) scale. Neither study demonstrated an additional therapeutic benefit of 120 mg daily compared with 60 mg daily, and the higher dosage was associated with more frequent adverse effects and early discontinuance of therapy.

The manufacturer states that the efficacy of duloxetine for long-term use (i.e., exceeding 3 months) has not been established by controlled studies to date. However, longer-term efficacy of the drug has been demonstrated for up to 6 months in extension phases of 2 controlled studies to date. The manufacturer recommends that the decision to continue therapy with the drug be based on individual patient response.

■ **Stress Urinary Incontinence** Duloxetine has been used for the management of moderate to severe stress urinary incontinence (SUI)† in women. In a number of placebo-controlled clinical trials involving women with predominantly SUI receiving duloxetine or placebo for up to 12 weeks, duloxetine was significantly better than placebo in reducing the frequency of incontinence episodes (which were reduced by approximately 50% in patients receiving duloxetine) and improving patients' quality of life (as assessed by Incontinence Quality of Life questionnaire scores). Therapy with the drug generally was well tolerated in these studies, with nausea being the most commonly reported adverse effect.

Data from one subsequent analysis suggest that the beneficial effects of duloxetine in women with SUI are maintained for up to 30 months. In addition, some data suggest that combining duloxetine and pelvic floor muscle training exercises may be more effective than either treatment alone. The potential role of duloxetine therapy relative to other forms of treatment (including pelvic floor muscle training, management of fluid intake and voiding, weight loss, devices, and surgery) remains to be established and requires additional study.

Dosage and Administration

■ **Administration** Duloxetine hydrochloride is administered orally without regard to meals. Duloxetine hydrochloride delayed-release capsules should be swallowed whole and should *not* be chewed or crushed, nor should the contents be sprinkled on food or mixed with liquids.

■ **Dosage** Dosage of duloxetine hydrochloride is expressed in terms of duloxetine.

Patients receiving duloxetine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

The manufacturer recommends that an interval of at least 2 weeks elapse when switching a patient from a monoamine oxidase (MAO) inhibitor to duloxetine. In addition, an interval of at least 5 days should elapse when switching from duloxetine to an MAO inhibitor.

Because withdrawal effects may occur (see Withdrawal Effects under Warnings/Precautions: Other Warnings and Precautions in Cautions), abrupt discontinuance of duloxetine should be avoided. When duloxetine therapy is discontinued, dosage should be tapered gradually and the patient carefully monitored to reduce the risk of withdrawal symptoms. If intolerable symptoms occur following dosage reduction or upon discontinuance of treatment, duloxetine therapy may be reinstituted at the previously prescribed dosage until such symptoms abate. Clinicians may resume dosage reductions at that time but at a more gradual rate.

Major Depressive Disorder For the management of major depressive disorder, the recommended initial dosage of duloxetine in adults is 40 mg daily (given as 20 mg twice daily) to 60 mg daily (given either as 60 mg once daily or 30 mg twice daily). In some patients, it may be desirable to initiate therapy with a dosage of 30 mg once daily given for 1 week, followed by an increase to 60 mg once daily. Although duloxetine dosages of 120 mg daily have been effective, there is no evidence that dosages exceeding 60 mg daily provide additional therapeutic benefit. Safety of dosages exceeding 120 mg daily has not been adequately evaluated.

While the optimum duration of duloxetine therapy has not been established, it generally is agreed that acute depressive episodes require several months or longer of sustained antidepressant therapy. Systematic evaluation of duloxetine has shown that its antidepressant efficacy is maintained for periods of up to 26 weeks in patients receiving 60 mg daily. The manufacturer recommends a maintenance dosage of 60 mg once daily in adults. The manufacturer also recommends that the usefulness of duloxetine be reevaluated periodically in patients receiving long-term therapy.

Generalized Anxiety Disorder For the management of generalized anxiety disorder, the recommended initial adult dosage of duloxetine is 60 mg once daily. In some patients, it may be desirable to initiate therapy with a dosage of 30 mg once daily given for 1 week, followed by an increase to 60 mg once daily. Dosage may be increased in increments of 30 mg once daily (up to a maximum dosage of 120 mg once daily). However, no additional benefit has been demonstrated from duloxetine dosages exceeding 60 mg once daily.

While the optimum duration of duloxetine therapy has not been established, it generally is agreed that generalized anxiety disorder is a chronic condition. The manufacturer states that the efficacy of duloxetine for long-term use (i.e., exceeding 10 weeks) has not been established by controlled studies and that the usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Neuropathic Pain For the management of neuropathic pain associated with diabetic peripheral neuropathy, the recommended adult dosage of duloxetine is 60 mg once daily. Duloxetine dosages exceeding 60 mg daily do not appear to provide substantially greater therapeutic benefit and clearly are less well tolerated. For patients for whom tolerability is a concern, a lower initial dosage may be considered. Because progression of diabetic peripheral neuropathy is highly variable and management of pain is empirical, efficacy of the drug must be assessed individually. The manufacturer states that the efficacy of duloxetine for long-term use (i.e., exceeding 12 weeks) has not been established by controlled studies.

Fibromyalgia For the management of fibromyalgia, the recommended adult dosage of duloxetine is 60 mg once daily. The manufacturer states that treatment should be initiated at 30 mg once daily for one week to allow patients to adjust to the drug before increasing the dosage to 60 mg once daily. Some patients may respond to the initial dosage of 30 mg once daily. Duloxetine dosages exceeding 60 mg daily do not appear to provide greater therapeutic benefit, even in patients not responding to a dosage of 60 mg daily, and are associated with a higher incidence of adverse effects.

Fibromyalgia is recognized as a chronic condition. The manufacturer states that efficacy of duloxetine in the management of fibromyalgia has been demonstrated in placebo-controlled studies lasting up to 3 months, and that the efficacy of the drug for longer-term use (i.e., exceeding 3 months) has not been established in controlled studies. However, efficacy of the drug has been demonstrated for up to 6 months in extension phases of 2 controlled studies. The manufacturer recommends that the decision to continue therapy with the drug be based on individual patient response.

Stress Urinary Incontinence Although the optimum dosage and duration of duloxetine therapy for the treatment of stress urinary incontinence† in women remain to be established, the most commonly used dosage in controlled trials has been 80 mg daily, usually given as 40 mg twice daily (dosage range: 20–120 mg daily). Some patients may benefit (i.e., reduced risk of nausea and dizziness) from initiating therapy with a duloxetine dosage of 20 mg twice daily for 2 weeks before increasing to the usual dosage of 40 mg twice daily. If adverse effects are bothersome during the first few weeks of therapy at the usual dosage, the dosage may be reduced to 20 mg twice daily. The safety of higher dosages (i.e., 120 mg daily), which have been used in a limited number of women with more severe cases of stress urinary incontinence, requires additional study.

■ **Special Populations** Although there are no specific dosage recommendations for geriatric patients, extra caution is recommended when the duloxetine dosage is increased in elderly patients.

Although the manufacturer makes no specific dosage recommendation for smoking patients, some clinicians recommend a slightly increased duloxetine dosage (by about 15%) in patients who smoke. (See Drug Interactions: Smoking.)

In patients with mild to moderate renal impairment (creatinine clearance 30–80 mL/minute), a lower initial dosage and gradual increase in dosage may be considered. The manufacturer recommends that duloxetine *not* be administered to patients with end-stage renal disease (requiring dialysis), severe renal impairment (creatinine clearance less than 30 mL/minute), or any hepatic insufficiency. (See Specific Populations under Cautions: Warnings/Precautions.)

Treatment of Pregnant Women during the Third Trimester Because some neonates exposed to duloxetine and other selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) or selective serotonin-reuptake inhibitors late in the third trimester of pregnancy have developed severe com-

plications, consideration may be given to cautiously tapering duloxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Pregnancy under Warnings/Precautions: Specific Populations, in Cautions.)

Cautions

■ **Contraindications** Concurrent or recent (i.e., within 2 weeks) therapy with a monoamine oxidase (MAO) inhibitor. (See Drug Interactions: Monoamine Oxidase Inhibitors.)

Uncontrolled angle-closure glaucoma.

Known hypersensitivity to duloxetine or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** **Worsening of Depression and Suicidality Risk.** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Pediatric Use under Cautions: Specific Populations) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

Other Warnings and Precautions **Hepatic Effects.** Hepatic failure, sometimes fatal, has been reported in duloxetine-treated patients. The cases presented as hepatitis accompanied by abdominal pain, hepatomegaly, and markedly elevated serum transaminase concentrations (more than 20 times the upper limit of normal) with or without jaundice, reflecting a mixed or hepatocellular pattern of hepatic injury. Duloxetine should be discontinued in any patient who develops jaundice or other evidence of clinically important hepatic dysfunction; therapy should not be resumed unless another cause for the hepatic dysfunction can be established.

Cases of cholestatic jaundice with minimal elevation of serum transaminase concentrations also have been reported. Postmarketing reports indicate that elevated serum transaminase, bilirubin, and alkaline phosphatase concentrations have occurred in duloxetine-treated patients with chronic hepatic disease or cirrhosis.

Duloxetine has been shown to increase the risk of serum transaminase elevations in clinical trials; such elevations resulted in discontinuance of the drug in 0.3% of patients. The median time to detection of the transaminase elevation was about 2 months. In placebo-controlled trials, elevations in serum ALT concentrations to more than 3 times the upper limit of normal occurred in 1.1% of the duloxetine-treated patients compared with 0.2% of those receiving placebo. There was evidence of a dose-response relationship for ALT (SGPT) and AST (SGOT) elevations of more than 3 times the upper limit of normal and more than 5 times the upper limit of normal, respectively.

Because of the possibility that duloxetine and alcohol may interact to cause hepatic injury or that duloxetine may aggravate preexisting hepatic disease, duloxetine should not ordinarily be prescribed to patients with a history of excessive alcohol consumption or evidence of chronic hepatic disease. Patients and clinicians should be aware of the signs and symptoms of hepatic injury (e.g., pruritus, dark urine, jaundice, right upper quadrant tenderness, unexplained flu-like symptoms), and clinicians should promptly investigate such manifestations in patients receiving the drug.

Orthostatic Hypotension and Syncope. Orthostatic hypotension and syncope reported with therapeutic dosages; although these effects tend to occur within the first week of therapy, they may occur at any time during therapy; particularly following increases in dosage. Risk of decreased blood pressure may be greater in patients concomitantly receiving other drugs that produce orthostatic hypotension (such as antihypertensive agents); in patients receiving potent inhibitors of the cytochrome P-450 (CYP) 1A2 isoenzyme (see Drug Interactions: Drugs Affecting Hepatic Microsomal Enzymes); or in those receiving duloxetine dosages exceeding 60 mg daily. Discontinuance of the drug should be considered in patients experiencing symptomatic orthostatic hypotension and/or syncope during duloxetine therapy.

Serotonin Syndrome. Potentially life-threatening serotonin syndrome reported with selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs), including duloxetine, or selective serotonin-reuptake inhibitors (SSRIs), particularly with concurrent administration of other serotonergic drugs (e.g., serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"]) or drugs that impair serotonin metabolism (e.g., monoamine oxidase [MAO] inhibitors). Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea).

Concurrent therapy with MAO inhibitors used for treatment of depression is contraindicated. (See Drug Interactions: Monoamine Oxidase Inhibitors.)

If concurrent therapy with duloxetine and a 5-HT_1 receptor agonist is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated.

Concomitant use of duloxetine and serotonin precursors (e.g., tryptophan) is not recommended.

Abnormal Bleeding. SSRIs and SNRIs, including duloxetine, may increase the risk of bleeding events. Concurrent administration of aspirin, nonsteroidal anti-inflammatory agents, warfarin, and other anticoagulants may add to this risk. Case reports and epidemiologic studies have demonstrated an association between the use of drugs that interfere with serotonin reuptake and the occurrence of GI bleeding. Bleeding events related to SSRI and SNRI use have ranged from ecchymoses, hematomas, epistaxis, and petechiae to life-threatening hemorrhages. The manufacturer recommends that patients be advised of the risk of bleeding associated with the concomitant use of duloxetine and aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation. (See Drug Interactions: Drugs Affecting Hemostasis.)

Withdrawal Effects. Because withdrawal effects (e.g., dysphoric mood, irritability, agitation, nausea/vomiting, dizziness, sensory disturbances, anxiety, confusion, headache, lethargy, emotional lability, insomnia, nightmares, hypomania, tinnitus, seizures) may occur, abrupt discontinuance of duloxetine should be avoided. (See Dosage and Administration: Dosage.)

If intolerable symptoms occur following dosage reduction or discontinuance, reinstitute previously prescribed dosage until symptoms abate, then resume more gradual dosage reductions.

Activation of Mania/Hypomania. Activation of mania and hypomania has occurred in patients with major depressive disorder receiving duloxetine. Use with caution in patients with a history of mania.

Seizures. The risk of seizures associated with duloxetine use has not been systematically evaluated, but seizures have been reported in patients receiving the drug; therefore, use with caution in patients with a history of seizures.

Blood Pressure. May increase blood pressure. Monitor blood pressure prior to and periodically during duloxetine therapy.

Clinically Important Drug Interactions. Because both CYP1A2 and CYP2D6 are responsible for duloxetine metabolism, the potential exists for clinically important drug interactions when duloxetine is concurrently administered with CYP1A2 inhibitors, CYP2D6 inhibitors, and CYP2D6 substrates.

Concurrent therapy with MAO inhibitors used for treatment of depression is contraindicated. (See Serotonin Syndrome under Warnings/Precautions: Other Warnings and Precautions, in Cautions and also see Drug Interactions: Monoamine Oxidase Inhibitors.)

Because of the possibility that duloxetine and alcohol may interact to cause hepatic injury, duloxetine should not ordinarily be prescribed to patients with a history of excessive alcohol consumption or evidence of chronic hepatic disease. (See Hepatic Effects under Warnings/Precautions: Other Warnings and Precautions, in Cautions and also see Drug Interactions: Alcohol.)

Potential pharmacologic interaction when duloxetine is given with or substituted for other centrally acting drugs, including those with a similar mechanism of action; CNS-active drugs should be used with caution in patients receiving duloxetine.

Hyponatremia/Syndrome of Inappropriate Antidiuretic Hormone Secretion. Treatment with SSRIs and SNRIs, including duloxetine, may result in hyponatremia. In many cases, hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Cases with serum sodium concentrations lower than 110 mmol/L have been reported and hyponatremia appeared reversible when duloxetine was discontinued. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia. Signs and symptoms of hyponatremia include headache, difficulty concentrating, memory impairment, confusion, weakness, and unsteadiness, which may lead to falls; more severe and/or acute cases have been associated with hallucinations, syncope, seizures, coma, respiratory arrest, and death. Initiate appropriate medical intervention and consider drug discontinuance in patients with symptomatic hyponatremia.

Concomitant Illnesses. Experience with duloxetine in patients with concomitant diseases is limited. (See Hepatic Impairment and see Renal Impairment under Warnings/Precautions: Specific Populations, in Cautions.)

Because alterations in gastric motility may affect the stability of the enteric coating of the pellets contained in duloxetine capsules, the drug should be used with caution in patients with conditions that may slow gastric emptying (e.g., in some patients with diabetes mellitus).

Duloxetine has not been systematically evaluated in patients with a recent history of myocardial infarction or unstable coronary artery disease; such patients were generally excluded from clinical studies. The manufacturer states that duloxetine use was not associated with the development of clinically important ECG abnormalities in controlled clinical studies of up to 13 weeks' duration.

Duloxetine worsens glycemic control in some patients with diabetes. In the 12-week acute treatment phase of 3 clinical studies in patients with diabetic peripheral neuropathy, small increases in fasting blood glucose were observed in the duloxetine-treated patients compared with those receiving placebo. In the extension phase of these studies, which lasted up to 52 weeks, fasting blood glucose increased by 12 mg/dL in the duloxetine-treated patients and decreased by 11.5 mg/dL in the routine care group; increases in glycosylated hemoglobin (hemoglobin A_{1c}) were observed in both groups of patients although the average increase was 0.3% greater in the duloxetine-treated patients compared with those receiving routine care.

Controlled Narrow-Angle Glaucoma. Possible increased risk of mydriasis; use with caution in patients with *controlled* narrow-angle glaucoma. Contraindicated in patients with such glaucoma that is not controlled.

Urinary Hesitation and Retention. Duloxetine belongs to a class of drugs known to affect urethral resistance. If symptoms of urinary hesitation develop during therapy, consider possibility that they may be drug-related. (See Uses: Stress Urinary Incontinence.)

Cases of urinary retention have been reported during postmarketing experience; in some of these cases, hospitalization and/or catheterization has been necessary.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Some neonates exposed to selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) or selective serotonin-reuptake inhibitors late in the third trimester of pregnancy have developed complications that have sometimes been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special-care nurseries. Such complications can arise immediately upon delivery and usually last several days or up to 2–4 weeks. Clinical findings reported to date in the neonates have included respiratory distress, cyanosis, apnea, seizures, temperature instability or fever, feeding difficulty, dehydration, excessive weight loss, vomiting, hypoglycemia, hypotonia, hyperreflexia, tremor, jitteriness, irritability, lethargy, reduced or lack of reaction to pain stimuli, and constant crying. These clinical features appear to be consistent with either a direct toxic effect of the SNRI or selective serotonin-reuptake inhibitor or, possibly, a drug withdrawal syndrome. It should be noted that, in some cases, the clinical picture was consistent with serotonin syndrome (see Drug Interactions: Drugs Associated with Serotonin Syndrome, in Fluoxetine Hydrochloride 28:16.04.20). When treating a pregnant woman with duloxetine during the third trimester of pregnancy, the clinician should carefully consider the potential risks and benefits of such therapy. Consideration may be given to cautiously tapering duloxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Treatment of Pregnant Women during the Third Trimester under Dosage and Administration: Special Populations.)

Lactation. Duloxetine is distributed into human milk. At steady state, concentrations in breast milk are approximately one-fourth the maternal plasma concentrations. Because the safety of duloxetine in infants is not known, use in nursing women is not recommended. However, if the clinician determines that the potential benefits of duloxetine therapy for the mother outweigh the potential risks to the infant, dosage adjustment is not required since lactation does not affect pharmacokinetics.

Pediatric Use. Safety and efficacy of duloxetine in children younger than 18 years of age have not been established.

FDA warns that a greater risk of suicidal thinking or behavior (suicidality) occurred during first few months of antidepressant treatment (4%) compared with placebo (2%) in children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders based on pooled analyses of 24 short-term, placebo-controlled trials of 9 antidepressant drugs (selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants). However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

Carefully consider these findings when assessing potential benefits and risks of duloxetine in a child or adolescent for any clinical use. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Geriatric Use. Approximately 5.9, 33, and 7.9% of patients studied in clinical trials of duloxetine for major depressive disorder, diabetic peripheral neuropathy, and fibromyalgia, respectively, were 65 years of age or older. The generalized anxiety disorder clinical trials did not include sufficient numbers of patients 65 years of age or older to determine whether they respond differently than younger adults. Although no overall differences in efficacy or safety were observed between geriatric and younger patients in the major depressive disorder, diabetic peripheral neuropathic pain, and fibromyalgia clinical trials and other clinical experience has not revealed any evidence of age-related differences, the possibility that some older patients may exhibit increased sensitivity to the drug cannot be ruled out.

Clinically important hyponatremia has been reported in geriatric patients, who may be at greater risk for this adverse effect. (See Hyponatremia/Syndrome of Inappropriate Antidiuretic Hormone Secretion under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Hepatic Impairment. Substantially increased exposure to duloxetine; use is not recommended in patients with hepatic insufficiency or with substantial alcohol use. (See Hepatic Effects under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Renal Impairment. Increased plasma concentrations of duloxetine and its metabolites; use is not recommended in patients with end-stage renal disease (requiring dialysis) or severe renal impairment (creatinine clearance less than 30 mL/minute).

Population pharmacokinetic analyses suggest that mild to moderate renal impairment has no clinically important effect on duloxetine apparent clearance.

■ **Common Adverse Effects** Adverse effects reported in 5% or more of patients with major depressive disorder receiving duloxetine and at an incidence at least twice that reported with placebo include nausea, dry mouth, constipation, decreased appetite, fatigue, somnolence, and increased sweating.

Adverse effects reported in 5% or more of patients with generalized anxiety disorder receiving duloxetine and at an incidence at least twice that reported with placebo include nausea, fatigue, dry mouth, somnolence, constipation, insomnia, decreased appetite, vomiting, hyperhidrosis, decreased libido, delayed ejaculation, and erectile dysfunction.

Adverse effects reported in 5% or more of patients with diabetic peripheral neuropathy receiving duloxetine and at an incidence at least twice that reported with placebo include nausea, somnolence, dizziness, dry mouth, constipation, hyperhidrosis, decreased appetite, and asthenia.

Adverse effects reported in 5% or more of patients with fibromyalgia receiving duloxetine and at an incidence at least twice that reported with placebo include nausea, dry mouth, constipation, decreased appetite, somnolence, agitation, and hyperhidrosis.

Drug Interactions

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Substrates of cytochrome P-450 (CYP) 2D6 isoenzyme (e.g., tricyclic antidepressants [TCAs; amitriptyline, desipramine, imipramine, nortriptyline], phenothiazines, class IC antiarrhythmics [flecainide, propafenone]): potential pharmacokinetic (increased AUC of the substrate) interactions. Use with caution. Consider monitoring plasma TCA concentrations and reducing the TCA dosage if a TCA is administered concurrently with duloxetine.

Substrates of CYP1A2, CYP3A, CYP2C9, or CYP2C19 isoenzymes: clinically important pharmacokinetic interaction generally is considered unlikely.

■ **Drugs Affecting Hepatic Microsomal Enzymes** Potent inhibitors of CYP1A2 (e.g., fluvoxamine, some quinolone anti-infective agents [e.g., ciprofloxacin, enoxacin]): potential pharmacokinetic (increased plasma duloxetine concentrations) interaction. Avoid concomitant use.

Potent inhibitors of CYP2D6 (e.g., fluoxetine, paroxetine, quinidine) isoenzymes: potential pharmacokinetic interaction (increased plasma duloxetine concentrations).

Concomitant administration of duloxetine and fluvoxamine, a potent CYP1A2 inhibitor, in poor CYP2D6 metabolizers resulted in a sixfold increase in duloxetine area under the plasma concentration-time curve (AUC) and peak plasma concentrations.

■ **Drugs Affecting Hemostasis** Altered anticoagulant effects, including increased bleeding, have been reported when selective serotonin-reuptake inhibitors (SSRIs) or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs), including duloxetine, were concurrently administered with warfarin or other anticoagulants. The manufacturer recommends carefully monitoring patients receiving warfarin during initiation and discontinuance of duloxetine therapy.

Potential pharmacologic (increased risk of bleeding) interaction with aspirin or other nonsteroidal anti-inflammatory agents; use with caution.

■ **Drugs that Affect Gastric Acidity** Theoretical risk of altered duloxetine bioavailability if administered with drugs that increase gastric pH. However, no clinically important effect was demonstrated when duloxetine was administered with aluminum- and magnesium-containing antacids or famotidine.

Whether the concomitant administration of proton-pump inhibitors affects duloxetine absorption is currently unknown.

■ **Alcohol** Potential pharmacologic (increased risk of hepatotoxicity) interaction; avoid concomitant use in patients with substantial alcohol use. (See Hepatic Effects under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Duloxetine has not been shown to potentiate the impairment of mental and motor skills caused by alcohol.

■ **Antihypertensive Agents** Potential pharmacologic (increased risk of hypotension and syncope) interaction.

■ **Benzodiazepines** Lorazepam does not appear to affect the pharmacokinetics of duloxetine.

Temazepam does not appear to affect the pharmacokinetics of duloxetine.

■ **CNS-active Drugs** Potential pharmacologic interaction when given with or substituted for other centrally acting drugs, including those with a similar mechanism of action; use with caution.

■ **5-HT$_1$ Receptor Agonists ("Triptans")** Pharmacologic interaction (potentially life-threatening serotonin syndrome) if used concurrently with 5-HT$_1$ reeeptor agonists (e.g., almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan). If concomitant use is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, when dosage is increased, or when another serotonergic agent is initiated. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

■ **Monoamine Oxidase (MAO) Inhibitors** Pharmacologic interaction (potentially fatal serotonin syndrome); concomitant use is contraindicated. The manufacturer recommends that at least 2 weeks should elapse between discontinuance of an MAO inhibitor and initiation of duloxetine and that at least 5 days elapse between discontinuance of duloxetine therapy and initiation of MAO inhibitor therapy. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

■ **Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors** Potential pharmacologic interaction (potentially life-threatening serotonin syndrome); concurrent administration not recommended. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

Concomitant administration of duloxetine and fluvoxamine, a potent CYP1A2 inhibitor, in poor CYP2D6 metabolizers resulted in a six-fold increase in duloxetine AUCs and peak plasma concentrations.

■ **Serotonergic Drugs** Potential pharmacologic interaction (potentially life-threatening serotonin syndrome) with drugs affecting serotonergic neurotransmission, including linezolid (an anti-infective agent that is a nonselective, reversible MAO inhibitor), lithium, tramadol, and St. John's wort (*Hypericum perforatum*); use with caution. Concurrent administration of serotonin precursors (such as tryptophan) is not recommended. (See Serotonin Syndrome under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Smoking** Potential pharmacokinetic interaction (reduced duloxetine bioavailability and plasma concentrations). The manufacturer states that routine dosage adjustment is not necessary. However, some clinicians recommend a small increase in duloxetine dosage (about 15%) in patients who smoke.

■ **Theophylline** Although small increases (averaging from 7–20%) in theophylline AUCs have been reported during concurrent administration of theophylline and duloxetine, combined use of these drugs reportedly has been well tolerated and routine theophylline dosage adjustment does not appear to be necessary during concomitant administration.

■ **Thioridazine** Potential pharmacokinetic (increased plasma thioridazine concentrations) interaction with resulting increased risk of serious ventricular arrhythmias and sudden death; concomitant use is not recommended by manufacturer of duloxetine.

Description

Duloxetine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is an antidepressant and anxiolytic agent. The drug also has demonstrated analgesic activity in animal models of chronic and persistent pain and in clinical trials evaluating the drug's activity in conditions associated with chronic pain (e.g., neuropathic pain, fibromyalgia). Duloxetine hydrochloride is pharmacologically related to venlafaxine hydrochloride and desvenlafaxine succinate.

The exact mechanisms of the antidepressant, anxiolytic, and central pain inhibitory actions of duloxetine have not been fully elucidated, but appear to be associated with the drug's potentiation of serotonergic and noradrenergic activity in the CNS. Like venlafaxine and desvenlafaxine, duloxetine is a potent inhibitor of neuronal serotonin and norepinephrine reuptake and a less potent inhibitor of dopamine reuptake. Duloxetine does not inhibit monoamine oxidase (MAO) and has not demonstrated significant affinity for dopaminergic, adrenergic, cholinergic, γ-aminobutyric acid (GABA), glutamate, histaminergic, and opiate receptors in vitro.

Although the precise mechanism of action of duloxetine in stress urinary incontinence is unknown, it is thought to be related to potentiation of serotonin and norepinephrine activity in the sacral spinal cord, which increases urethral closure forces and thereby reduces involuntary urine loss.

Duloxetine is extensively metabolized in the liver, principally via oxidation by the cytochrome P-450 (CYP) 2D6 and 1A2 isoenzymes. Duloxetine is a moderate inhibitor of CYP2D6 and a somewhat weak inhibitor of CYP1A2. The drug is not an inhibitor of CYP2C9, CYP2C19, or CYP3A, nor is it an inducer of CYP1A2 or CYP3A.

Advice to Patients

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment. FDA recommends providing written patient information (medication guide) explaining risks of suicidality each time the drug is dispensed.

Importance of promptly reporting any manifestations of liver dysfunction (e.g., pruritus, dark urine, jaundice, right upper quadrant tenderness, unexplained flu-like symptoms) to clinician.

Importance of informing patient of risk of severe liver injury associated with concomitant use of duloxetine and heavy alcohol intake. (See Hepatic Effects under Warnings/Precautions: Other Warnings and Precautions and also see Drug Interactions: Alcohol.)

Risk of psychomotor impairment; importance of exercising caution while operating hazardous machinery, including automobile driving, until patient gains experience with the drug's effects.

Importance of advising patients of risk of orthostatic hypotension and syncope, particularly during initial therapy and subsequent dosage escalation and during concomitant therapy with drugs that may potentiate the orthostatic effect of duloxetine.

Importance of informing patients of risk of serotonin syndrome with concurrent use of duloxetine and 5-HT$_1$ receptor agonists (also called triptans), tramadol, or other serotonergic agents. Importance of seeking immediate medical attention if symptoms of serotonin syndrome develop.

Importance of taking medication exactly as prescribed by the clinician. Importance of informing patients that the delayed-release capsules should be swallowed whole and should not be chewed or crushed, nor should the capsule contents be sprinkled on food or mixed with liquids.

Importance of continuing duloxetine therapy even if a response is not evident within 1–4 weeks, unless directed otherwise.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., bipolar disorder, liver disease) or family history of suicidality or bipolar disorder. Risk of bleeding associated with concomitant use of duloxetine with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Venlafaxine Hydrochloride

■ Venlafaxine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is a phenylethylamine-derivative antidepressant and anxiolytic agent.

Uses

■ **Major Depressive Disorder** Venlafaxine hydrochloride is used in the treatment of major depressive disorder. Efficacy of venlafaxine conventional tablets for the management of major depression has been established in several placebo-controlled studies in outpatient settings in patients who had major depression and in 1 placebo-controlled study in a hospital setting in patients who had major depression with melancholia. Efficacy of venlafaxine extended-release capsules for the treatment of major depression also has been established by controlled studies of 8–12 weeks' duration in outpatient settings; however, the safety and efficacy of venlafaxine extended-release capsules in hospitalized patients with major depression have not been adequately evaluated.

In 4 studies of 6 weeks' duration in adult outpatients with major depression, venlafaxine in dosages of 75–225 mg daily administered in 2 or 3 divided doses as conventional tablets was found to be superior to placebo on at least 2 of the following 3 clinical measures of depression: Hamilton Depression Rating Scale (HAM-D) total score, HAM-D depressed mood item, and the Clinical Global

although differences in certain animal models have been observed and additive effects appear to occur when the drug is combined with these anticonvulsants.

Although the precise mechanism of action of topiramate is unknown, data from electrophysiologic and biochemical studies have revealed 4 properties that may contribute to the drug's efficacy for seizure disorders and migraine prophylaxis. At pharmacologically relevant concentrations, topiramate blocks voltage-dependent sodium channels; augments the activity of γ-aminobutyric acid (GABA) at some subtypes of the GABA-A receptor; antagonizes the AMPA/kainate subtype of the glutamate receptor; and inhibits carbonic anhydrase (particularly CA-II and CA-IV isoenzymes). In general, anticonvulsant drugs are thought to act by one or more of the following mechanisms: modulating voltage-dependent ion (e.g., sodium) channels involved in action potential propagation or burst generation, enhancement of GABA inhibitory activity, and/or inhibition of excitatory amino acid neurotransmitter (e.g., glutamate, aspartate) activity.

Topiramate exhibits effects on cultured neurons similar to those observed with phenytoin and carbamazepine, and such effects are suggestive of an inactive state-dependent block of voltage-dependent sodium channels. Topiramate reduces the duration of epileptiform bursts of neuronal firing and decreases the number of action potentials in studies of cultured rat hippocampal neurons with spontaneous epileptiform burst activity. Topiramate also decreases the frequency of action potentials elicited by depolarizing electric current in cultured rat hippocampal neurons. Depolarization and firing of an action potential results from the rapid inflow of sodium ions through voltage-dependent sodium channels in the neuronal cell membrane. After firing, a neuron enters a period of inactivation during which it is unable to fire again even if the sodium channel is open. A slow action potential firing rate allows the neuron sufficient time to recover from inactivation, and the normal period of inactivation has a minimal effect on low-frequency firing. During a partial seizure, neurons characteristically undergo high-frequency depolarization and firing of action potentials which is uncommon during normal physiologic neuronal activity. Some anticonvulsant drugs (e.g., phenytoin, carbamazepine) preferentially bind to voltage-dependent sodium channels during their inactivated state, slow the rate of recovery of sodium channels from their period of inactivation, and limit the ability of the neuron to depolarize and fire at high frequencies.

Topiramate enhances the activity of the inhibitory neurotransmitter GABA at a nonbenzodiazepine site on $GABA_A$ receptors. Activation of the postsynaptic $GABA_A$ receptor by GABA causes inhibition by increasing the inward flow of chloride ions, resulting in hyperpolarization of the postsynaptic cell; in chloride ion-depleted murine cerebellar granule cells, therapeutic concentrations of topiramate (in combination with GABA) enhance GABA-evoked inward flux of chloride ions in a concentration-dependent manner. Benzodiazepines act at $GABA_A$ receptors to enhance GABA-evoked inward flow of chloride ions, but the benzodiazepine antagonist flumazenil does not appear to inhibit topiramate enhancement of GABA-evoked currents in $GABA_A$ cortical neuronal receptors. Topiramate also does not appear to increase duration of chloride ion channel opening. Therefore, topiramate may potentiate $GABA_A$-evoked chloride ion flux by a mechanism other than $GABA_A$-receptor modulation.

Topiramate antagonizes a non-*N*-methyl-d-aspartate (NMDA) glutamate receptor and the kainate/α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor subtype. Although topiramate had no apparent effect on glutamate receptors of the NMDA subtype in cultured rat hippocampal neurons, topiramate antagonized the ability of kainate to activate the kainate/AMPA glutamate receptor subtype, and these effects were shown to be concentration dependent. Glutamate, the principal excitatory neurotransmitter amino acid in the brain, interacts with specific neuronal membrane receptors, including ion channel coupled (ionotropic) (e.g., NMDA, kainate/AMPA, kainate) receptor subtypes and with G-protein coupled (metabotropic) receptors that modulate intracellular second-messengers. Glutamate is responsible for a variety of neurologic functions, including cognition, memory, movement, and sensation, and excessive activation of glutamate receptors may mediate injury or destruction of neurons in some acute neurologic disorders and chronic neurodegenerative diseases. The pathogenesis of seizures is thought to be mediated at least in part through excessive stimulation of glutamate receptors. In spontaneously epileptic rats, topiramate has reduced extracellular hippocampal concentrations of both glutamate and aspartate, and a correlation existed between reduction in glutamate concentrations and suppression of tonic seizures.

In animals, topiramate exhibits anticonvulsant activity in the maximal electroshock seizure (MES) test, suggesting that, like phenytoin, it may be effective in the management of partial and tonic-clonic (grand mal) seizures in humans. Topiramate also exhibited dose-dependent inhibition of absence-like seizures, which was antagonized by pretreatment with haloperidol. In animals, topiramate was ineffective or weakly effective in blocking clonic seizures induced by pentylenetetrazole, indicating that the drug may not enhance GABA inhibitory activity substantially.

Although the precise mechanism(s) of action of topiramate in the management of alcohol dependence is unclear, topiramate enhances GABA-mediated inhibitory neurotransmission and inhibits glutamatergic stimulatory neurotransmission; such changes appear to decrease dopaminergic activity in the mesocorticolimbic areas of the brain, which have been associated with alcohol dependence.

Topiramate inhibits carbonic anhydrase CA-II and CA-IV isoenzymes and, like other carbonic anhydrase inhibitors (e.g., acetazolamide, dichlorphenamide), the drug may promote the formation of renal calculi by increasing urinary pH and decreasing the excretion of urinary citrates. In premarketing studies, renal calculi were reported to occur in 1.5% of patients receiving topiramate, an incidence 2–4 times that expected in a similar untreated population, but most patients who developed calculi elected to continue therapy with the drug. Use of topiramate with other carbonic anhydrase inhibitors may increase the risk of renal calculi and therefore should be avoided.

†Use is not currently included in the labeling approved by the US Food and Drug Administration.

Valproate Sodium / Valproic Acid / Divalproex Sodium

Sodium Dipropylacetate, Sodium α-Propylvalerate, DPA Sodium / Dipropylacetic Acid, 2-Propylvaleric Acid, DPA / Valproate Semisodium

■ Valproic acid, valproate sodium, and divalproex sodium are carboxylic acid-derivative anticonvulsants that also are used to treat acute manic episodes or for prophylaxis of migraine headache as well as certain other psychiatric disorders.

Uses

■ **Seizure Disorders** Valproic acid, valproate sodium, or divalproex sodium is used alone or with other anticonvulsants (e.g., ethosuximide) in the prophylactic management of simple and complex absence (petit mal) seizures. The drugs also may be used in conjunction with other anticonvulsants in the management of multiple seizure types that include absence seizures. Valproic acid is considered a drug of choice for absence or atypical absence seizures.

Valproic acid, valproate sodium, or divalproex sodium is used alone or with other anticonvulsants (e.g., carbamazepine, phenytoin) in the prophylactic management of complex partial seizures that occur either by themselves or in association with other seizure types. Some clinicians state that valproic acid may be considered a drug of choice for the management of complex partial seizures. Two randomized, placebo-controlled trials, one of valproic acid as monotherapy and one of valproic acid as adjunctive therapy, demonstrated that the drug decreased the frequency of seizures in patients inadequately controlled by other therapies (e.g., carbamazepine, phenytoin, phenobarbital).

Valproic acid has been used and is considered by some clinicians as a drug of choice for management of other generalized seizures, including primary generalized tonic-clonic seizures†, atypical absence†, myoclonic†, or atonic seizures†, especially for those patients with more than one type of generalized seizure. In addition, some clinicians state that valproic acid may be used as a drug of choice for the management of simple partial seizures†. Valproic acid also has been administered rectally† or by intragastric drip† with some success in the management of status epilepticus refractory to IV diazepam†. A parenteral formulation of valproic acid has been studied and has been effective when administered IV† in the management of status epilepticus.

Valproic acid has been used with some success in the treatment of Lennox-Gastaut syndrome and infantile spasms.

■ **Bipolar Disorder** Divalproex sodium is used in the treatment of manic episodes associated with bipolar disorder; valproic acid† and valproate sodium† also have been used. Because there are only minor differences in the pharmacokinetics of the formulations, and because all forms of the drug circulate in plasma as valproic acid, the term "valproic acid" will be used in the following discussion.

Valproic acid has been used as monotherapy or as part of combination therapy (e.g., with lithium, antipsychotic agents [e.g., olanzapine], antidepressants, carbamazepine) in the treatment of acute manic episodes. The American Psychiatric Association (APA) currently recommends combined therapy with valproic acid plus an antipsychotic agent or with lithium plus an antipsychotic agent as first-line drug therapy for the acute treatment of more severe manic or mixed episodes and monotherapy with one of these drugs for less severe episodes. For mixed episodes, valproic acid may be preferred over lithium. Valproic acid or lithium also is recommended for the initial acute treatment of rapid cycling.

A manic episode is a distinct period of abnormally and persistently elevated, expansive, or irritable mood. Typical symptoms include pressure of speech, motor hyperactivity, reduced need for sleep, flight of ideas, grandiosity, poor judgment, aggressiveness, and possible hostility. Efficacy of valproic acid in

the treatment of manic episodes was established in short-term, placebo-controlled, parallel-group trials in patients hospitalized with bipolar disorder, manic (DSM-IIIR); response to therapy was assessed using objective rating scales such as the Young Mania Rating Scale (YMRS), an augmented Brief Psychiatric Rating Scale (BPRS-A), the Mania Rating Scale (MRS), and the Global Assessment Scale (GAS). One study specifically enrolled patients who were intolerant of or unresponsive to previous lithium therapy. Up to 40% of patients fail to respond to or are intolerant of lithium therapy for manic episodes; such patients may demonstrate a response to valproic acid, although response to valproic acid appears to be independent of prior response to lithium therapy. Valproic acid therapy appears to be about as effective as lithium for the treatment of manic episodes. In one placebo-controlled trial, 48% of patients receiving valproic acid demonstrated a response to the drug as measured by changes in the Manic Syndrome subscale of the MRS; 49% of patients receiving lithium responded to therapy, while 25% of patients receiving placebo responded. Antimanic response to valproic acid typically occurs within 1–2 weeks of initiating therapy. Valproic acid therapy also appears to be effective in specific types of mania, including rapid-cycling mania and dysphoric mania, which have been reported to be poorly responsive to lithium.

Although the manufacturer states that safety and efficacy of long-term (i.e., longer than 3 weeks) valproic acid therapy have not been established in the treatment of manic episodes, valproic acid also has been used, alone or in combination therapy, for long-term or maintenance antimanic therapy†, and APA currently considers the best empiric evidence to support the use of valproic acid or lithium for maintenance therapy. Antimanic efficacy has been maintained from several months to more than 10 years, and such long-term therapy appears to decrease the frequency and severity of bipolar episodes over extended periods of time; however, further study is required to establish the efficacy of valproic acid as maintenance therapy of manic episodes. Valproic acid does not appear to be as effective for the management of the depressive component of bipolar disorder†; although some evidence suggests that long-term valproic acid therapy may be moderately effective in the prophylaxis of depressive episodes, its acute effects on depression appear to be limited. Some clinicians recommend that valproic acid therapy be used in patients with bipolar disorder or schizoaffective disorder, bipolar type, who have responded inadequately to or have been unable to tolerate treatment with lithium salts or other therapy (e.g., carbamazepine), particularly if the patient displays residual manic symptoms, or in the presence of rapid cycling, dysphoric mania or hypomania, associated neurologic abnormalities, or organic brain disorder.

■ **Migraine** ***Prophylaxis of Chronic Attacks*** Divalproex sodium is used in the prophylaxis of migraine headache, with or without associated aura; valproic acid† and sodium valproate† also have been used. Because there are only minor differences in the pharmacokinetics of the formulations, and because all forms of the drug circulate in plasma as valproic acid, the term "valproic acid" will be used in the following discussion. Because valproic acid may pose a hazard to the fetus (see Cautions: Pregnancy, Fertility, and Lactation), it should be considered for women of childbearing potential only after this risk has been discussed thoroughly with the patient and weighed against the potential benefits of treatment. Some clinicians state that effective contraception during valproic acid therapy should be strongly encouraged.

The US Headache Consortium states that there is good evidence from multiple well-designed clinical trials that valproic acid has medium to high efficacy for the prophylaxis of migraine headache. Valproic acid was demonstrated to be effective in the prophylaxis of migraine headache in 2 randomized, double-blind, placebo-controlled trials in patients with at least a 6-month history of migraine, with or without associated aura. Patients also had to experience at least 2 migraines per month in the 3 months prior to enrollment in the studies; patients were excluded if they had cluster headaches. Although women of childbearing potential were excluded from one study because of the teratogenic properties of valproic acid, they were included in the other, provided that they were practicing an effective form of contraception. In both studies, after a 4-week single-blind placebo baseline period, patients were randomized to receive either valproic acid or placebo during a 12-week treatment period consisting of a 4-week titration period and an 8-week maintenance period. Assessment of treatment outcome was based on 4-week migraine headache rates during the 12-week treatment period. In the first study, dosage titration was guided by the use of actual or sham trough total serum valproate concentrations for patients receiving valproic acid or placebo, respectively. The mean dosage of valproic acid was 1087 mg daily (range: 500–2500 mg daily), with dosages of more than 500 mg being given in 3 divided doses daily. Patients receiving valproic acid experienced a substantial decrease in the mean 4-week migraine headache rate compared with those receiving placebo (3.5 versus 5.7, respectively). In the second study, patients were randomized to receive (after titration from an initial dosage of 250 mg daily) 500, 1000, or 1500 mg of valproic acid daily or placebo, administered as 2 daily doses. Efficacy of valproic acid in the second study was to be determined by comparing the 4-week migraine headache rate in the combined groups of patients receiving 1000 and 1500 mg of valproic acid to that of patients receiving placebo. However, the manufacturer reports that the mean 4-week migraine headache rates in patients receiving valproic acid 500, 1000, or 1500 mg daily were 3.3, 3, or 3.3, respectively, compared to a rate of 4.5 in patients receiving placebo, and that the rate in the combined groups of patients receiving 1000 or 1500 mg daily was substantially lower than that of the placebo group.

In addition, valproic acid (given once daily as an extended-release tablet) was demonstrated to be effective in the prophylaxis of migraine headache in a 12-week, multicenter, double-blind, placebo-controlled clinical trial in patients with a history of migraine headaches with or without associated aura.

Other studies also have shown valproic acid to be effective in the prophylaxis of migraine. In one comparative single-blind, placebo-controlled, crossover study, valproic acid was shown to be as effective in migraine prophylaxis as propranolol.

Acute Attacks IV† valproate sodium has been used for the acute† management of migraine headache; however, the role of the drug relative to other acute therapies (selective serotonin type 1-like receptor agonists ["triptans"], ergot alkaloids, antiemetics, nonsteroidal anti-inflammatory agents [NSAIAs], butalbital-containing analgesics, opiate analgesics) requires further elucidation. Results of several studies, including open-label, comparative, randomized, prospective, retrospective, and/or double-blind, studies and at least one placebo-controlled study, as well as case reports, indicate that IV valproate sodium may alleviate acute migraine attacks in patients with or without aura and generally appears to be well tolerated. Efficacy generally was evaluated in terms of a reduction in headache severity as rated by the patient (i.e., a reduction in pain from severe or moderately severe to mild or absent usually using a 3- or 4-point scale) or by a visual analog pain score (VAS). Limited data indicate that 300-mg to 1-g IV valproate sodium doses (some of which were repeated at the same initial dose or less) were associated with relief of migraine headache, usually within 1 to several hours.

IV valproate sodium also has been used in the management of chronic daily headache† in a limited number of patients some of whom have had an inadequate response to dihydroergotamine or when dihydroergotamine was contraindicated.

Further study and experience are needed to more clearly define the role of IV valproate sodium in the management of acute migraine attacks and other headaches.

For further information on management and classification of migraine headache, see Vascular Headaches: General Principles in Migraine Therapy, under Uses, in Sumatriptan 28:32.28.

■ **Schizophrenia** Valproic acid or divalproex sodium has been used as an adjunct to antipsychotic agents in the symptomatic management of schizophrenia† in patients who fail to respond sufficiently to an adequate trial of an antipsychotic agent alone. The American Psychiatric Association (APA) and some clinicians state that anticonvulsant agents such as valproic acid or divalproex sodium may be useful adjuncts in schizophrenic patients with prominent mood lability or with agitated, aggressive, hostile, or violent behavior. In general, for such adjunctive therapy, valproic acid or divalproex sodium is administered in the same dosage and with the same resulting therapeutic plasma concentrations as that in the management of seizure disorders. The APA states that, with the exception of patients with schizophrenia whose illness has strong affective components, valproic acid or divalproex sodium alone has not been shown to be substantially effective in the long-term treatment of schizophrenia.

While some evidence suggested potential benefit of valproic acid in relieving tardive dyskinesia in patients receiving long-term antipsychotic drug therapy†, recent systematic review of randomized controlled trials with nonbenzodiazepine γ-aminobutyric acid (GABA) agonists such as valproic acid found the evidence for such benefit unconvincing, and indicated that any possible benefit may be outweighed by adverse effects. For additional information on the management of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Other Uses** Some experts recommend use of valproic acid for the treatment of aggressive outbursts in children with ADHD. For a more detailed discussion on the management of ADHD, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.04.

Valproic acid used alone or in conjunction with GABA was ineffective in the treatment of chorea† (including Huntington's chorea). Valproic acid has been effective in a limited number of patients with organic brain syndrome†.

Dosage and Administration

■ **Administration** Valproate sodium can be administered orally or by IV infusion and valproic acid and divalproex sodium are administered orally. Valproic acid also has been administered rectally by enema or in wax-based suppositories.

Patients who are currently receiving or beginning therapy with valproic acid, valproate sodium, or divalproex sodium and/or any other anticonvulsant for any indication should be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. (See Cautions: Nervous System Effects and Cautions: Precautions and Contraindications.)

Oral Administration Valproic acid, valproate sodium, and divalproex sodium are administered orally. Valproic acid capsules should be swallowed whole; not chewed, in order to prevent local irritation to the mouth and throat. If GI irritation occurs, the drug may be administered with food. Patients who are unable to tolerate the GI effects of valproic acid or valproate sodium may tolerate divalproex sodium. When switching to divalproex sodium delayed-release tablets in patients receiving valproic acid, the same daily dose and schedule should be used. After stabilization with divalproex sodium therapy, the daily dose may be divided and administered 2 or 3 times daily in selected patients. Extended-release tablets of divalproex sodium are administered once daily; patients should be advised that the extended-release tablets must be swallowed intact and not chewed or crushed. Valproate sodium oral solution should not be administered in carbonated drinks because valproic acid will be liberated and may cause local irritation to the mouth and throat as well as an unpleasant taste.

The commercially available capsules containing coated particles of divalproex sodium (Depakote®) may be swallowed intact or the entire contents of

the capsule(s) may be sprinkled on a small amount (about 5 mL) of semisolid food (e.g., applesauce, pudding) immediately prior to administration. The mixture containing coated particles from the capsules should not be chewed. The mixture of coated particles and semisolid food should not be stored for future use. Patients receiving divalproex sodium capsules containing coated particles should be instructed not to be concerned if they notice coated particles in their stool, because these particles do not completely dissolve and may be passed in the stool.

The manufacturer states that although the extent of GI absorption of valproic acid from capsules containing coated particles or delayed-release tablets of divalproex sodium is equivalent, peak and trough plasma concentrations achieved with these dosage forms may vary (e.g., higher peak valproic acid concentrations generally are achieved with the delayed-release tablets). Although these differences are unlikely to be clinically important, increased monitoring of plasma valproic acid concentrations is recommended if one dosage form is substituted for the other.

The manufacturer states that although it is agreed that pharmacologic treatment beyond an initial response in patients with manic episodes is desirable, both for the maintenance of initial response and for prevention of new manic episodes, the safety and efficacy of long-term (i.e., longer than 3 weeks) valproic acid therapy for manic episodes have not been established in controlled clinical trials and that clinicians who elect to use such therapy for extended periods (i.e., longer than 3 weeks) should continually reevaluate the usefulness of valproic acid therapy in the individual patient. The manufacturer states that the safety of valproic acid for longer-term antimanic therapy is supported by data from record reviews involving approximately 360 patients treated for longer than 3 months.

IV Administration Valproate sodium injection is intended for IV use only.

For IV use, the manufacturer states that the appropriate dose of valproate sodium injection should be diluted with at least 50 mL of a compatible IV solution (e.g., 5% dextrose injection, 0.9% sodium chloride injection, lactated Ringer's injection). Diluted IV solutions of the drug should be infused IV over 60 minutes.

Rapid IV infusion of valproate sodium has been associated with an increased risk of adverse effects and is not currently included in the manufacturer's labeling. However, rates exceeding 20 mg/minute or infusion periods less than 60 minutes have been studied in a limited number of patients with seizure disorders and in patients with acute migraine headaches, and such administration generally appeared to be well tolerated. In a study of the safety of initial 5- to 10-minute IV infusions of valproate sodium (1.5–3 mg/kg per minute of valproic acid), patients generally tolerated such rapid infusions of the drug; the study was not designed to assess the efficacy of the regimen. The drug also appeared to be well tolerated in studies evaluating efficacy in the management of acute migraine attacks† when valproate sodium doses of 300 mg to 1 g were infused IV at rates ranging from 17–250 mg/minute or occasionally by direct rapid ("bolus") IV injection (100-mg doses).

Use of rapid infusions in patients receiving the IV preparation as a parenteral replacement for oral valproic acid has not been established.

Valproate sodium injection and diluted solutions of the drug should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

■ **Dosage** Dosage of valproate sodium and divalproex sodium is expressed in terms of valproic acid. Dosage must be carefully and slowly adjusted according to individual requirements and response.

Seizure Disorders **IV Dosage.** IV valproate sodium therapy may be employed in patients in whom oral therapy is temporarily not feasible, but therapy should be switched to oral administration as soon as clinically possible. IV administration of the drug can be used for monotherapy or as adjunctive therapy in the management of seizure disorders. The manufacturer states that the usual total daily dosages of valproic acid are equivalent for IV or oral administration, and the doses and frequency of administration employed with oral therapy in seizures disorders are expected to be the same with IV therapy, although plasma concentration monitoring and dosage adjustment may be necessary. The use of IV therapy for longer than 14 days has not been studied to date. The manufacturer also states that the use of IV valproate sodium for initial monotherapy has not been systematically studied; however, usual dosages and titration employed with oral therapy can be employed with parenteral therapy. Patients receiving dosages near the maximum recommended dosage of 60 mg/kg daily should be monitored closely, particularly when enzyme-inducing drugs are not used concomitantly.

Oral Dosage. Various valproic acid dosage regimens have been used in published studies. A correlation between plasma valproic acid concentration and therapeutic effect has not been established; however, a therapeutic range of 50–100 mcg/mL has been suggested.

For the management of complex partial seizures, the manufacturers state that the usual initial dosage of valproic acid as monotherapy or as adjunctive therapy, when being added to a current therapeutic regimen, for adults and children 10 years of age and older is 10–15 mg/kg daily. For the management of simple or complex absence seizures, the manufacturer states that the usual initial dosage of valproic acid is 15 mg/kg daily. Dosage may be increased by 5–10 mg/kg daily at weekly intervals until seizures are controlled or adverse effects prevent further increases in dosage. The manufacturers state that the maximum recommended dosage is 60 mg/kg daily. These dosage recommendations also apply when anticonvulsant therapy is being initiated with divalproex sodium as delayed- or extended-release formulations.

When converting a patient from a current anticonvulsant to valproic acid therapy for the treatment of complex partial seizures, valproic acid therapy should be initiated at usual starting doses. The dose of the current anticonvulsant may be decreased by 25% every 2 weeks, either starting concomitantly with the initiation of valproic acid therapy or delayed by 1–2 weeks if there is a concern that seizures are likely to occur with a reduction. The speed and duration of withdrawal of the current anticonvulsant can be highly variable, and patients should be monitored closely during this period for increased seizure frequency. In order to prevent adverse GI effects, the manufacturers state that the drug should be administered in 2 or more divided doses when the dosage exceeds 250 mg daily. When divalproex sodium delayed-release tablets are administered, a twice-daily dosing regimen is suggested whenever feasible and appears to adequately maintain plasma valproic acid concentrations in most patients receiving the drug. The frequency of adverse effects (particularly hepatic effects) may be dose related. The benefit of improved seizure control which may accompany higher dosages should therefore be weighed carefully against the risk of adverse effects.

When converting a patient whose seizure disorder is controlled with delayed-release divalproex sodium tablets to the extended-release tablets, the drug should be administered once daily using a total daily dose that is 8–20% higher than the corresponding delayed-release dosage that the patient was receiving. For patients whose delayed-release daily dosage cannot be directly converted to a corresponding commercially available extended-release dosage, clinicians may consider increasing the delayed-release total daily dosage to the next higher dosage before converting to the appropriate extended-release dosage.

For the management of status epilepticus refractory to IV diazepam†, 400–600 mg of valproic acid was administered rectally† by enema or in wax base suppositories at 6-hour intervals.

Bipolar Disorder The initial dosage of valproic acid in the treatment of manic episodes is 750 mg daily in divided doses. The dose of valproic acid should be increased as quickly as possible to achieve the lowest therapeutic dose producing the desired clinical effect or desired serum concentration; however, the manufacturer recommends that the dose not exceed 60 mg/kg daily. In placebo-controlled studies of valproic acid for the treatment of manic episodes, the trough serum valproic acid concentration that produced the desired clinical effect ranged from 50–125 mcg/mL. Maximum serum concentrations generally were achieved within 14 days after initiating therapy.

Dosing guidelines for maintenance therapy† with valproic acid are less evidence-based than those for acute therapy, and dosages lower than those employed for acute therapy occasionally have been used. A 1-year study with divalproex sodium found an association between higher serum concentrations and increased appetite and decreased platelet and leukocyte counts.

Migraine **Prophylaxis of Chronic Attacks.** In the prophylaxis of migraine, with or without associated aura, the recommended initial dosage of valproic acid is 250 mg twice daily. Some patients may benefit from doses of up to 1 g daily; however, in clinical trials, there was no evidence that doses of valproic acid exceeding this resulted in greater efficacy.

For the prophylaxis of migraine headache in adults, the recommended initial dosage of divalproex sodium as extended-release tablets is 500 mg once daily for 1 week; dosage may then be increased to 1 g once daily. Although maintenance dosages other than 1 g once daily have not been evaluated in patients with migraine headache, the effective dosage range for these patients is 500 mg to 1 g daily. It should be considered that divalproex sodium extended-release tablets and divalproex sodium delayed-release tablets are *not* bioequivalent. If a patient requires smaller dosage adjustment than that available using the extended-release tablets, the delayed-release tablets should be used instead. If a patient misses a dose of divalproex sodium extended-release tablets, the dose should be taken as soon as possible, unless it is almost time for the next dose. However, if the patient skips a dose, a double dose of divalproex sodium extended-release tablets should *not* be taken to make up for the missed dose.

Acute Attacks. For the acute management of migraine headache† in adults and adolescents, the optimum IV dosage, frequency, and rate of administration have not been established. In most reports, IV valproate sodium was given in doses of 300 mg to 1 g diluted in a compatible IV infusion (e.g., 5% dextrose injection, 0.9% sodium chloride injection) solution (usually about 100–250 mL) and infused IV at rates ranging from 17–100 mg/minute. In some patients, the dose was administered more rapidly (e.g., 500 mg over 2 minutes, 100 mg by direct ["bolus"] IV injection). A repeat dose (equal to the initial dose or less) was given to some patients within a few hours, if reduction of pain was not sufficient. In one study, 500-mg doses of valproate sodium were administered every 8 hours for 2 days. Some patients have received direct IV injections of 100-mg doses repeated at 5-minute intervals or infusions of a single 500-mg dose (diluted in 5 mL of 0.9% sodium chloride injection) into a free-flowing IV line of 0.9% sodium chloride injection.

When IV valproate sodium has been used in the management of chronic daily headache, an initial dose of 15 mg/kg was administered over 30 minutes followed by a dose of 5 mg/kg (infused over 15 minutes) given every 8 hours.

Dosage in Geriatric Patients Because of a decrease in unbound clearance of valproic acid, the starting dosage should be reduced. Subsequent dosage should be increased more slowly in geriatric patients. In addition, the manufacturer recommends regular monitoring of fluid and nutritional intake, dehydration, somnolence, and other adverse effects in these individuals. Dosage reduction or discontinuance of valproic acid should be considered in geriatric patients with decreased food or fluid intake and in those with excessive somnolence. The ultimate therapeutic dosage in these patients should be determined on the basis of tolerability and clinical response.

Cautions

The adverse effect profile of parenteral valproate sodium can be expected to include all of the effects associated with oral administration of the drug. In addition, IV infusion of valproate sodium may cause local effects at the injection site and effects associated with the rate of infusion. (See Cautions: Local and Infusion-related Effects.)

■ **GI Effects** Nausea, vomiting, abdominal pain, anorexia, diarrhea, and dyspepsia may occur in patients receiving valproic acid. The most frequent adverse effects of valproic acid following initiation of therapy with the drug are nausea, vomiting, and indigestion. These adverse effects usually are transient, rarely require discontinuance of therapy, and can be minimized by administering the drug with meals or by beginning therapy with low doses and increasing the dose very gradually. While divalproex sodium shares the toxic GI potential of valproic acid, the frequency of adverse GI effects appears to be lower and the effects possibly less severe with divalproex sodium than with valproic acid; patients who are unable to tolerate the GI effects of valproic acid or valproate sodium may tolerate divalproex sodium, but GI intolerance to divalproex sodium can also occur. Both anorexia with some weight loss and increased appetite with weight gain have been reported in patients receiving valproic acid. Eructation, fecal incontinence, gastroenteritis, glossitis, flatulence, hematemesis, periodontal abscess, tooth disorder, dry mouth, stomatitis, and constipation were reported in 1–5% of patients receiving valproic acid in clinical trials. Dysphagia, gum hemorrhage, and mouth ulceration also have occurred in greater than 1% of patients receiving the drug.

■ **Pancreatitis** Cases of life-threatening pancreatitis have been reported in children and adults shortly after initial use or after several years of therapy with valproic acid. Pancreatitis may be hemorrhagic with a rapid progression from initial symptoms to death. Development of manifestations suggestive of pancreatitis (e.g., abdominal pain, nausea, vomiting, and/or anorexia) requires prompt medical evaluation. (See Cautions: Precautions and Contraindications.) It should be considered that patients receiving valproic acid are at greater risk of developing pancreatitis than that expected in the general population and, in addition, pancreatitis recurred on rechallenge with the drug in several patients. In clinical trials involving 2416 patients, 2 cases of pancreatitis without alternative etiology were reported, representing 1044 patient-years experience.

■ **Nervous System Effects** Sedation and drowsiness may occur with valproic acid therapy, especially in patients receiving other anticonvulsants. (See Drug Interactions: CNS Depressants, Antidepressants, and Anticonvulsants.) Somnolence, asthenia, dizziness, and tremor generally are the most frequently reported adverse nervous system effects in patients receiving valproic acid in clinical trials. Ataxia, emotional lability, abnormal thinking, amnesia, and depression have been reported in up to 5–8% of patients receiving the drug. Some patients have reported increased alertness, insomnia, and nervousness during valproic acid therapy. Coma has been reported rarely in patients receiving valproic acid as monotherapy or in combination with phenobarbital. Rarely, patients have developed encephalopathy with or without fever, without evidence of hepatic dysfunction or abnormal valproic acid plasma concentrations, shortly after the introduction of valproic acid therapy. Although this condition can be reversible upon discontinuance of the drug, there have been fatalities in patients with hyperammonemic encephalopathy, often in patients with underlying urea cycle disorder. (See Cautions: Precautions and Contraindications.) Hearing loss, either reversible or irreversible, has been reported in patients receiving valproic acid therapy; however, a causal relationship to the drug has not been established.

Between 1–5% of patients receiving valproic acid in clinical trials experienced anxiety, confusion, headache, myasthenia, abnormal gait, paresthesia, hypertonia, incoordination, abnormal dreams, personality disorder, hallucinations, euphoria, agitation, catatonia, dysarthria, speech disorder, hypokinesia, increased reflexes, tardive dyskinesia, or vertigo. Asterixis, hypesthesia, parkinsonism, hostility, emotional upset, and psychosis/acute psychosis also have occurred rarely. Hyperactivity, aggressiveness, and other behavioral disturbances have been reported in a few children receiving valproic acid. Several reports have noted reversible cerebral atrophy and dementia in association with valproic acid therapy.

The US Food and Drug Administration (FDA) has analyzed suicidality reports from placebo-controlled studies involving 11 anticonvulsants, including valproic acid, and found that patients receiving anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%). FDA's analysis included 199 randomized, placebo-controlled studies of 11 anticonvulsants (carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, and zonisamide) involving over 43,000 patients 5 years of age or older; the studies evaluated the effectiveness of the anticonvulsants in epilepsy, psychiatric disorders (e.g., bipolar disorder, depression, anxiety), and other conditions (e.g., migraine, neuropathic pain). This increased suicidality risk was observed as early as one week after beginning therapy and continued through 24 weeks. The results were generally consistent among the 11 drugs studied. In addition, patients who were treated for epilepsy, psychiatric disorders, and other conditions were all found to be at increased risk for suicidality when compared with placebo; there did not appear to be a specific demographic subgroup of patients to which the increased risk could be attributed. However, the relative risk for suicidality was found to be higher in patients with epilepsy compared with patients who were given one of the drugs for psychiatric or other conditions. (See Cautions: Precautions and Contraindications.)

■ **Hepatic Effects** Minor elevations in serum concentrations of aminotransferases (transaminases) and lactate dehydrogenase occur frequently in patients receiving valproic acid and appear to be dose related. Occasionally, increases in serum bilirubin concentration and abnormal changes in other hepatic function test results occur; these results may reflect potentially serious hepatotoxicity. (See Cautions: Precautions and Contraindications.) Hepatic failure resulting in death has occurred in patients receiving valproic acid, usually during the first 6 months of therapy. Clinical experience indicates that children younger than 2 years of age, especially those receiving multiple anticonvulsants or those with congenital metabolic disorders, severe seizure disorders accompanied by mental retardation, or organic brain disease, have a considerably increased risk of developing fatal hepatotoxicity compared with older patient groups. (See Cautions: Precautions and Contraindications.) Above 2 years of age, the frequency of fatal hepatotoxicity decreases considerably in progressively older patient groups. Severe or fatal hepatotoxicity induced by valproic acid may be preceded by nonspecific symptoms such as loss of seizure control, malaise, weakness, lethargy, anorexia, and vomiting.

Between 1–5% of patients receiving valproic acid in clinical trials experienced increased ALT (SGPT) and increased AST (SGOT) concentrations.

■ **Endocrine and Metabolic Effects** Hyperammonemic encephalopathy, including some fatalities, has been reported in patients with urea cycle disorders, particularly ornithine carbamoyltransferase deficiency, following initiation of valproic acid therapy. Hyperammonemia may occur in patients receiving valproic acid and may occur in the absence of abnormal hepatic function test results. Development of symptoms of unexplained hyperammonemic encephalopathy (e.g., lethargy, vomiting, changes in mental status) requires prompt medical evaluation. (See Cautions: Precautions and Contraindications.)

Hyponatremia and inappropriate antidiuretic hormone (ADH) secretion also have been reported. Hyperglycinemia has been reported in patients receiving valproic acid and was associated with a fatal outcome in one patient with preexisting nonketotic hyperglycinemia. Between 1–5% of patients receiving valproic acid in clinical trials experienced dysmenorrhea, amenorrhea, vaginitis, metrorrhagia, or vaginal hemorrhage. Breast enlargement, galactorrhea, irregular menses, polycystic ovaries, hyperandrogenism, weight gain, Fanconi's syndrome (principally reported in children), and parotid gland swelling have occurred in some patients receiving valproic acid. Abnormal thyroid function test results and decreased carnitine concentrations also have been reported; however, the clinical importance of these abnormalities has not been elucidated.

■ **Hematologic Effects** Valproic acid inhibits the secondary phase of platelet aggregation and may prolong bleeding time. In one study of valproic acid monotherapy for seizures, 27% of patients receiving approximately 50 mg/kg per day had at least one platelet count of 75,000/mm^3. Approximately half of the patients discontinued therapy, with their platelet counts returning to normal; the remaining patients experienced normalization of their platelet counts with continued valproic acid therapy. In this study, the probability of thrombocytopenia appeared to increase significantly at total valproate serum concentrations of 110 mcg/mL or greater (females) or 135 mcg/mL or greater (males). Ecchymosis, petechiae, bruising, hematoma formation, epistaxis, frank hemorrhage, lymphocytosis, leukopenia, eosinophilia, macrocytosis, acute intermittent porphyria, decreased fibrinogen concentrations, anemia (including macrocytic anemia, with or without folate deficiency), bone marrow suppression, pancytopenia, and aplastic anemia also have been reported.

■ **Dermatologic and Sensitivity Reactions** Between 1–5% of patients receiving valproic acid in clinical trials experienced seborrhea, dry skin, pruritus, furunculosis, rash (including maculopapular), or discoid lupus erythematosus. Transient alopecia, cutaneous vasculitis, generalized pruritus, anaphylaxis, photosensitivity, Stevens-Johnson syndrome, erythema nodosum, and erythema multiforme have been reported in patients receiving valproic acid therapy. Rare cases of toxic epidermal necrolysis have been reported, including a fatal case in a 6-month-old infant receiving valproic acid therapy; however, the infant was receiving other drugs concomitantly. An additional case of fatal toxic epidermal necrosis was reported in a 35-year-old patient with acquired immunodeficiency syndrome (AIDS) who was taking several concomitant drugs and who had a history of multiple cutaneous drug reactions.

■ **Local and Infusion-related Effects** In addition to the usual adverse effects associated with oral therapy, IV infusion of valproate sodium can produce local effects at the site of injection as well as adverse effects associated with the rate of IV infusion. In clinical trials involving healthy adults as well as patients with seizure disorders at total IV dosages of 120–6000 mg daily, adverse local effects at the site of infusion were reported in up to 2.6% of patients and included pain (2.6%), injection site reaction (2.4%), and inflammation (0.6%). In these trials, about 2% of patients discontinued parenteral therapy with the drug because of adverse effects, principally because of nausea and vomiting and elevated amylase. Other reasons for discontinuing parenteral valproate sodium therapy included hallucinations, pneumonia, headache, injection site reaction, and abnormal gait.

Dizziness and injection site pain were reported more frequently when valproate sodium was infused IV at a rate of 100 mg/minute relative to slower rates that ranged up to 33 mg/minute. At an IV infusion rate of 200 mg/minute, dizziness and taste perversion occurred more frequently than at an IV infusion rate of 100 mg/minute. In clinical trials, the maximum IV infusion rate studied was 200 mg/minute.

■ **Ocular and Otic Effects** Diplopia, amblyopia, nystagmus, and tinnitus have been reported in up to 7–16% of patients receiving valproic acid in clinical trials. Other adverse ocular and otic effects reported in patients receiv-

ing valproic acid include abnormal vision, otitis media, conjunctivitis, dry eyes, ocular pain, ocular disorder, photophobia, otic pain, and otic disorder. Reversible and irreversible hearing loss (including deafness) has been reported; however, a causal relationship has not been established.

■ **Other Adverse Effects** Infection has been reported in up to 20% of patients receiving valproic acid in clinical trials. Back pain, fever, flu syndrome, bronchitis, rhinitis, pharyngitis, dyspnea, and peripheral edema have been reported in up to 5–12% of patients receiving the drug in clinical trials. Increased cough, chest pain, tachycardia, hypertension, palpitation, arrhythmia, bradycardia, hypotension, postural hypotension, taste perversion, hiccups, facial edema, pneumonia, sinusitis, dysuria, urinary incontinence, cystitis, urinary frequency, arthralgia, myalgia, arthrosis, leg cramps, twitching, malaise, chills, fever with chills, sweating, vasodilation, cyst, neck pain, neck rigidity, and accidental injury also may occur. Adverse effects reported rarely in patients receiving valproic acid include muscular weakness, interstitial nephritis, enuresis, urinary tract infection, bone pain, lupus erythematosus, and fatigue. A case of reversible skeletal muscle weakness and ventilatory failure also has been reported in a geriatric patient receiving valproic acid therapy.

■ **Precautions and Contraindications** Since divalproex sodium is a prodrug of valproate, it shares the toxic potentials of valproic acid, and the usual cautions, precautions, and contraindications of valproic acid therapy should be observed with divalproex sodium therapy.

Patients should be warned that valproic acid may impair ability to perform hazardous activities requiring mental alertness or physical coordination (e.g., operating machinery or driving a motor vehicle).

FDA has informed healthcare professionals about an increased risk of suicidality (suicidal behavior or ideation) observed in an analysis of studies using various anticonvulsants compared with placebo. (See Cautions: Nervous System Effects.) FDA recommends that all patients who are currently receiving or beginning therapy with any anticonvulsant for any indication be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or unusual changes in mood or behavior. Symptoms such as anxiety, agitation, hostility, mania, and hypomania may be precursors to emerging suicidality. Clinicians should inform patients, their families, and caregivers of the potential for an increased risk of suicidality so that they are aware and able to notify their clinician of any unusual behavioral changes. Patients, family members, and caregivers also should be advised not to make any changes to the anticonvulsant regimen without first consulting with the responsible clinician. They should pay close attention to any day-to-day changes in mood, behavior, and actions; since changes can happen very quickly, it is important to be alert to any sudden differences. In addition, patients, family members, and caregivers should be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). If these or any new and worrisome behaviors occur, the responsible clinician should be contacted immediately. FDA also recommends that clinicians who prescribe valproic acid or any other anticonvulsant balance the risk for suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician must consider whether the emergence of these symptoms in any given patient may be related to the illness being treated.

Results of in vitro studies indicate that valproate appears to stimulate replication of some strains of human immunodeficiency virus (HIV) and cytomegalovirus (CMV) under certain experimental conditions. The clinical importance of these in vitro findings, including any relevance to patients receiving maximally suppressive antiretroviral therapy, is not known. (See Pharmacology: Antiviral Effects.) It has been suggested that these in vitro effects should be considered when interpreting test results concerning the clinical condition of HIV-infected patients (e.g., plasma HIV RNA levels) or patients with CMV infection.

Since valproic acid may cause serious and potentially fatal hepatotoxicity, hepatic function tests should be performed before and at frequent intervals during therapy with the drug, especially during the first 6 months. Since results of hepatic function tests may not be abnormal in all instances, clinicians must also consider the results of careful interim medical history and physical examination of the patient. Valproic acid therapy should be discontinued immediately in the presence of suspected or apparent substantial hepatic dysfunction. In some patients, hepatic dysfunction has progressed despite discontinuance of the drug. Since elevations in hepatic enzyme concentrations may be dose related, the benefit of improved seizure control which may accompany higher doses of the drug must be weighed against the potential risks. Valproic acid should be used with caution in patients with a history of hepatic disease. Children and patients receiving multiple anticonvulsants or those with congenital metabolic disorders, severe seizure disorders accompanied by mental retardation, or organic brain disease may be at particular risk of hepatotoxicity. Because children younger than 2 years of age, especially those with the previously listed conditions, have a considerably increased risk of developing fatal hepatotoxicity compared with older patient groups, valproic acid should be used in these patients only with extreme caution and as a single agent; the benefits of seizure control must be weighed against the potential risks. Above 2 years of age, the frequency of fatal hepatotoxicity decreases considerably in progressively older patient groups. Valproic acid should *not* be used in patients with hepatic disease or substantial hepatic dysfunction.

Because the use of valproic acid has been associated with life-threatening pancreatitis in children and adults (see Cautions: Pancreatitis), patients and guardians should be instructed that if symptoms of pancreatitis (e.g., abdominal pain, nausea, vomiting, anorexia) develop, prompt medical evaluation is needed. If pancreatitis is diagnosed, valproic acid usually should be discontinued and alternative therapy for the underlying medical condition should be initiated as clinically indicated.

Because the use of valproic acid has been associated with hyperammonemic encephalopathy, patients should be advised that if symptoms of this disorder (e.g., lethargy, vomiting, changes in mental status) develop, they should notify their clinician promptly. (See Cautions: Endocrine and Metabolic Effects.) If such symptoms are present, plasma ammonia concentrations should be determined, and, if these concentrations are increased, valproic acid therapy should be discontinued. Appropriate treatment of hyperammonemia should be initiated and the patient should be evaluated for urea cycle disorders. Asymptomatic elevation of ammonia concentrations is more common than hyperammonemic encephalopathy. In patients with asymptomatic elevations, plasma ammonia concentrations should be closely monitored and, if elevations persist, discontinuance of valproic acid therapy should be considered. Prior to the initiation of valproic acid therapy, an evaluation for urea cycle disorders should be considered in patients with a history of unexplained encephalopathy or coma, encephalopathy associated with a protein load, pregnancy-related or postpartum encephalopathy, unexplained mental retardation, or history of elevated plasma ammonia or glutamine concentrations; patients with cyclical vomiting and lethargy, episodic extreme irritability, ataxia, low BUN concentration, or protein avoidance; patients with a family history of urea cycle disorders or unexplained infant deaths (particularly males); and patients with other signs or symptoms of urea cycle disorders.

Anticonvulsant drugs (including valproic acid) should not be discontinued abruptly in patients receiving the drugs to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life.

Since valproic acid may cause thrombocytopenia and inhibit platelet aggregation, platelet counts, bleeding time, and coagulation studies should be determined before and periodically during therapy with the drug and before surgery is performed in patients receiving the drug. In one study of the drug as monotherapy for seizures, 27% of patients receiving approximately 50 mg/kg per day of valproic acid had at least one platelet count of 75,000/mm^3 or less; the probability of thrombocytopenia appeared to increase significantly at total serum valproate concentrations of 110 mcg/mL or greater (females) or 135 mcg/mL or greater (males). Some clinicians have recommended thromboelastography as a more reliable method to assess the effects of valproic acid on coagulation. If clinical evidence of hemorrhage, bruising, or a disorder of hemostasis coagulation occurs during valproic acid therapy, dosage should be reduced or the drug withdrawn pending further evaluation.

Valproic acid is contraindicated in patients with known hypersensitivity to the drug. Valproic acid also is contraindicated in patients with known urea cycle disorders. (See Cautions: Endocrine and Metabolic Effects.)

■ **Pediatric Precautions** Experience with valproic acid therapy in the management of seizures indicates that children younger than 2 years of age are at an increased risk of developing fatal hepatotoxicity. (See Cautions: Precautions and Contraindications.) The drug should be used with extreme caution and as single-agent therapy in such children, and the benefits of valproic acid therapy weighed against the risks. The incidence of fatal hepatotoxicity decreases considerably in progressively older patient groups (i.e., older than 2 years of age).

Younger children, especially those receiving enzyme-inducing drugs, will require larger maintenance doses to attain targeted total and unbound valproic acid concentrations for the management of seizures. The variability in free fraction limits the clinical usefulness of monitoring total serum valproic acid concentrations alone. Interpretation of valproic acid concentration in children should include consideration of factors that affect hepatic metabolism and protein binding.

The safety and efficacy of valproic acid for acute manic episodes in patients younger than 18 years of age and for migraine prophylaxis in patients younger than 16 years of age have not been established. In addition, safety and efficacy of divalproex sodium extended-release tablets in pediatric patients have not been established and use of this preparation in this age group is not recommended.

The safety of valproate sodium injection has not been studied in pediatric patients younger than 2 years of age. If a decision is made to use the injection in this age group, the manufacturer states that it should be used with extreme caution and only as monotherapy, and the potential benefits should be weighed against the possible risks. No unusual adverse effects were observed in clinical trials employing IV valproate sodium for the management of seizure disorders in 24 pediatric patients 2–17 years of age.

■ **Geriatric Precautions** The safety and efficacy of valproic acid in geriatric patients (older than 65 years of age) for the treatment of manic episodes associated with bipolar disorder or prevention of migraine headaches have not been established.

In a case review of almost 600 patients treated with valproic acid for manic episodes, approximately 12% of patients were older than 65 years of age. A higher percentage of these patients reported accidental injury, infection, pain, somnolence, or tremor during valproic acid therapy compared with younger patients. Discontinuance of valproic acid therapy occasionally was associated with somnolence or tremor. The manufacturer states that it is unclear whether these events indicate additional risks of drug therapy or whether they result

from preexisting medical conditions or concomitant medication use in these geriatric patients.

Results of a double-blind, multicenter study of geriatric patients (mean age: 83 years) with dementia who were receiving valproic acid (125 mg daily, titrated to a target daily dosage of 20 mg/kg) indicate that the incidence of somnolence was higher in patients receiving valproic acid than in those receiving placebo and discontinuance of therapy because of somnolence was higher in those receiving valproic acid than in those receiving placebo. In about 50% of patients with somnolence, a reduced nutritional intake and weight loss also were observed. The incidence of dehydration also appeared to be higher in geriatric patients receiving valproic acid than in those receiving placebo. In the patients who experienced the mentioned adverse effects, a trend for lower baseline albumin concentration, lower valproic acid clearance, and higher BUN was observed. Therefore, it is recommended that initial dosage of valproic acid be reduced and subsequent dosages be increased more slowly in geriatric patients. In addition, the manufacturer recommends regular monitoring of fluid and nutritional intake, dehydration, somnolence, and other adverse effects in these individuals. Dosage reduction or discontinuance of valproic acid should be considered in geriatric patients with decreased food or fluid intake and in those with excessive somnolence.

■ **Mutagenicity and Carcinogenicity** Studies of valproic acid that used bacterial and mammalian test systems have shown no evidence to date of a mutagenic potential for the drug.

In rats and mice receiving valproic acid dosages of 80 and 170 mg/kg daily for 2 years, an increased incidence of subcutaneous fibrosarcomas occurred in male rats at the higher dosage level and a dose-related trend for an increased incidence of benign pulmonary adenomas was observed in male mice. The importance of these findings to humans is not known.

■ **Pregnancy, Fertility, and Lactation** Safe use of valproic acid during pregnancy has not been established. Adverse fetal effects have been observed in reproduction studies in rats and mice. Valproic acid can cause teratogenic effects in humans, such as neural tube defects (e.g., spina bifida). Several reports suggest an association between use of valproic acid in pregnant, epileptic women and an increased incidence of birth defects (particularly neural tube defects) in children born to these women; such malformations may be associated with high plasma concentrations during the first trimester. Some experts state that prophylactic use of folic acid may prevent or decrease the incidence of neural tube defects. Valproic acid should be used in pregnant women with seizure disorders or women with seizure disorders who might become pregnant only if the drug is clearly shown to be essential in the management of their seizures. Women should be apprised of the potential hazard to the fetus; this is especially important when valproic acid therapy is being contemplated or used for the management of a spontaneously reversible condition not ordinarily associated with permanent injury or risk of death (e.g., prophylaxis of migraine headache). Tests to detect neural tube and other defects using current accepted procedures should be considered a part of routine prenatal care in childbearing women receiving valproic acid for the management of seizure disorders.

Other congenital anomalies (e.g., craniofacial defects, cardiovascular malformations, anomalies involving various body systems) compatible and incompatible with life also have been reported in children of women treated with valproic acid during pregnancy; sufficient data to determine the incidence of these anomalies are not available. The higher incidence of congenital anomalies in the children of women with seizure disorders treated with anticonvulsant drugs during pregnancy cannot be regarded as a direct effect of such therapy. There are intrinsic methodologic problems in obtaining adequate drug teratogenicity data in humans. Genetic factors and/or the epileptic disorder also may contribute to the development of congenital anomalies.

Patients receiving valproic acid may develop clotting abnormalities. A pregnant patient taking multiple anticonvulsant agents, including valproic acid, developed hypofibrinogenemia; the patient then gave birth to an infant with afibrogenemia, who subsequently died of hemorrhage. If valproic acid is to be used during pregnancy, clotting parameters should be monitored closely. Hepatic failure, resulting in the death of a neonate and an infant, also has been reported following the use of valproic acid during pregnancy.

Anticonvulsant drugs should *not* be discontinued in pregnant women in whom the drugs are administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases when the severity and frequency of the seizure disorder are such that discontinuance of therapy does not pose a serious threat to the patient, discontinuance of the drugs may be considered prior to and during pregnancy; however, it cannot be stated with any certainty that even minor seizures do not pose some hazard to the fetus. The clinician should carefully weigh these considerations in treating or counseling epileptic women of childbearing potential.

The effect of valproic acid on the development of the testes and on sperm production and fertility in humans is not known. Chronic toxicity studies in rats and dogs demonstrated reduced spermatogenesis and testicular atrophy. Further animal studies are ongoing.

Since valproic acid is distributed into milk, the drug should be used with caution in nursing women; the potential effects on a nursing infant are not known.

Drug Interactions

■ **CNS Depressants, Antidepressants, and Anticonvulsants** Additive CNS depression may occur when valproic acid is administered concomitantly with other CNS depressants including other anticonvulsants (particularly phenobarbital and primidone) and alcohol. If valproic acid is used in conjunction with other CNS depressant drugs including alcohol, caution should be used to avoid overdosage.

Valproic acid displaces diazepam from its albumin binding sites and also inhibits its metabolism. In a study in a limited number of healthy individuals, coadministration of valproic acid (1.5 g daily) increased the free fraction of diazepam (10 mg) by 90%; plasma clearance and volume of distribution of free diazepam were decreased by 25% and 20%, respectively. The elimination half-life of diazepam was unaffected by concomitant valproic acid administration.

Concomitant use of amitriptyline (a single 50-mg oral dose) and valproic acid (500 mg twice daily) resulted in a 21% decrease in the plasma clearance of amitriptyline and a 34% decrease in the net clearance of nortriptyline (the pharmacologically active metabolite of amitriptyline). In addition, increased amitriptyline concentrations have been reported rarely in patients receiving amitriptyline concomitantly with valproic acid; concomitant use has rarely been associated with toxicity. The manufacturer states that monitoring of amitriptyline concentrations should be considered for patients receiving valproic acid concomitantly with amitriptyline.

Because valproic acid may potentiate the effects of monoamine oxidase inhibitors and other antidepressants, dosage reduction of these drugs may be necessary if valproic acid is administered to patients receiving antidepressants.

Valproic acid inhibits the metabolism of ethosuximide. Administration of a single 500-mg dose of ethosuximide to a limited number of healthy individuals receiving valproic acid (800–1600 mg daily) resulted in a 25% increase in ethosuximide elimination half-life and a 15% decrease in total ethosuximide clearance when compared with ethosuximide administration alone. Patients receiving concomitant valproic acid and ethosuximide therapy, especially if receiving other concomitant anticonvulsant therapy, should have their serum drug concentrations monitored carefully.

Concomitant administration of valproic acid with felbamate (1.2 g daily) in a limited number of patients with epilepsy resulted in a 35% increase in mean peak serum valproic acid concentration, from 86 to 115 mcg/mL when compared with administration of valproic acid alone. Increasing the felbamate dose to 2.4 g daily resulted in another 16% increase in mean peak valproic acid concentration to 133 mcg/mL. A decrease in valproic acid dosage may be required when initiating concomitant felbamate therapy.

Valproic acid inhibits lamotrigine metabolism. In a steady-state study in healthy individuals, the elimination half-life of lamotrigine increased from 26 to 70 hours when concomitant valproic acid was administered. Lamotrigine dosage should be decreased when valproic acid therapy is initiated.

Concomitant administration of valproic acid and phenobarbital (or primidone which is metabolized to phenobarbital) can result in increased phenobarbital plasma concentrations and excessive somnolence. This combination can produce CNS depression (possibly severe) even without substantial increases in serum concentrations of either drug. A few patients have become comatose during therapy with valproic acid and phenobarbital. In a study of concomitant valproic acid (250 mg twice daily for 14 days) and single-dose phenobarbital (60 mg) administration in a limited number of healthy individuals, a 50% increase in phenobarbital half-life, a 30% decrease in phenobarbital clearance, and a 50% increase in unchanged phenobarbital excreted in the urine were observed. If valproic acid is used with a barbiturate, the patient should be closely observed for possible neurologic toxicity, plasma concentrations of the barbiturate should be monitored if possible, and the dosage of the barbiturate decreased if necessary.

Serum concentrations of carbamazepine have been reported to decrease by 17% and concentrations of the metabolite carbamazepine-10,11-epoxide have been reported to increase by 45% during concomitant therapy with valproic acid; such interaction may result in carbamazepine CNS toxicity (e.g., acute psychotic reaction). In addition, carbamazepine has been reported to decrease plasma valproic acid concentrations by altering its clearance during concomitant therapy, which may be clinically important. Discontinuance of carbamazepine following concomitant carbamazepine/valproic acid therapy has been reported to result in increased valproic acid concentrations. If concomitant therapy is being undertaken, or if a patient currently is receiving concomitant carbamazepine/valproic acid therapy and one agent is to be discontinued, careful therapeutic drug monitoring should be considered.

Concomitant administration of valproic acid and clonazepam has produced absence status; therefore, some clinicians recommend that concomitant use of these drugs be avoided.

Valproic acid has been associated both with decreased plasma phenytoin concentrations and increased seizure frequency and with increased plasma concentrations of free phenytoin and phenytoin intoxication. Therefore, it is important to monitor plasma phenytoin concentrations whenever valproic acid is added to or withdrawn from the patient's therapy and adjust the dosage of phenytoin as required. Since valproic acid also may interact with other anticonvulsants, it is advisable to monitor plasma concentrations of concomitantly administered anticonvulsants during initial valproic acid therapy.

■ **Anti-infective Agents** *Acyclovir* In a child receiving both phenytoin and valproic acid, short-term oral therapy with acyclovir apparently reduced the plasma concentrations of both anticonvulsant agents to subtherapeutic levels; an increase in seizure frequency and a worsening in the EEG were observed. Although further study is needed to confirm the effects of acyclovir on the pharmacokinetics of anticonvulsant agents, such concomitant therapy should be undertaken with caution.

Antiretroviral Agents Concomitant use of valproic acid (250 or 500 mg every 8 hours) and oral zidovudine (100 mg every 8 hours) for 4 days in a limited number of adults with human immunodeficiency virus (HIV) infection resulted in an 80% increase in the area under the concentration-time curve (AUC) of zidovudine. The effect of concomitant zidovudine on the pharmacokinetics of valproic acid was not evaluated. Although the clinical importance of this interaction between zidovudine and valproic acid is not known, patients receiving both drugs should be monitored more closely for zidovudine-related adverse effects. Severe anemia has been reported following initiation of valproic acid therapy (500 mg twice daily) in an HIV-infected adult who was receiving an antiretroviral regimen that contained zidovudine, lamivudine, and abacavir; the patient had stable hematologic status at the time valproic acid was started. The manufacturer of zidovudine states that a reduction in zidovudine dosage may be considered if a patient experiences substantial anemia or other severe adverse effect while receiving zidovudine concomitantly with valproic acid.

Hepatotoxicity was reported in an HIV-infected adult receiving valproic acid concomitantly with an antiretroviral regimen containing ritonavir, saquinavir, stavudine, and nevirapine. It has been suggested that this may have occurred as the result of a pharmacokinetic interaction between valproic acid and ritonavir and/or nevirapine.

Concomitant use of efavirenz and valproic acid in HIV-infected adults does not appear to affect the pharmacokinetics of either drug.

Concomitant use of the fixed combination of lopinavir and ritonavir with valproic acid may result in slightly increased lopinavir concentrations, but does not affect valproic acid concentrations. It has been suggested that this pharmacokinetic interaction is not clinically important.

Rifampin A study of administration of a single dose of valproic acid (7 mg/kg) given 36 hours after short-term rifampin administration (600 mg daily for 5 days) revealed a 40% increase in the clearance of valproic acid. Valproic acid dosage adjustment may be required when rifampin therapy is initiated.

■ **Other Drugs** Since valproic acid may affect bleeding time (see Cautions: Hematologic Effects), it should be administered with caution in patients receiving drugs which affect coagulation such as aspirin or warfarin. In addition, valproic acid potentially may displace warfarin from its plasma albumin binding sites. Although the clinical relevance of this interaction is unknown, coagulation tests should be monitored if concomitant valproic acid and anticoagulant therapy is undertaken.

In a study of a limited number of pediatric patients receiving valproic acid and antipyretic aspirin therapy (11–16 mg/kg), a decrease in valproic acid protein binding and metabolism was observed. Free valproic acid concentration increased fourfold, compared with valproic acid therapy alone. The oxidative metabolic pathway of valproic acid was inhibited, resulting in a decrease in excretion of valproic acid metabolites, from 25% to 8.3% of total metabolites excreted. Concomitant aspirin and valproic acid therapy should be instituted with caution.

In vitro studies demonstrated that addition of tolbutamide to plasma samples of patients receiving valproic acid therapy resulted in an increase in the unbound tolbutamide fraction from 20% to 50%. The clinical importance of this displacement is unknown.

Limited pharmacokinetic studies reveal little to no interaction following concomitant administration of valproic acid with the following drugs: antacids, chlorpromazine, haloperidol, H_2-receptor antagonists (i.e., ranitidine, cimetidine), acetaminophen, clozapine, lithium, lorazepam, or oral contraceptives.

Laboratory Test Interferences

■ **Tests for Urinary Ketones** A ketone metabolite in the urine of patients receiving valproic acid may produce false-positive results for urine ketones.

■ **Tests for Thyroid Function** Valproic acid reportedly alters thyroid function test results, but the clinical importance of this effect is not known.

Acute Toxicity

■ **Manifestations** Overdosage of valproic acid may produce somnolence, heart block, or deep coma. One adult who ingested 36 g of valproic acid (as valproate sodium) in addition to 1 g of phenobarbital and 300 mg of phenytoin experienced deep coma 4 hours after ingestion of the drugs. The patient recovered following supportive therapy. Fatalities have been reported following valproic acid overdosage; however, patients have recovered from serum valproic acid concentrations as high as 2.12 mg/mL.

■ **Treatment** Treatment of valproic acid intoxication consists of general supportive therapy, particularly maintenance of adequate urinary output. Because the drug is rapidly absorbed, gastric lavage may be of limited value; since absorption of divalproex sodium delayed-release tablets is delayed, the value of gastric lavage or emesis will vary with time since ingestion if this form of the drug has been ingested. In overdose situations, the free or unbound serum valproic acid concentration is high. Hemodialysis or tandem hemodialysis with hemoperfusion may result in significant removal of drug. Naloxone has been reported to reverse the CNS depressant effects of valproic acid overdosage; however, naloxone should be used with caution since it could also theoretically reverse the anticonvulsant effects of valproic acid.

Pharmacology

■ **Anticonvulsant Effects** The mechanism of the anticonvulsant effects of valproic acid is not known. Effects of the drug may be related, at least in part, to increased brain concentrations of the inhibitory neurotransmitter, γ-aminobutyric acid (GABA). Animal studies have shown that valproic acid inhibits GABA transferase and succinic aldehyde dehydrogenase, enzymes which are important for GABA catabolism. Results of one study indicate the drug inhibits neuronal activity by increasing potassium conductance. In animals, valproic acid protects against seizures induced by electrical stimulation as well as those induced by pentylenetetrazol.

■ **Antiviral Effects** Valproic acid inhibits histone deacetylase I (HDACI) (an enzyme that maintains latency of human immunodeficiency virus [HIV] in resting $CD4^+$ T-cells) and induces HIV expression from resting $CD4^+$ T-cells ex vivo. It has been suggested that this effect may be useful in depleting latent infection in resting $CD4^+$ T-cells in HIV-infected patients. Although highly active antiretroviral therapy (HAART) suppresses plasma HIV-1 RNA levels and restores immune function, the presence of replication-competent provirus in resting $CD4^+$ T-cells and persistent HIV replication prevent HAART from eradicating HIV infection. Efficacy of valproic acid in depleting HIV from resting $CD4^+$ T-cells has been evaluated in a small proof-of-concept pilot study in 4 HIV-infected adults (plasma HIV-1 RNA levels less than 50 copies/mL for at least 2 years) receiving HAART. Enfuvirtide was added to the HAART regimens (to prevent the spread of virus in the presence of valproic acid) and, after 4–6 weeks of this intensified regimen, valproic acid (500–750 mg twice daily) was added. After 16–18 weeks of combined valproic acid and enfuvirtide-intensified HAART, there was a substantial decline in the frequency of replication-competent HIV in circulating resting $CD4^+$ T-cells. These preliminary findings suggest that use of valproic acid with HAART and enfuvirtide may represent a new therapeutic approach that possibly represents a step toward the elimination of HIV infection in resting $CD4^+$ T-cells and eventual cure of HIV infection. However, it is unclear whether latently infected $CD4^+$ T-cells are the only reservoir for HIV, and larger, controlled studies are needed to investigate the possible benefits of valproic acid in HIV-infected patients.

Pharmacokinetics

■ **Absorption** *Oral Administration* Following oral administration, valproate sodium is rapidly converted to valproic acid in the stomach. Valproic acid is rapidly and almost completely absorbed from the GI tract. Absorption of the drug is delayed but not decreased by administration with meals; administration of the drug with milk products does not affect the rate or degree of absorption. Following oral administration of divalproex sodium extended-release tablets, divalproex sodium dissociates into valproic acid in the GI tract. Following oral administration of divalproex sodium delayed-release tablets and passage of the tablets into the upper small intestine, divalproex sodium dissociates into valproic acid, which is then absorbed; because of the enteric coating, absorption is delayed compared with that following oral administration of valproic acid capsules or valproate sodium solution. The bioavailability of valproate from divalproex sodium delayed-release tablets and capsules containing coated particles has been shown to be equivalent to that of valproic acid capsules. The absolute bioavailability of divalproex sodium extended-release tablets following oral administration of a single dose after a meal is about 90%. The manufacturer states that divalproex sodium extended-release tablets and delayed-release tablets are not bioequivalent. Results of 2 multiple-dose studies indicate that divalproex sodium extended-release tablets (administered either in the fasting state or immediately before small meals) have an average bioavailability of 81–89% relative to divalproex sodium delayed-release tablets given twice daily. Administration of divalproex sodium with food would be expected to slow absorption but not affect the extent of absorption.

Peak plasma concentrations of valproic acid are usually attained 1–4 hours following a single oral dose of the acid or the sodium salt, 3–5 hours following a single oral dose of divalproex sodium, and 7–14 hours following oral administration of multiple doses of divalproex sodium extended-release tablets. There is wide interindividual variation in plasma concentrations of the drug with a specific dose. Results of a multiple-dose study indicate that following oral administration of divalproex sodium extended-release tablets once daily average plasma concentrations of the drug are 10–20% lower than those achieved with twice-daily administration of divalproex sodium delayed-release tablets. Plasma concentrations of valproic acid required for therapeutic or toxic effects have not been definitely established. Some reports indicate that therapeutic plasma concentrations may be 50–100 mcg/mL of total (bound and unbound) valproic acid and that concentrations in this range are maintained in most adults receiving 1.2–1.5 g of valproic acid daily. However, the possibility that some patients may be controlled with lower or higher plasma concentrations and that the free fraction of valproic acid increases with increasing dosage should be considered. (See Pharmacokinetics: Distribution.) The onset of therapeutic effects is several days to more than one week following initiation of valproic acid therapy.

The relationship between dose and total valproic acid concentration is nonlinear; concentration does not increase proportionally with dose, because of saturable protein binding. The pharmacokinetics of unbound drug are linear.

Parenteral Administration Equivalent valproic acid dosages as the IV injection (available as valproate sodium), administered over 1 hour, or various conventional or delayed-release oral formulations (available as valproate sodium or divalproate sodium) are expected to result in equivalent peak and trough plasma concentrations and total systemic exposure to the valproic acid. Although the rate of valproic acid absorption may vary with

the specific formulation, any such differences should be of minor clinical importance under steady-state conditions achieved with chronic therapy for seizure disorders.

When oral divalproate sodium delayed-release tablets or IV valproate sodium (as a 1-hour infusion) was administered at a dosage of 250 mg of valproic acid every 6 hours for 4 days in healthy males, the resulting area under the plasma concentration-time curves (AUCs) and peak and trough plasma concentrations of the drug were equivalent at steady state as well as after the initial dose. However, the time to reach peak plasma concentrations was delayed with the tablets, occurring at approximately 4 hours after an oral dose versus at the end of the 1-hour infusion with the IV dose. Because the pharmacokinetics of unbound valproic acid are linear, bioequivalence between IV valproate sodium and oral delayed-release divalproate sodium can be expected up to maximum dosages of 60 mg/kg daily. The AUCs and peak plasma concentrations also were equivalent in healthy males receiving single 500-mg doses as the IV injection (infused over 1 hour) or valproate sodium oral solution. In addition, patients maintained on valproic acid dosages of 750–4250 mg daily (given in divided doses every 6 hours) as oral delayed-release divalproate sodium tablets alone or while stabilized on another anticonvulsant (e.g., carbamazepine, phenytoin, or phenobarbital) exhibited comparable plasma concentrations when switched from oral divalproate sodium to IV valproate sodium (as 1-hour infusions).

When valproate sodium (at a dosage of 1 g of valproic acid) was administered IV over 5, 10, 30, and 60 minutes in healthy individuals, peak plasma concentrations of the drug averaged 145 mcg/mL after the 5-minute infusion compared with 115 mcg/mL after the 60-minute infusion. However, plasma concentrations measured at 90–120 minutes after initiation of the valproate sodium infusions were similar for the 4 rates of infusion.

■ **Distribution** Valproic acid is rapidly distributed; distribution appears to be restricted to plasma and rapidly exchangeable extracellular water. Volume of distribution of total or free valproic acid is 11 or 92 L/1.73 m^2, respectively. Valproic acid has been detected in CSF (approximately 10% of serum concentrations), saliva (about 1% of plasma concentrations), and milk (about 1–10% of plasma concentrations). The drug crosses the placenta.

Plasma protein binding of valproic acid is concentration dependent; the free fraction of drug increases from 10% at a concentration of 40 mcg/mL to 18.5% at a concentration of 130 mcg/mL. Protein binding of valproic acid is decreased in geriatric patients, in patients with renal impairment or hepatic disease, or in the presence of other protein-bound drugs. Conversely, valproic acid may displace other drugs from protein binding sites. Because of decreased protein binding of the drug in special patient populations (i.e., patients with renal or hepatic disease), monitoring of total drug concentrations may be misleading, owing to the increased free fraction of valproic acid.

■ **Elimination** Valproic acid is eliminated by first-order kinetics and reportedly has an elimination half-life of 5–20 hours (average 10.6 hours). Elimination half-lives in the lower portion of the range are usually observed in patients receiving other anticonvulsants concomitantly. Half-lives of up to 30 hours have been reported following overdosage of valproate sodium.

Mean plasma clearance of total or free valproic acid is 0.56 or 4.6 L/hour per 1.73 m^2, respectively. Drug clearance may be decreased in special patient populations (e.g., patients with renal failure, geriatric patients). Because hemodialysis typically reduces plasma valproic acid concentration by about 20%, generally there is no dosage adjustment required in patients with renal failure (i.e., creatinine clearance less than 10 mL/min). Geriatric patients should receive lower initial doses of the drug. (See Dosage and Administration: Dosage.)

Pediatric patients (i.e., age range 3 months to 10 years) have 50% higher clearance of the drug expressed by weight (i.e., mL/minute per kg); over the age of 10 years, pharmacokinetic parameters of valproic acid approximate those in adults. Neonates (i.e., younger than 2 months) have a markedly decreased clearance of valproic acid compared with older children and adults, possibly because of delayed development of metabolic enzyme systems and an increased volume of distribution. In one study, the elimination half-life in children younger than 10 days old ranged from 10–67 hours, compared with 7–13 hours in children older than 2 months.

Valproic acid is metabolized principally in the liver by *beta* (over 40%) and *omega* oxidation (up to 15–20%). Valproic acid metabolites are excreted in urine; 30–50% of an administered dose is excreted as glucuronide conjugates. Less than 3% of an administered dose is excreted in urine unchanged. The major metabolite in urine is 2-propyl-3-ketopentanoic acid; minor urinary metabolites are 2-propylglutaric acid, 2-propyl-5-hydroxypentanoic acid, 2-propyl-3-hydroxypentanoic acid, and 2-propyl-4-hydroxypentanoic acid. Small amounts of the drug are also excreted in feces and in expired air. Results of studies in rats suggest the drug may undergo enterohepatic circulation.

Liver disease impairs the ability to eliminate valproic acid. In one study, the clearance of free valproic acid was decreased by 50% in a limited number of patients with cirrhosis and by 16% in a limited number of patients with acute hepatitis, compared with healthy individuals. Half-life of valproic acid was increased from 12 to 18 hours.

Chemistry and Stability

■ **Chemistry** Valproic acid, valproate sodium, and divalproex sodium are carboxylic acid-derivative anticonvulsants. Valproic acid is structurally unrelated to other commercially available anticonvulsants; it lacks nitrogen and/or an aromatic moiety found in most anticonvulsants. Divalproex sodium is a stable coordination compound consisting of valproic acid and valproate sodium in a 1:1 molar ratio and is formed during partial neutralization of valproic acid with sodium hydroxide. Divalproex sodium is a prodrug of valproate, dissociating into valproate in the GI tract.

Valproic Acid Valproic acid occurs as a colorless to pale yellow, slightly viscous, clear liquid with a characteristic odor and is slightly soluble in water and freely soluble in alcohol. Valproic acid has a pK_a of 4.8.

Valproate Sodium Valproate sodium occurs as a white, crystalline, very hygroscopic powder with a saline taste and is very soluble in water and in alcohol.

Valproate sodium injection is a sterile solution of the drug in water for injection. The injection occurs as a clear, colorless solution; sodium hydroxide and/or hydrochloric acid may be added to adjust the pH to 7.6.

Divalproex Sodium Divalproex sodium occurs as a white powder with a characteristic odor and is insoluble in water and very soluble in alcohol.

■ **Stability** ***Valproic Acid*** USP recommends that valproic acid capsules be stored in tight containers at 15–30°C; however, the manufacturer of Depakene® recommends that the capsules be stored in tight containers at 15–25°C.

Valproate Sodium Valproate sodium oral solution has a pH of 7–8. Valproate sodium oral solution should be stored in tight containers at a temperature less than 30°C; freezing should be avoided.

Valproate sodium injection should be stored at a controlled room temperature of 15–30°C. Because the injection does not contain a preservative, unused portions of the solution should be discarded. When stored in glass or PVC containers at 15–30°C, valproate sodium injection that has been further diluted with at least 50 mL of 5% dextrose injection, 0.9% sodium chloride injection, or lactated Ringer's injection is stable for at least 24 hours.

Divalproex Sodium Divalproex sodium delayed-release tablets should be stored in tight, light-resistant containers at a temperature less than 30°C; divalproex sodium capsules containing coated particles should be stored at a temperature less than 25°C. Divalproex sodium extended-release tablets should be stored at 25°C, but may be exposed to temperatures ranging from 15–30°C.

For further information on uses and dosage and administration of valproic acid, see the Anticonvulsants General Statement 28:12.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Valproate Sodium

Oral		
Solution	250 mg (of valproic acid) per 5 mL*	Depakene® Syrup, Abbott Valproate Sodium Oral Solution
Parenteral		
Injection, for IV use	100 mg (of valproic acid) per mL*	Depacon®, Abbott Valproate Sodium Injection

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Valproic Acid

Oral		
Capsules, liquid-filled	250 mg*	Depakene®, Abbott

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Divalproex Sodium

Oral		
Capsules (containing coated particles)	equivalent to valproic acid 125 mg	Depakote® Sprinkle, Abbott
Tablets, delayed-release	equivalent to valproic acid 125 mg	Depakote®, Abbott
	equivalent to valproic acid 250 mg	Depakote®, Abbott
	equivalent to valproic acid 500 mg	Depakote®, Abbott
Tablets, extended-release	equivalent to valproic acid 250 mg	Depakote® ER, Abbott
	equivalent to valproic acid 500 mg	Depakote® ER, Abbott

†Use is not currently included in the labeling approved by the US Food and Drug Administration

other indications, both psychiatric and nonpsychiatric, should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

Bipolar Disorder Precautions It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Pediatric Precautions Safety and efficacy of nefazodone in children have not been established.

FDA has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. (See Cautions: Pediatric Precautions, in Fluoxetine Hydrochloride 28:16.04.20.) Anyone considering the use of nefazodone in a child or adolescent for any clinical use must therefore balance the potential risks with the clinical need. (See Suicidality Precautions under Dosage and Administration: Administration.)

■ **Dosage** Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Suicidality Precautions under Dosage and Administration: Administration.)

Major Depressive Disorder For the treatment of major depressive disorder in adults, the recommended initial dosage of nefazodone hydrochloride is 100 mg twice daily. Based on the tolerance and clinical response of the patient, dosage may be increased by increments of 100–200 mg daily at intervals of not less than 1 week up to a maximum of 600 mg daily. While a relationship between dosage and antidepressant effect has not been established, the effective dosage of nefazodone hydrochloride in controlled clinical studies generally ranged from 300–600 mg daily.

Because geriatric or debilitated patients may have reduced nefazodone clearance and/or increased sensitivity to the adverse effects of CNS-active drugs, therapy with nefazodone hydrochloride should be initiated at a dosage of 50 mg twice daily in such patients and subsequent dosage adjustments generally made in smaller increments and at longer intervals than in younger patients. A nefazodone hydrochloride dosage of 200–400 mg daily generally provided optimum therapeutic effect in patients 65 years of age or older in controlled studies.

Although the optimum duration of nefazodone therapy has not been established, acute depressive episodes may require 6 months or longer of sustained antidepressant medication. Whether the dosage of nefazodone required to induce remission of depression would be comparable to that required to maintain euthymia currently is not known.

■ **Dosage in Renal and Hepatic Impairment** While the manufacturer makes no specific recommendations for modification of dosage in patients with hepatic impairment, AUC values for nefazodone and its active metabolite hydroxynefazodone are increased by approximately 25% in patients with cirrhosis; therefore, nefazodone should be used with caution in patients with clinically important hepatic dysfunction. The manufacturer makes no specific recommendations for modification of dosage in patients with renal impairment. Limited data indicate that steady-state plasma concentrations of nefazodone in patients with renal impairment (creatinine clearance: 7–60 mL/minute per 1.73 m^2 body surface area) do not differ from those in healthy individuals.

Description

Nefazodone is a phenylpiperazine-derivative antidepressant agent. While the drug is structurally related to trazodone, nefazodone differs chemically and pharmacologically from selective serotonin-reuptake inhibitors, monoamine oxidase inhibitors, and tricyclic and tetracyclic antidepressant agents. The exact mechanism of antidepressant action of nefazodone has not been fully elucidated but appears more complex than other antidepressant agents and may involve inhibition of reuptake of serotonin (5-hydroxytryptamine [5-HT]) at the presynaptic membrane, antagonism at serotonin type 2 (5-HT_2) receptors, and down-regulation of 5-HT_2 receptor binding sites. Nefazodone also inhibits presynaptic reuptake of norepinephrine and exhibits α_1-adrenergic blocking activity. In vitro studies have demonstrated that the drug possesses little or no affinity for α_2-adrenergic, β-adrenergic, muscarinic, dopaminergic, histamine H_1, 5-HT_{1A}, or GABA-benzodiazepine receptors.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications.

	200 mg*	Nefazodone Hydrochloride Tablets
	250 mg*	Nefazodone Hydrochloride Tablets

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Trazodone Hydrochloride

■ Trazodone hydrochloride is a triazolopyridine-derivative antidepressant that is chemically and structurally unrelated to tricyclic or tetracyclic antidepressants or to selective serotonin-reuptake inhibitors.

Uses

■ **Major Depressive Disorder** Trazodone is used in the treatment of major depressive disorder. The drug is used in patients who exhibit a prominent and relatively persistent (nearly every day for at least 2 weeks) depressed or dysphoric mood that usually interferes with daily functioning and is manifested as a change in appetite, psychomotor agitation or retardation, a loss of interest in usual activities, a decrease in sexual drive, increased fatigability, a change in sleep, feelings of guilt or worthlessness, slowed thinking or impaired concentration, and/or suicidal ideation or attempts. Trazodone has been used effectively in the treatment of patients who have major depression with or without prominent anxiety. In addition, trazodone has been used effectively in patients with major depression in hospital, institutional, and outpatient settings. Unlike tricyclic antidepressants, trazodone generally has not been reported to precipitate hypomanic or manic attacks in patients with bipolar disorder; however, further study is needed to determine the safety and efficacy of trazodone when used alone as an antidepressant in these patients.

Trazodone is particularly effective in reducing affective and ideational manifestations of depression, especially anxiety, apathy, irritability, and suicidal thoughts. Somatic signs and symptoms associated with depression, including sleep disturbances and fatigue, are also reduced during trazodone therapy. Most clinical studies have shown that the antidepressant effect of usual dosages of trazodone in patients with moderate to severe depression is about equal to that of usual dosages of amitriptyline, imipramine, or doxepin. However, trazodone has reportedly caused fewer adverse effects (e.g., anticholinergic effects) than these tricyclic antidepressants. (See Cautions: Anticholinergic Effects.) Although trazodone has been reported to have a slightly more rapid onset of action than amitriptyline, desipramine, or imipramine, this has not been established.

Trazodone has been used in patients with major depression who have associated anxiety. Based on limited data, the antidepressant effect of usual dosages of trazodone appears to be greater than that of amitriptyline or imipramine in these patients. Trazodone is particularly effective in reducing anxiety, tension, somatic symptoms, insomnia, and psychomotor retardation in these patients.

For further information on treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidal risk, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in Fluoxetine Hydrochloride 28:16.04.20.

■ **Schizophrenic Disorder** Although trazodone has been used in the treatment of schizophrenic disorder†, the drug is less effective than chlorpromazine. Depressive symptomatology may improve during trazodone therapy, but the drug does not appear to relieve psychotic symptoms in most schizophrenic patients. Based on limited data, trazodone has little value when used alone in patients with chronic schizophrenic disorder without depression; however, it

may be a useful adjunct to antipsychotic agents (e.g., phenothiazines) in patients with chronic schizophrenic disorder and associated depression. Unlike tricyclic antidepressants, trazodone does *not* appear to worsen psychotic symptoms in these patients.

■ **Alcohol Dependence** Trazodone has been used in the adjunctive treatment of alcohol dependence†. In a limited number of patients with alcohol dependence, oral (50–75 mg daily) or IV (50 mg twice daily) trazodone has reduced tremor, depression, and anxiety. In one study, trazodone was more effective in patients who had pronounced affective symptomatology during periods of intoxication and abstention than in those who only had affective symptomatology during intoxication. Further study is needed to determine the efficacy of trazodone in the treatment of alcohol dependence.

■ **Erectile Dysfunction** Trazodone has been used in a limited number of patients for the treatment of erectile dysfunction† (ED, impotence); however, the American Urological Association (AUA) states that such therapy currently is not recommended. Although some studies indicated that trazodone was more effective than placebo for the treatment of erectile dysfunction, other comparative studies did not. In addition, pooled analysis of these studies failed to show a statistically beneficial effect of the drug on sexual function, although subgroup analysis suggested possible benefit in those with psychogenic erectile dysfunction.

■ **Other Uses** Trazodone may be useful in the treatment of some patients with anxiety states† (anxiety neuroses). In one study, the drug reduced anxiety, tension, somatic symptoms, and insomnia in most of these patients. Based on limited data, trazodone appears to have a greater anxiolytic effect than some other antidepressant agents (e.g., tricyclic antidepressants); however, further study is needed to confirm this finding.

Trazodone has been used in the symptomatic treatment of a limited number of patients with drug-induced dyskinesias†. In one placebo-controlled study in patients with levodopa-induced dyskinesias, oral trazodone (60–120 mg daily) reduced signs and symptoms of dyskinesia by up to 50%. In this study, most patients showed some improvement, with greatest improvement in facial, oro-buccal-facial, and neck dyskinesias. In another study, IV trazodone (50 mg twice daily) eliminated chronic chlorpromazine- and haloperidol-induced tardive dyskinesias in some patients. The decrease in tremor was accompanied by a reduction in anxiety, which may be partly responsible for the favorable effect of trazodone on tremor in these patients. Additional studies are required to determine the efficacy of trazodone in the treatment of drug-induced dyskinesias.

Dosage and Administration

■ **Administration** Trazodone hydrochloride is administered orally. The drug should be taken shortly after a meal or light snack. If drowsiness occurs, a major portion of the daily dose may be given at bedtime or dosage may be reduced.

■ **Dosage** There is a wide range of individual trazodone hydrochloride dosage requirements, and dosage must be carefully adjusted according to individual tolerance and response, using the lowest possible effective dosage.

Patients receiving trazodone should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications.)

Major Depressive Disorder For the treatment of major depressive disorder, the usual initial adult dosage of trazodone hydrochloride is 150 mg daily given in divided doses. Dosage may be increased by 50 mg/day every 3 or 4 days, depending on the patient's therapeutic response and tolerance. The maximum dosage for outpatients usually should not exceed 400 mg daily. Dosages up to 600 mg daily may be required in hospitalized, institutionalized, or severely depressed patients. Dosages up to 800 mg daily have been used in the treatment of some patients with severe depression; however, the manufacturers do not recommend exceeding a dosage of 600 mg daily.

Although symptomatic relief may be seen in some patients during the first week of therapy, optimum antidepressant effect usually occurs within 2 weeks. About 25% of patients who respond to trazodone require up to 4 weeks of therapy to reach optimum response.

To avoid recurrence of depressive symptoms, trazodone therapy may be required for several months following optimum therapeutic response. Dosage during prolonged maintenance therapy should be kept at the lowest effective level; once an adequate response has been achieved, dosage should be gradually reduced and subsequently adjusted according to the patient's therapeutic response and tolerance.

Cautions

Trazodone hydrochloride apparently causes fewer adverse anticholinergic effects than currently available tricyclic antidepressant agents. Other adverse effects, including cardiovascular effects, also appear to occur less frequently with trazodone than with currently available tricyclic antidepressants.

The incidence and severity of adverse reactions to trazodone in relation to dosage and duration of therapy have not been fully characterized; however, adverse effects appear to occur more frequently at dosages greater than 300 mg/day. Total trazodone hydrochloride dosages up to 800 mg daily have been well tolerated by some patients. Adverse effects appear to be mild to moderate in severity and may decrease after the first few weeks of trazodone therapy. Adverse effects may be obviated by a reduction in dosage or alteration in dosage schedule. Serious reactions requiring discontinuance of therapy are relatively rare.

■ **Nervous System Effects** Adverse nervous system effects occur frequently during the first few weeks of therapy with trazodone. The most frequent adverse effect associated with trazodone therapy is drowsiness, which occurs in 20–50% of patients receiving the drug. Other less frequent adverse nervous system effects of trazodone include dizziness and lightheadedness, nervousness, fatigue, malaise, weakness, heaviness or fullness of the head, headache, and insomnia. Confusion, incoordination, anger or hostility, agitation, decreased concentrating ability, impaired memory, impaired speech, disorientation, hallucinations or delusions, and excitement have also occurred. Hypomania, nightmares or vivid dreams, tonic-clonic seizures, tremors, and paresthesias and akathisia occur rarely.

■ **Anticholinergic Effects** Although bothersome anticholinergic effects commonly occur with tricyclic antidepressants, these effects appear to occur less frequently with trazodone. Dry mouth has been reported in about 15–30% of patients during trazodone therapy; it has been suggested that this effect may result from an α-adrenergic blocking effect rather than an anticholinergic effect of trazodone. In several placebo-controlled studies, the incidence of dry mouth was similar in trazodone- and placebo-treated patients. Other anticholinergic effects such as blurred vision, constipation, and urinary retention have been reported less frequently.

■ **Genitourinary Effects** Trazodone therapy has been associated with priapism, with surgical intervention required in approximately one-third of reported cases; in some cases, permanent impairment of erectile function or impotence has resulted. Male patients receiving trazodone who experience prolonged or inappropriate penile erections should immediately discontinue the drug and consult their physician. Decreased or increased libido, retrograde ejaculation, impotence, inhibited female orgasm (anorgasmia), increased urinary frequency, delayed urine flow, and hematuria have also been associated with trazodone therapy.

■ **GI Effects** Adverse GI effects of trazodone include nausea and vomiting, dysgeusia, and abdominal and gastric disorders. Flatulence and diarrhea have also been reported.

■ **Cardiovascular Effects** Trazodone is thought to be less cardiotoxic than currently available tricyclic antidepressant agents. (See Pharmacology: Cardiovascular Effects.) Hypotension (including orthostatic hypotension) is the most frequent adverse cardiovascular effect of trazodone, occurring in about 5% of patients receiving the drug. In most patients, hypotension is mild and not dose related. Syncope, shortness of breath, chest pain, tachycardia, palpitations, and hypertension have also occurred. Bradycardia has occurred in a few patients during long-term therapy.

Various ECG changes have occurred in patients receiving trazodone. In patients with preexisting cardiac disease, trazodone may be arrhythmogenic. PVCs, ventricular couplets, and short episodes (3 or 4 beats) of ventricular tachycardia have occurred in these patients. Arrhythmias have also been reported in patients without preexisting cardiac disease. Cardiac arrest has also been reported. Myocardial infarction has been reported, but this effect has not been attributed directly to trazodone.

■ **Hematologic Effects** Occasional decreases in leukocyte and neutrophil counts have occurred in some patients receiving trazodone. These changes were not considered clinically important and did not require discontinuance of the drug. Anemia has also been associated with trazodone therapy in a few patients.

■ **Other Adverse Effects** Musculoskeletal aches and pains have occurred in about 5% of patients receiving trazodone. A few patients have developed muscle twitches. Pruritus, rash, urticaria, acne, photosensitivity, edema, nasal or sinus congestion, eye irritation, sweating or clamminess, early or absent menses, and tinnitus have been reported in some patients receiving trazodone. Allergic reactions and hypersalivation have rarely occurred. Minimal increases in serum concentrations of alkaline phosphatase, AST (SGOT), and ALT (SGPT) have occurred in some patients receiving trazodone.

■ **Precautions and Contraindications** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Cautions: Pediatric Precautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age, and a reduced risk was observed in adults 65 years of age or older. It currently is unknown whether the suicidality risk extends to longer-term use (i.e., beyond

several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage. Because of the possibility of comorbidity between major depressive disorder and other psychiatric and nonpsychiatric disorders, the same precautions observed when treating patients with major depressive disorder should be observed when treating patients with other psychiatric and nonpsychiatric disorders.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Patients should be warned that trazodone may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle). Patients also should be warned that trazodone may enhance their response to alcohol, barbiturates, or other CNS depressants. Since the risk of dizziness or lightheadedness may be increased during fasting conditions, patients should be advised to take trazodone shortly after a meal or light snack. In addition, total drug absorption may be up to 20% greater when the drug is taken with food rather than on an empty stomach. Because priapism has been associated with trazodone therapy, patients should be instructed to discontinue the drug and consult a physician if prolonged or inappropriate penile erection occurs.

Until additional clinical experience on the safety of trazodone in patients with cardiovascular disease is obtained, it is recommended that these patients be closely monitored, particularly for arrhythmias, while receiving the drug. (See Cautions: Cardiovascular Effects.) It is also recommended that trazodone *not* be used during the initial recovery phase of myocardial infarction.

Leukocyte and differential counts should be performed in patients who develop fever and sore throat or other signs of infection while receiving trazodone. The drug should be discontinued in patients whose leukocyte or absolute neutrophil count decreases to less than normal levels. (See Cautions: Hematologic Effects.)

Trazodone is contraindicated in patients who are hypersensitive to the drug.

■ **Pediatric Precautions** Safety and efficacy of trazodone in children younger than 18 years of age have not been established.

FDA warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. The risk of suicidality for these drugs was identified in a pooled analysis of data from a total of 24 short-term (4–16 weeks), placebo-controlled studies of 9 antidepressants (i.e., bupropion, citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, venlafaxine) in over 4400 children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders. The analysis revealed a greater risk of adverse events representing suicidal behavior or thinking (suicidality) during the first few months of treatment in pediatric patients receiving antidepressants than in those receiving placebo. The average risk of such events was 4% among children and adolescents receiving these drugs, twice the risk (2%) that was observed among those receiving placebo. However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

The risk of suicidality in FDA's pooled analysis differed across the different psychiatric indications, with the highest incidence observed in the major depressive disorder studies. In addition, although there was considerable variation in risk among the antidepressants, a tendency toward an increase in suicidality risk in younger patients was found for almost all drugs studied. It is currently unknown whether the suicidality risk in pediatric patients extends to longer-term use (i.e., beyond several months).

As a result of this analysis and public discussion of the issue, FDA has directed manufacturers of all antidepressants to add a boxed warning to the labeling of their products to alert clinicians of this suicidality risk in children and adolescents and to recommend appropriate monitoring and close observation of patients receiving these agents. (See Cautions: Precautions and Contraindications.) The drugs that are the focus of the revised labeling are all drugs included in the general class of antidepressants, including those that have not been studied in controlled clinical trials in pediatric patients, since the available data are not adequate to exclude any single antidepressant from an increased risk of suicidality. In addition to the boxed warning and other information in professional labeling on antidepressants, FDA currently recommends that a patient medication guide explaining the risks associated with the drugs be provided to the patient each time the drugs are dispensed.

Anyone considering the use of trazodone in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need.

■ **Mutagenicity and Carcinogenicity** In vitro tests have *not* shown trazodone to be mutagenic. No evidence of carcinogenesis was seen in animals receiving oral trazodone dosages up to 300 mg/kg daily for 18 months.

■ **Pregnancy, Fertility, and Lactation** Trazodone has been shown to be teratogenic in rats and rabbits when given at dosages 15–50 times the maximum human dosage. The drug also caused increased fetal resorption and other adverse fetal effects in rats when given at dosages approximately 30–50 times the suggested maximum human dosage. There are no adequate and controlled studies to date using trazodone in pregnant women, and the drug should be used during pregnancy only when the potential benefits justify the possible risks to the fetus.

The effect of trazodone on fertility in humans is not known. Impotence, retrograde ejaculation, and decreased or increased libido have occurred in some individuals during trazodone therapy. Reproduction studies in male and female rats using trazodone dosages up to 150 times the usual human dosage have not revealed evidence of impaired fertility.

Because trazodone is distributed into milk, the drug should be used with caution in nursing women.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes** Results of in vitro studies indicate that metabolism of trazodone is mediated by the cytochrome P-450 (CYP) 3A4 isoenzyme, and the possibility exists that drugs that inhibit or induce this isoenzyme may affect the pharmacokinetics of trazodone. Other metabolic pathways that may be involved in the metabolism of trazodone have not been well characterized.

Concomitant use of trazodone with inhibitors of CYP3A4 can result in substantially increased plasma concentrations of trazodone and increase the potential for adverse effects. In one study, concomitant use of ritonavir (200 mg twice daily for 2 days) and trazodone (a single 50-mg dose) in healthy individuals increased maximum plasma concentrations and decreased clearance of trazodone by 34 and 52%, respectively, and increased area under the plasma concentration-time curve (AUC) and half-life of trazodone by greater than two-fold. Adverse effects (e.g., nausea, hypotension, syncope) also were observed with concomitant use of trazodone and ritonavir. The manufacturers of trazodone state that a reduction in trazodone dosage should be considered in patients receiving a potent inhibitor of the CYP3A4 isoenzyme (e.g., indinavir, itraconazole, ketoconazole, nefazodone, ritonavir) concomitantly with trazodone.

Concomitant use of trazodone (100–300 mg daily) with carbamazepine (400 mg daily), an inducer of CYP3A4, decreased plasma concentrations of trazodone and an active metabolite, *m*-chlorophenylpiperazine, by 76 and 60%, respectively. Patients receiving trazodone and carbamazepine concomitantly should be closely monitored and dosage of trazodone increased if necessary.

■ **Serotonergic Agents** ***Fluoxetine*** Elevated plasma trazodone concentrations and adverse effects possibly associated with trazodone toxicity have been reported occasionally during concomitant trazodone and fluoxetine therapy. Although the exact mechanism has not been established, it has been suggested that fluoxetine may inhibit the hepatic metabolism of many antidepressant agents, including trazodone. In addition, both trazodone and fluoxetine possess serotonergic activity; therefore, the possibility of serotonin syndrome also should be considered in patients receiving trazodone and fluoxetine or other selective serotonin-reuptake inhibitor therapy concurrently. For detailed information on serotonin syndrome, see Drug Interactions: Drugs Associated with Serotonin Syndrome in Fluoxetine Hydrochloride 28:16.04.20 and the Monoamine Oxidase Inhibitors General Statement 28:16.04.12. Further study is needed, but current evidence suggests that patients receiving trazodone and fluoxetine concomitantly should be observed closely for adverse effects; monitoring of plasma trazodone concentrations also should be considered and trazodone dosage reduced as necessary.

Monoamine Oxidase Inhibitors It is not known whether interactions between trazodone and monoamine oxidase (MAO) inhibitors can occur. Unlike tricyclic antidepressants, trazodone does not interfere with catecholamine uptake by the adrenergic neuron or the pressor response to tyramine. Therefore, an interaction between trazodone and MAO inhibitors is unlikely. However, both trazodone and MAO inhibitors possess serotonergic activity; therefore, the possibility that serotonin syndrome may occur during concurrent

therapy should be considered. For detailed information on serotonin syndrome, see Drug Interactions: Drugs Associated with Serotonin Syndrome in Fluoxetine Hydrochloride 28:16.04.20 and the Monoamine Oxidase Inhibitors General Statement 28:16.04.12. Because of the absence of clinical experience, if MAO inhibitors are discontinued shortly before or are to be given concomitantly with trazodone, it is recommended that trazodone therapy be initiated cautiously and dosage increased gradually until optimum response is achieved.

Other Serotonergic Agents Trazodone possesses serotonergic activity and rarely has been associated with serotonin syndrome when combined with other serotonergic agents, including buspirone, phenelzine, and dextropropoxyphene. Because severe complications and even fatalities have accompanied the serotonin syndrome, trazodone probably should be used with caution in patients receiving or who recently have received other serotonergic agents. For additional information on potentially serious drug interactions that may occur between trazodone and other serotonergic agents, see Drug Interactions: Drugs Associated with Serotonin Syndrome, in Fluoxetine Hydrochloride 28:16.04.20 and the Monoamine Oxidase Inhibitors General Statement 28:16.04.12.

■ **General Anesthetics** Since little is known about the interaction between trazodone and general anesthetics, it is recommended that trazodone be discontinued for as long as clinically feasible prior to elective surgery.

■ **Electroconvulsive Therapy** Pending further accumulation of clinical data on the concurrent use of trazodone and electroconvulsive therapy (ECT), concurrent use of these therapies should be avoided.

■ **CNS Depressants** Trazodone may be additive with, or may potentiate the action of, other CNS depressants such as opiates or other analgesics, barbiturates or other sedatives, anesthetics, or alcohol. When trazodone is used concomitantly with other CNS depressants, caution should be used to avoid excessive sedation.

■ **Hypotensive Agents** Because trazodone can cause hypotension, including orthostatic hypotension and syncope, concomitant administration of antihypertensive therapy may require a reduction in dosage of the antihypertensive agent(s). Trazodone has been shown to inhibit the hypotensive effect of various antihypertensive agents (e.g., clonidine, methyldopa) in animals; however, this inhibition has not always been reproducible. It is not known whether trazodone can inhibit the hypotensive effect of these agents in humans, and the clinical importance of this potential interaction has not been determined.

■ **Other Drugs** Increased serum digoxin or phenytoin concentrations have reportedly occurred in patients receiving trazodone concurrently with either drug.

■ **Food** The rate and extent of absorption of trazodone are affected by the presence of food. When trazodone is taken shortly after the ingestion of food, there may be a slight increase in the amount of drug absorbed, a decrease in peak plasma concentration of the drug, and a lengthening of the time to reach the peak plasma concentration. Total drug absorption may be up to 20% greater when the drug is taken with food rather than on an empty stomach. In animals, the rate of absorption has been delayed when trazodone was administered concomitantly with food because of a decrease in the rate of transfer of the drug from the stomach to the small intestine.

The effect of food on absorption of trazodone during long-term administration of the drug is not considered clinically important. Concomitant administration of trazodone with food is generally recommended since it appears to decrease the incidence of dizziness or lightheadedness.

Acute Toxicity

Limited information is available on the acute toxicity of trazodone.

■ **Pathogenesis** The acute lethal dose of trazodone in humans is not known. In addition, there is no clearly defined relationship between plasma trazodone concentration and severity of intoxication. The oral LD_{50} of trazodone is 610 mg/kg in mice, 486 mg/kg in rats, 560 mg/kg in rabbits, and 500 mg/kg in dogs. In animals, lethal doses produced dyspnea, salivation, prostration, and clonic seizures.

■ **Manifestations** One patient who intentionally ingested 7.5 g of trazodone experienced only drowsiness and weakness; the patient was aroused at the time of hospitalization and emesis was induced. Another patient had an uneventful recovery after ingesting 9.2 g of trazodone. There have been several reports of accidental ingestion in children; however, the exact amounts ingested are unknown. Each of these children exhibited only lethargy and drowsiness, and recoveries were uneventful. Fatalities have occurred in adults who intentionally ingested trazodone and other drugs (e.g., alcohol, chloral hydrate, amobarbital, chlordiazepoxide, meprobamate) concurrently.

In general, overdosage of trazodone may be expected to produce effects that are extensions of common adverse reactions; vomiting, drowsiness, and lethargy have been the principal effects reported. Other reported effects associated with acute trazodone overdosage have included orthostatic hypotension, tachycardia, coma, headache, tinnitus, dizziness, dyspnea, shivering, aching muscles, incontinence, and dry mouth. Unlike tricyclic antidepressant overdosage, seizures and arrhythmias do not appear to be associated with trazodone overdosage.

■ **Treatment** Treatment of trazodone overdosage generally involves symptomatic and supportive care; there is no specific antidote for trazodone intoxication. In acute overdosage, the stomach should be emptied immediately by inducing emesis or by gastric lavage. If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of vomitus. Although administration of activated charcoal after gastric lavage and/or emesis has been useful in the treatment of acute overdosage with tricyclic antidepressants, the effect of activated charcoal on the absorption of trazodone is not currently known. Appropriate therapy should be instituted if hypotension or excessive sedation occurs. Forced diuresis may be useful in facilitating elimination of the drug. It is not known if trazodone is dialyzable; however, because of extensive protein binding of the drug, hemodialysis is probably *not* effective in enhancing elimination of trazodone.

Pharmacology

The pharmacology of trazodone is complex and in some ways resembles that of tricyclic antidepressants, benzodiazepines, and phenothiazines; however, the overall pharmacologic profile of trazodone differs from each of these classes of drugs.

■ **Nervous System Effects** The precise mechanism of antidepressant action of trazodone is unclear, but the drug has been shown to selectively block the reuptake of serotonin (5-HT) at the presynaptic neuronal membrane. The effects of serotonin may thus be potentiated. Unlike other antidepressant agents (e.g., tricyclic antidepressants), trazodone may have a dual effect on the central serotonergic system. Animal studies indicate that trazodone acts as a serotonin agonist at high doses (6–8 mg/kg), while at low doses (0.05–1 mg/kg), it antagonizes the actions of serotonin. Trazodone does not appear to influence the reuptake of dopamine or norepinephrine within the CNS; however, animal studies indicate that trazodone may enhance release of norepinephrine from neuronal tissue. Trazodone does not cause serotonin release in vitro.

Although the mechanism of action of antidepressant agents may involve inhibition of the reuptake of various neurotransmitters at the presynaptic neuronal membrane, long-term therapy with antidepressant agents also affects postsynaptic neuronal receptor binding sites, resulting in some adaptive changes in neurotransmission. Long-term administration of trazodone reportedly decreases the number of postsynaptic serotonergic (i.e., serotonin$_2$) and β-adrenergic binding sites in the brain of animals. Although the clinical importance of these effects is not known, the decrease in binding sites is associated with a functional increase in serotonergic activity and a reduction in the sensitivity of adenylate cyclase to stimulation by β-adrenergic agonists. It has been suggested that postsynaptic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of trazodone. Further study is needed to determine the role of binding site alteration in the antidepressant action of trazodone and other antidepressants.

In animals, trazodone's effect on various avoidance behaviors is similar to that of phenothiazines. Unlike phenothiazines, however, trazodone potentiates the effects of serotonin. Trazodone does not potentiate the actions of levodopa or alter neuronal concentrations of acetylcholine. Trazodone does not inhibit monoamine oxidase, and unlike amphetamine-like drugs, does not stimulate the CNS.

Unlike many currently available antidepressants, trazodone exhibits little, if any, anticholinergic activity in vitro. Clinical studies show a lower incidence of anticholinergic effects (e.g., dry mouth, blurred vision, urinary retention, constipation) associated with trazodone use than with tricyclic antidepressant use. (See Cautions: Anticholinergic Effects.)

Trazodone produces varying degrees of sedation in normal and mentally depressed patients. The sedative effect is thought to result principally from central α_1-adrenergic blocking activity and possibly from a histamine blocking action of the drug. Trazodone may cause EEG changes, including increased slow-wave and alpha-wave activity. Some increase in fast-wave activity also occurs. Trazodone increases total sleep time, decreases the number and duration of awakenings in depressed patients, and decreases rapid eye movement (REM) sleep. Unlike tricyclic antidepressants, trazodone does not increase stage 4 sleep.

Although the exact mechanism of action has not been determined, trazodone has an anxiolytic effect. This finding is supported by animal studies in which trazodone is active in certain antianxiety test systems. In addition, the drug has demonstrated anxiolytic activity in patients with major depression who also have associated anxiety. (See Uses: Major Depressive Disorder.)

Therapeutic dosages of trazodone do not appear to affect respiration; however, the effect of higher dosages of trazodone in patients with ventilatory insufficiency is not known.

Like many other centrally acting agents, trazodone exhibits analgesic activity in a variety of analgesic test systems. Trazodone also has weak skeletal muscle relaxant activity but lacks anticonvulsant effects.

Trazodone possesses potent peripheral α-adrenergic blocking activity in animals following IV administration of 3–10 mg/kg. In addition, in animals, the drug blocks the peripheral effects of serotonin, epinephrine, norepinephrine, and histamine. The peripheral antihistaminic effects of trazodone are weaker than those of tricyclic antidepressants.

■ **Cardiovascular Effects** The cardiovascular effects of trazodone have been studied in animals and to a limited extent in humans. Unlike other antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors), trazodone has been associated with only minimal cardiovascular effects. (See Cautions: Cardiovascular Effects.) The absence of substantial anti-

cholinergic activity and catecholamine-potentiating effects appears to be the principal reason for the general lack of cardiovascular effects of trazodone.

Trazodone exhibits α-adrenergic blocking activity and does not inhibit catecholamine reuptake. Unlike tricyclic antidepressants, trazodone blocks the pressor response to norepinephrine and lowers arterial blood pressure. However, in one study in normotensive patients with endogenous depression, the effect of trazodone on systemic blood pressure was equivocal. Trazodone does not block the neuronal uptake of tyramine; thus, unlike tricyclic antidepressants, the drug has no effect on the pressor response to this sympathomimetic amine.

Although trazodone does *not* appear to have substantial arrhythmogenic activity, arrhythmias have occurred in some patients with preexisting cardiac disease during trazodone therapy. (See Cautions: Cardiovascular Effects.) In animals, trazodone does *not* affect intra-atrial, ventricular septal, ventricular free-wall, His-Purkinje, or AV nodal conduction. At doses up to 30 mg/kg in animals, trazodone produces only minimal ECG changes, including prolongation of the QT interval and a decrease in heart rate. Unlike tricyclic antidepressants, trazodone does not exert direct quinidine-like cardiotoxic properties. In addition, trazodone does *not* exert a negative inotropic effect at therapeutic dosages; the drug may decrease aortic blood flow as a result of a decrease in heart rate.

To date, there have been no published studies comparing the cardiovascular effects of therapeutic dosages of trazodone with those of antidepressants such as mianserin, nomifensine, or zimelidine. Although available data suggest that trazodone is less cardiotoxic than tricyclic antidepressant agents at therapeutic dosages, the cardiovascular effects of trazodone overdosage have not been well described.

■ **Other Effects** Trazodone may affect the endocrine system. Following oral administration of a single 50-mg dose in one study in healthy adults, trazodone caused a decrease in mean serum prolactin concentration. However, in another study in depressed patients, trazodone did not alter mean serum prolactin concentration following oral administration of 200 mg daily for 2 weeks.

Trazodone-induced antagonism of α_2-adrenergic receptors may relax the tissues and enhance arterial inflow in penile vascular and corporal smooth muscle resulting in an erection.

Pharmacokinetics

In all studies described in the Pharmacokinetics section, trazodone was administered as the hydrochloride salt.

■ **Absorption** Trazodone is rapidly and almost completely absorbed from the GI tract following oral administration. The rate and extent of absorption are affected by the presence of food. When trazodone is taken shortly after the ingestion of food, there may be a slight increase (up to 20%) in the amount of drug absorbed, a decrease in peak plasma concentration of the drug, and a lengthening of the time to reach the peak plasma concentration.

Peak plasma concentrations of trazodone occur approximately 1 hour after oral administration when the drug is taken on an empty stomach or 2 hours after oral administration when taken with food. Following oral administration of multiple doses of trazodone (25 mg 2 or 3 times daily), steady-state plasma concentrations of the drug are usually attained within 4 days and exhibit wide interpatient variation. Following oral administration of a single 25-mg dose of radiolabeled trazodone to healthy adults in one study, mean peak plasma drug concentrations of 650 and 480 ng/mL occurred at 1.5 and 2.5 hours after ingestion, in the fasted and nonfasted state, respectively. Following oral administration of single doses of 25, 50, or 100 mg of trazodone to healthy, fasted adults in another study, mean peak plasma trazodone concentrations were 490, 860, and 1620 ng/mL, respectively. The areas under the plasma concentration-time curves (AUCs) were 3.44, 5.95, and 11.19 mcg-h/mL, for the 25-, 50-, and 100-mg doses, respectively. Limited crossover data are available comparing AUCs in fasted and nonfasted patients; however, it appears that the presence of food slightly increases the AUC for trazodone.

The therapeutic range for plasma trazodone concentrations and the relationship of plasma concentrations to clinical response and toxicity have not been established.

■ **Distribution** Distribution of trazodone into human body tissues and fluids has not been determined. Following oral administration of trazodone in animals, the drug and its metabolites are distributed mainly into the liver, kidneys, small intestine, lungs, adrenal glands, and pancreas, with lower concentrations being distributed into adipose tissue, heart, and skeletal muscle. Trazodone crosses the blood-brain barrier in animals, and concentrations of the drug in the brain are higher than those in plasma during the first 8 hours after oral ingestion.

In vitro, trazodone is 89–95% bound to plasma proteins at plasma trazodone concentrations of 100–1500 ng/mL.

Although it is not known if trazodone crosses the placenta in humans, the drug crosses the placenta in animals. Following a single oral dose of 50 mg, trazodone is distributed into milk in concentrations approximately 10% of maternal plasma concentrations, with a milk-to-plasma ratio (based on areas under the plasma and milk concentration-time curves) of about 0.1–0.2. Based on these data, it is estimated that a nursing infant would ingest less than 0.1% of the dose. It is not known whether trazodone metabolites are distributed into milk.

■ **Elimination** Plasma concentrations of trazodone decline in a biphasic manner. The half-life of trazodone in the initial phase ($t_{1/2\alpha}$) is about 3–6 hours and the half-life in the terminal phase ($t_{1/2\beta}$) is about 5–9 hours. The clearance of trazodone from the body shows wide interindividual variation. The manufacturers state that the drug may accumulate in plasma in some individuals.

Trazodone is extensively metabolized in the liver via hydroxylation, oxidation, *N*-oxidation, and splitting of the pyridine ring. A hydroxylated metabolite and oxotriazolopyridinpropionic acid (an inactive metabolite excreted in urine) are conjugated with glucuronic acid. Results of in vitro studies indicate that metabolism of trazodone to an active metabolite, *m*-chlorophenylpiperazine, is mediated by the cytochrome P-450 (CYP) 3A4 isoenzyme. The manufacturers state that other metabolic pathways involved in metabolism of trazodone have not been well characterized. Results from animal studies indicate that trazodone does not induce its own metabolism.

Approximately 70–75% of an oral dose of trazodone is excreted in urine within 72 hours of administration, principally as metabolites. About 20% of an oral dose of trazodone is excreted in urine as oxotriazolopyridinpropionic acid and its conjugates, and about 10% as a dihydrodiol metabolite; less than 1% of a dose is excreted unchanged. The remainder of an oral dose of the drug is excreted in feces via biliary elimination, principally as metabolites.

Chemistry and Stability

■ **Chemistry** Trazodone hydrochloride is a triazolopyridine-derivative antidepressant. The drug is chemically and structurally unrelated to tricyclic or tetracyclic antidepressants or to selective serotonin-reuptake inhibitors. Trazodone hydrochloride occurs as a white, odorless, crystalline powder with a bitter taste and is freely soluble in water and sparingly soluble in alcohol. The drug has a pK_a of 6.7.

■ **Stability** Commercially available trazodone hydrochloride tablets should be stored at room temperature in tight, light-resistant containers and protected from temperatures greater than 40°C.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

TRICYCLICS AND OTHER NOREPINEPHRINE-REUPTAKE INHIBITORS 28:16.04.28

Tricyclic Antidepressants General Statement

■ Tricyclic antidepressants contain a 3-ring structure and differ structurally and pharmacologically from other currently available antidepressants (e.g., selective serotonin-reuptake inhibitors, monoamine oxidase inhibitors).

Uses

■ **Major Depressive Disorder** Tricyclic antidepressants are used in the treatment of major depressive disorder. A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being

30 mg total amphetamine (as 7.5 mg, with Amphetamine Aspartate 7.5 mg, Dextroamphetamine Saccharate 7.5 mg, and Dextroamphetamine Sulfate 7.5 mg)*	**Adderall** (C-II; double-scored), Shire
	Dextroamphetamine Saccharate, Amphetamine Aspartate, Dextroamphetamine Sulfate, and Amphetamine Sulfate Tablets (C-II; double-scored)

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Dextroamphetamine

■ Dextroamphetamine is the dextrorotatory isomer of amphetamine.

Uses

Dextroamphetamine sulfate alone and in fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is used in the treatment of narcolepsy and as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD).

■ Narcolepsy and Attention Deficit Hyperactivity Disorder

Dextroamphetamine sulfate alone and in fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is used in the treatment of narcolepsy and as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in children, adolescents, and adults.

ADHD usually is characterized by developmentally inappropriate symptoms (e.g., moderate to severe distractibility, short attention span, hyperactivity, emotional lability, impulsivity). The final diagnosis of this disorder should not be made if these symptoms are of only comparatively recent origin. Nonlocalizing (soft) neurologic signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of CNS dysfunction may or may not be warranted. Drug therapy is not indicated in all children with ADHD, and such therapy should be considered only after a complete evaluation including medical history has been performed. The decision to use amphetamines should depend on the age of the child and the clinician's assessment of the severity and duration of symptoms and should not depend solely on one or more behavioral characteristics. When symptoms of ADHD are associated with acute stress reactions, use of amphetamines usually is not recommended. For a more detailed discussion on the management of ADHD, including the use of stimulants such as dextroamphetamine, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.92.

Dosage and Administration

■ Administration

Preparations containing dextroamphetamine sulfate are administered orally. The commercially available extended-release capsules containing dextroamphetamine sulfate and dextroamphetamine saccharate in fixed-combination with amphetamine sulfate and amphetamine aspartate (Adderall XR®) may be swallowed intact with or without food or the entire contents of a capsule(s) may be sprinkled on a small amount of applesauce immediately prior to administration; subdividing the contents of a capsule is not recommended. The pellets contained in the capsules should not be chewed or crushed, and the sprinkle/food mixture must not be stored for use at a later time.

The initial dose of dextroamphetamine sulfate (alone or in fixed-combination preparations) is given on awakening; when the drug is given as conventional (short-acting) tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours. Because of the potential for insomnia, administration of dextroamphetamine sulfate conventional tablets (Dexedrine®), dextroamphetamine sulfate extended-release capsules (Dexedrine® Spansules®), or fixed-combination conventional tablets (Adderall®) in the late evening or administration of fixed-combination extended-release capsules (Adderall XR®) in the afternoon should be avoided.

■ Dosage

Dosage of dextroamphetamines should be adjusted according to individual response and tolerance; the smallest dose required to produce the desired response should always be used.

Narcolepsy In the treatment of narcolepsy, the usual dosage of dextroamphetamine sulfate given alone or the total dosage of amphetamines given in fixed-combination preparations containing dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate is 5–60 mg daily, depending upon the patient's age and response, usually given in divided doses. In patients 12 years of age and older, the initial dosage is 10 mg daily; daily dosage is increased by 10 mg at weekly intervals until the optimum response is attained. Although narcolepsy seldom occurs in children younger than 12 years of age, in pediatric patients 6–12 years of age, the recommended initial dosage of dextroamphetamine sulfate is 5 mg daily; daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained. When intolerable adverse effects occur (e.g., insomnia, anorexia), dosage should be reduced. Dextroamphetamine sulfate extended-release capsules may be used for once-daily dosing whenever appropriate.

Attention Deficit Hyperactivity Disorder Dextroamphetamine sulfate dosage for the treatment of attention deficit hyperactivity disorder (ADHD) should be individualized based on patient response and tolerance. The first dosage that produces an observable response may not be the optimum dosage to improve function, and titration to higher dosages should continue in an attempt to achieve a better response. Such a strategy may require subsequent lowering of dosage when higher dosages produce adverse effects or no further clinical improvement. The best dosage for a given patient is the one that provides optimum therapeutic effects with minimal adverse effects. Dosing schedules also may vary, although there currently are no consistent controlled studies comparing alternative dosing schedules. Patients who require relief only during school may respond adequately to a 5-day (i.e., school day) regimen while those requiring relief at home and school may need a daily regimen throughout the week.

As an adjunct in the treatment of ADHD in children 6 years of age and older, the initial dosage of dextroamphetamine sulfate given in conventional (short-acting) preparations is 5 mg once or twice daily; daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained. The usual dosage range is 5–15 mg twice daily or 5–10 mg 3 times daily. Total daily dosage rarely should exceed 40 mg. In children 3–5 years of age, the initial daily dosage is 2.5 mg; daily dosage is increased by 2.5 mg at weekly intervals until the optimum response is attained. When the drug is administered as conventional tablets in divided doses (2 or 3), additional doses are given at intervals of 4–6 hours. Dextroamphetamine sulfate extended-release capsules can be substituted for their respective conventional short-acting preparations if less frequent daily dosing is desirable.

Dextroamphetamine sulfate in fixed combination with other amphetamines (dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate) also is used as an adjunct in the treatment of ADHD in children 6 years of age and older; the initial total dosage of amphetamines is 5 mg once or twice daily. The daily dosage is increased by 5 mg at weekly intervals until the optimum response is attained; total daily dosage rarely should exceed 40 mg. In children 3–5 years of age, the initial daily dosage is 2.5 mg; daily dosage is increased by 2.5 mg at weekly intervals until the optimum response is attained. The manufacturer recommends that the initial dose of dextroamphetamine sulfate in fixed combination with other amphetamines be given on awakening; additional doses (1 or 2) are given at intervals of 4–6 hours. The usual dosage for intermediate-acting preparations (e.g., Dexedrine® Spansules®, Adderall®) in children 6 years of age and older is 5–30 mg once daily or 5–15 mg twice daily.

Alternatively, in patients who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another stimulant, dextroamphetamine therapy may be initiated with extended-release capsules containing dextroamphetamine sulfate in fixed-combination with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate (Adderall XR®). In children 6–12 years of age, the initial dosage of total amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 10 mg once daily; daily dosage may be increased in increments of 5 or 10 mg at weekly intervals to a maximum dosage of 30 mg daily. Treatment may be initiated with a dosage of 5 mg once daily when, in the opinion of the clinician, a lower initial dosage is appropriate. The usual dosage for such longer-acting preparations (e.g., Adderall XR®) is 10–30 mg daily. In adolescents 13–17 years of age, the initial dosage of total amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 10 mg once daily. Dosage may be increased to 20 mg once daily after 1 week if symptoms are not adequately controlled. In adults who are receiving drug therapy for ADHD for the first time or are being switched from therapy with another drug, the recommended dosage of amphetamines as fixed-combination extended-release capsules (Adderall XR®) is 20 mg once daily. Although dosages of up to 60 mg daily (as fixed-combination extended-release capsules) have been used in adolescents 13–17 years of age and adults in clinical studies, there is no evidence that dosages exceeding 20 mg daily provide any additional benefit in these patients. When switching from fixed-combination conventional tablets (Adderall®) to fixed-combination extended-release capsules (Adderall XR®), the total daily dosage of amphetamines may remain the same but should be given once daily.

When possible, therapy should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued treatment. Long-term use of fixed-combination extended-release capsules (i.e., more than 3 weeks in children or more than 4 weeks in adolescents or adults) has not been studied systematically. If fixed-combination extended-release capsules are used for extended periods, the usefulness of the drug should be periodically reevaluated.

Cautions

Dextroamphetamine shares the toxic potentials of amphetamines, and the usual cautions, precautions, and contraindications of amphetamine therapy should be observed. (See Cautions in the Amphetamines General Statement 28:20.04.)

Some commercially available preparations of dextroamphetamine (e.g., DextroStat®, Dexedrine® tablets) contain the dye tartrazine (FD&C yellow No. 5), which may cause allergic reactions including bronchial asthma in susceptible individuals. Although the incidence of tartrazine sensitivity is low, it frequently occurs in patients who are sensitive to aspirin.

Chemistry and Stability

■ **Chemistry** Dextroamphetamine is the dextrorotatory isomer of amphetamine. Dextroamphetamine sulfate occurs as a white, odorless, crystalline powder and has a bitter taste. Dextroamphetamine sulfate is freely soluble in water (about 1:10) and slightly soluble in alcohol (about 1:800). Dextroamphetamine sulfate also is commercially available as fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

■ **Stability** Preparations containing dextroamphetamine sulfate should be stored in tight, light-resistant containers at 15–30°C.

Preparations

Dextroamphetamine and dextroamphetamine sulfate preparations are subject to control under the Federal Controlled Substances Act of 1970 as schedule II (C-II) drugs.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Lisdexamfetamine Dimesylate

■ Prodrug of dextroamphetamine; noncatechol, sympathomimetic amine with CNS-stimulating activity.

Uses

■ **Attention-Deficit Hyperactivity Disorder** Lisdexamfetamine dimesylate is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD) (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction). Safety and efficacy for this indication have been established in controlled clinical trials in children 6–12 years of age and in adults.

Safety and efficacy of lisdexamfetamine dimesylate in the treatment of ADHD in children 6–12 years of age who met DSM-IV-TR criteria for ADHD (combined type or predominantly hyperactive-impulsive type) have been evaluated in 2 randomized, double-blind, placebo-controlled clinical studies (one phase 2 and one phase 3). The phase 2 crossover study was conducted in an analog classroom environment. In this study, dosage of amphetamines was titrated over a 3-week period using an extended-release formulation of mixed amphetamine salts (Adderall XR®) to a final dosage of 10, 20, or 30 mg daily; the children then were assigned to receive, in randomly determined sequence, 1 week each of treatment with extended-release mixed amphetamine salts (continued at the same dosage), lisdexamfetamine dimesylate (30, 50, or 70 mg

■ **CNS-active Drugs** Potential pharmacologic interaction when given with or substituted for other centrally acting drugs, including those with a similar mechanism of action; use with caution.

■ **5-HT$_1$ Receptor Agonists ("Triptans")** Pharmacologic interaction (potentially life-threatening serotonin syndrome) if used concurrently with 5-HT$_1$ receptor agonists (e.g., almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan). If concomitant use is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, when dosage is increased, or when another serotonergic agent is initiated. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

■ **Monoamine Oxidase (MAO) Inhibitors** Pharmacologic interaction (potentially fatal serotonin syndrome); concomitant use is contraindicated. The manufacturer recommends that at least 2 weeks should elapse between discontinuance of an MAO inhibitor and initiation of duloxetine and that at least 5 days elapse between discontinuance of duloxetine therapy and initiation of MAO inhibitor therapy. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

■ **Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors** Potential pharmacologic interaction (potentially life-threatening serotonin syndrome); concurrent administration not recommended. (See Serotonin Syndrome under Warnings/Precautions:Other Warnings and Precautions, in Cautions.)

Concomitant administration of duloxetine and fluvoxamine, a potent CYP1A2 inhibitor, in poor CYP2D6 metabolizers resulted in a six-fold increase in duloxetine AUCs and peak plasma concentrations.

■ **Serotonergic Drugs** Potential pharmacologic interaction (potentially life-threatening serotonin syndrome) with drugs affecting serotonergic neurotransmission, including linezolid (an anti-infective agent that is a nonselective, reversible MAO inhibitor), lithium, tramadol, and St. John's wort *(Hypericum perforatum)*; use with caution. Concurrent administration of serotonin precursors (such as tryptophan) is not recommended. (See Serotonin Syndrome under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Smoking** Potential pharmacokinetic interaction (reduced duloxetine bioavailability and plasma concentrations). The manufacturer states that routine dosage adjustment is not necessary. However, some clinicians recommend a small increase in duloxetine dosage (about 15%) in patients who smoke.

■ **Theophylline** Although small increases (averaging from 7–20%) in theophylline AUCs have been reported during concurrent administration of theophylline and duloxetine; combined use of these drugs reportedly has been well tolerated and routine theophylline dosage adjustment does not appear to be necessary during concomitant administration.

■ **Thioridazine** Potential pharmacokinetic (increased plasma thioridazine concentrations) interaction with resulting increased risk of serious ventricular arrhythmias and sudden death; concomitant use is not recommended by manufacturer of duloxetine.

Description

Duloxetine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is an antidepressant and anxiolytic agent. The drug also has demonstrated analgesic activity in animal models of chronic and persistent pain and in clinical trials evaluating the drug's activity in conditions associated with chronic pain (e.g., neuropathic pain, fibromyalgia). Duloxetine hydrochloride is pharmacologically related to venlafaxine hydrochloride and desvenlafaxine succinate.

The exact mechanisms of the antidepressant, anxiolytic, and central pain inhibitory actions of duloxetine have not been fully elucidated, but appear to be associated with the drug's potentiation of serotonergic and norudrenergic activity in the CNS. Like venlafaxine and desvenlafaxine, duloxetine is a potent inhibitor of neuronal serotonin and norepinephrine reuptake and a less potent inhibitor of dopamine reuptake. Duloxetine does not inhibit monoamine oxidase (MAO) and has not demonstrated significant affinity for dopaminergic, adrenergic, cholinergic, γ-aminobutyric acid (GABA), glutamate, histaminergic, and opiate receptors in vitro.

Although the precise mechanism of action of duloxetine in stress urinary incontinence is unknown, it is thought to be related to potentiation of serotonin and norepinephrine activity in the sacral spinal cord, which increases urethral closure forces and thereby reduces involuntary urine loss.

Duloxetine is extensively metabolized in the liver, principally via oxidation by the cytochrome P-450 (CYP) 2D6 and 1A2 isoenzymes. Duloxetine is a moderate inhibitor of CYP2D6 and a somewhat weak inhibitor of CYP1A2. The drug is not an inhibitor of CYP2C9, CYP2C19, or CYP3A, nor is it an inducer of CYP1A2 or CYP3A.

Advice to Patients

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment. FDA recommends providing written patient information (medication guide) explaining risks of suicidality each time the drug is dispensed.

Importance of promptly reporting any manifestations of liver dysfunction (e.g., pruritus, dark urine, jaundice, right upper quadrant tenderness, unexplained flu-like symptoms) to clinician.

Importance of informing patient of risk of severe liver injury associated with concomitant use of duloxetine and heavy alcohol intake. (See Hepatic Effects under Warnings/Precautions: Other Warnings and Precautions and also see Drug Interactions: Alcohol.)

Risk of psychomotor impairment; importance of exercising caution while operating hazardous machinery, including automobile driving, until patient gains experience with the drug's effects.

Importance of advising patients of risk of orthostatic hypotension and syncope, particularly during initial therapy and subsequent dosage escalation and during concomitant therapy with drugs that may potentiate the orthostatic effect of duloxetine.

Importance of informing patients of risk of serotonin syndrome with concurrent use of duloxetine and 5-HT$_1$ receptor agonists (also called triptans), tramadol, or other serotonergic agents. Importance of seeking immediate medical attention if symptoms of serotonin syndrome develop.

Importance of taking medication exactly as prescribed by the clinician. Importance of informing patients that the delayed-release capsules should be swallowed whole and should not be chewed or crushed, nor should the capsule contents be sprinkled on food or mixed with liquids.

Importance of continuing duloxetine therapy even if a response is not evident within 1–4 weeks, unless directed otherwise.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., bipolar disorder, liver disease) or family history of suicidality or bipolar disorder. Risk of bleeding associated with concomitant use of duloxetine with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[a] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Venlafaxine Hydrochloride

■ Venlafaxine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is a phenylethylamine-derivative antidepressant and anxiolytic agent.

Uses

■ **Major Depressive Disorder** Venlafaxine hydrochloride is used in the treatment of major depressive disorder. Efficacy of venlafaxine conventional tablets for the management of major depression has been established in several placebo-controlled studies in outpatient settings in patients who had major depression and in 1 placebo-controlled study in a hospital setting in patients who had major depression with melancholia. Efficacy of venlafaxine extended-release capsules for the treatment of major depression also has been established by controlled studies of 8–12 weeks' duration in outpatient settings; however, the safety and efficacy of venlafaxine extended-release capsules in hospitalized patients with major depression have not been adequately evaluated.

In 4 studies of 6 weeks' duration in adult outpatients with major depression, venlafaxine in dosages of 75–225 mg daily administered in 2 or 3 divided doses as conventional tablets was found to be superior to placebo on at least 2 of the following 3 clinical measures of depression: Hamilton Depression Rating Scale (HAM-D) total score, HAM-D depressed mood item, and the Clinical Global

Impression (CGI) Severity of Illness Scale. In these studies, higher dosages (i.e., dosages exceeding 225 mg daily) were not associated with greater response. In 2 short-term (8 or 12 weeks), placebo-controlled, flexible-dose (75–225 mg daily) studies with venlafaxine extended-release capsules in adult outpatients, venlafaxine was found to be superior to placebo on the same clinical measures of depression that were used in the studies of venlafaxine conventional tablets, as well as on the Montgomery-Asberg Depression Rating Scale (MADRS) total score and certain factors of the HAM-D, including the anxiety/somatization factor, the cognitive disturbance factor, the retardation factor, and the psychic anxiety score.

Venlafaxine also has been shown to be superior to placebo in the management of major depression with melancholia in a hospital setting. In a study of 4 weeks' duration, 65% of hospitalized patients with major depressive disorder and melancholia who received venlafaxine 150–375 mg daily (mean dosage of 350 mg daily) administered in 3 divided doses as conventional tablets had at least a 50% reduction in MADRS total score compared with 28% of those who received placebo. Patients who participated in this study had a mean baseline MADRS total score of 35 (range: 26–48); those with a baseline score of 4 or greater on the suicidal thought item of the MADRS were excluded from the study.

Results of long-term, relapse prevention studies in outpatients with major depression indicate that venlafaxine's antidepressant effects are maintained for up to 1 year. In these studies, patients who responded to an initial 8-week course of venlafaxine 75–225 mg once daily (as extended-release capsules) or an initial 26-week course of venlafaxine 100–200 mg daily in 2 divided doses (as conventional tablets) were randomized to receive either venlafaxine (same dosage range) or placebo. Patients receiving venlafaxine experienced substantially lower relapse rates than those receiving placebo. Relapse was defined in clinical studies with venlafaxine conventional tablets as a score of 4 or greater on the CGI Severity of Illness Scale and in clinical studies with venlafaxine extended-release capsules as a reappearance of major depressive disorder as defined by DSM-IV criteria and a CGI Severity of Illness score of 4 or greater (i.e., moderately severe depression), 2 consecutive scores of 4 or greater on the CGI Severity of Illness Scale, or a final CGI Severity of Illness score of 4 or greater for any patient who withdrew from the study for any reason.

For further information on treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidal risk, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in Fluoxetine Hydrochloride 28:16.04.20.

■ **Generalized Anxiety Disorder** Venlafaxine hydrochloride is used in the treatment of generalized anxiety disorder. Efficacy of venlafaxine extended-release capsules for the management of generalized anxiety disorder has been established in 4 randomized, multicenter, placebo-controlled studies of 2 or 6 months' duration in adult outpatients who met DSM-IV criteria for generalized anxiety disorder. Three studies employed fixed venlafaxine dosages, and the other employed a flexible dosing schedule. In the flexible-dose study, approximately 69% of patients receiving venlafaxine (75–225 mg daily as extended-release capsules) were categorized as responders (defined as a 40% or greater reduction from baseline in the Hamilton Rating Scale for Anxiety [HAM-A] total score or a score of 1 ["very much improved"] or 2 ["much improved"] on the Clinical Global Impressions [CGI] Global Improvement Scale) during weeks 6–28 of therapy compared with 42–46% of those receiving placebo. In separate clinical studies of 2 or 6 months' duration employing fixed dosages of venlafaxine (37.5, 75, 150, or 225 mg daily as extended-release capsules), venlafaxine was shown to be substantially more effective than placebo on HAM-A total score, both the HAM-A anxiety and tension items, and the CGI Scale. While a relationship between dosage (over the dosage range of 75–225 mg daily) and efficacy in generalized anxiety disorder has not been definitively established, dosages of 37.5 mg daily were not as consistently effective in one study as dosages of 75 or 150 mg daily.

■ **Social Phobia** Venlafaxine hydrochloride is used in the treatment of social phobia (social anxiety disorder). Efficacy of venlafaxine extended-release capsules in the treatment of social phobia has been established in 2 multicenter, placebo-controlled studies of 12 weeks' duration in adult outpatients who met DSM-IV criteria for social phobia. In these studies, venlafaxine (75–225 mg daily administered as extended-release capsules) was substantially more effective than placebo, as determined by change from baseline in the Liebowitz Social Anxiety Scale (LSAS) total score.

Subgroup analysis of these controlled studies in adult outpatients with social anxiety disorder did not reveal any evidence of gender-related differences in treatment outcome; there was insufficient information to determine the effect of age or race on outcome in these studies.

■ **Panic Disorder** Venlafaxine hydrochloride is used in the treatment of panic disorder with or without agoraphobia. Efficacy of venlafaxine extended-release capsules in the treatment of panic disorder has mainly been established in 2 multicenter, double-blind, placebo-controlled studies of 12 weeks' duration in adult outpatients who met DSM-IV criteria for panic disorder with or without agoraphobia. Venlafaxine was given in a fixed dosage of 75 or 150 mg once daily as extended-release capsules in one study and in a fixed dosage of 75 or 225 mg once daily as extended-release capsules in the other study. Venlafaxine was found to be substantially more effective than placebo, as determined by percentage of patients free of full-symptom attacks on the Panic and Anticipatory Anxiety Scale (PAAS), mean change from baseline on the Panic Disorder Severity Scale (PDSS) total score, and the percentage of patients rated as responders on the Clinical Global Impressions (CGI) Improvement Scale. While a relationship between dosage (over the dosage range of 75–225 mg daily) and efficacy in panic disorder has not been definitively established, efficacy was established for each dosage studied in these 2 trials.

Subgroup analysis of these controlled studies in adult outpatients with panic disorder did not reveal any evidence of gender-related differences in treatment outcome; there was insufficient information to determine the effect of age or race on outcome in these studies.

In a longer-term study, patients meeting DSM-IV criteria for panic disorder who had responded during the 12-week open phase of a clinical trial with venlafaxine (75, 150, or 225 mg once daily as extended-release capsules) were randomly assigned to either continue receiving venlafaxine in the same dosage range or be switched to placebo and observed for relapse. Relapse was defined as having 2 or more full-symptom panic attacks per week for 2 consecutive weeks or having discontinued therapy due to loss of effectiveness as determined by the study investigators. Patients who continued receiving venlafaxine therapy experienced a significantly longer time to relapse than those receiving placebo in this study.

■ **Vasomotor Symptoms** Venlafaxine has been used for the management of vasomotor symptoms† in women with breast cancer and in postmenopausal women. Therapy with the drug has improved both the frequency and severity of vasomotor symptoms (hot flushes [flushes]) in these women.

Most women receiving systemic antineoplastic therapy for breast cancer experience vasomotor symptoms, particularly those receiving tamoxifen therapy. In a randomized, double-blind, placebo-controlled study in 191 women with breast cancer (69% were receiving tamoxifen) who were experiencing 2 or more episodes of hot flushes daily, the percentage reductions in hot flush severity score at 4 weeks of treatment were 27% for placebo, 37% for venlafaxine 37.5 mg daily, 61% for venlafaxine 75 mg daily, and 61% for venlafaxine 150 mg daily. Comparisons among treatment groups showed that all 3 venlafaxine dosages were associated with a statistically significant reduction in hot flush frequency and severity; in addition, the 75-mg dosage was more effective than the 37.5-mg dosage, but the 150-mg dosage provided no additional benefit. The role of venlafaxine in managing vasomotor symptoms in women with breast cancer relative to other nonhormonal therapies (e.g., selective serotonin-reuptake inhibitors [SSRIs], gabapentin) remains to be determined. Well-designed, comparative studies are needed to establish optimum nonhormonal therapy, both in terms of efficacy and patient tolerance of adverse effects in these women.

Because of the risks associated with hormone replacement therapy (HRT) for vasomotor symptoms in perimenopausal and postmenopausal women, alternative nonhormonal therapies are being investigated. In a randomized, double-blind, placebo-controlled study in 80 postmenopausal women who were experiencing more than 14 hot flushes weekly, 12 weeks of venlafaxine 75 mg daily was associated with a 51% reduction in hot flush score (patient's perception of hot flush interference with daily living). Although there also was a reduction in hot flush severity, the difference did not reach statistical significance. The role of venlafaxine therapy relative to other nonhormonal therapies (e.g., SSRIs, gabapentin) for postmenopausal vasomotor symptoms, both in terms of efficacy and safety, remains to be established.

Current evidence indicates that venlafaxine is well tolerated in the short-term treatment of vasomotor symptoms associated with breast cancer treatment and with menopause. The principal adverse effects associated with venlafaxine therapy in women with vasomotor symptoms have been dry mouth, decreased appetite, nausea, constipation, and difficulty sleeping. Additional study and experience are needed to further elucidate the role of venlafaxine relative to other nonhormonal therapies and to establish longer-term (i.e., beyond 4–12 weeks) efficacy and safety.

The possible role of venlafaxine in the management of vasomotor symptoms† associated with antiandrogenic therapy in men with prostate cancer remains to be determined.

■ **Obesity** Although substantial changes in appetite and weight have been reported in clinical studies of venlafaxine for the management of major depression, generalized anxiety disorder, social phobia, and panic disorder, the manufacturer states that the drug, alone or in combination with weight loss agents such as phentermine, is *not* indicated for the management of exogenous obesity†. Concomitant use of venlafaxine and weight loss agents also is not recommended by the manufacturer because the safety and efficacy of these agents when used concomitantly have not been established.

Dosage and Administration

■ **Administration** Venlafaxine hydrochloride is administered orally. To minimize GI intolerance (e.g., nausea), the manufacturer recommends that conventional venlafaxine tablets be taken with food. Food does not appear to affect GI absorption of the drug. Venlafaxine extended-release capsules should be administered as a single daily dose with food at approximately the same time each day (in the morning or evening). The extended-release capsules should be swallowed whole with fluid or the entire contents of a capsule(s) may be sprinkled on a small amount of applesauce immediately prior to administration. The extended-release capsules of venlafaxine and their contents should not be divided, crushed, chewed, or placed in water. If the capsule contents are administered by sprinkling on applesauce, the patient should drink some water

after swallowing the entire mixture without chewing to ensure that the pellets are completely swallowed.

Risk of Sustained Hypertension Venlafaxine therapy has been associated with sustained increases in blood pressure in some patients. An analysis of patients with sustained hypertension and patients whose hypertension resulted in discontinuance of the drug revealed that most blood pressure elevations were modest in severity (i.e., 10–15 or 8–28 mm Hg increases in supine diastolic blood pressure among patients receiving conventional or extended-release venlafaxine, respectively). However, sustained blood pressure increases of this magnitude could have adverse consequences in patients receiving the drug. In addition, some cases of elevated blood pressure requiring immediate treatment have been reported during postmarketing surveillance of the drug. Therefore, the manufacturer recommends that preexisting hypertension be controlled before initiating venlafaxine therapy and that regular blood pressure monitoring be performed in patients receiving the drug. In patients who experience a sustained increase in blood pressure during venlafaxine therapy, dosage reduction or discontinuance of the drug should be considered.

Risk of Serotonin Syndrome or Neuroleptic Malignant Syndrome (NMS)-like Reactions Potentially life-threatening serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions have been reported with selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs), including venlafaxine, and selective serotonin-reuptake inhibitors (SSRIs) alone, but particularly with concurrent use of other serotonergic drugs (including serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"], drugs that impair the metabolism of serotonin [e.g., monoamine oxidase inhibitors], or antipsychotics or other dopamine antagonists). Manifestations of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. Patients receiving venlafaxine should be monitored for the development of serotonin syndrome or NMS-like signs and symptoms.

Serious (sometimes fatal) adverse reactions, possibly related to serotonin syndrome or NMS, have been reported in patients who received a monoamine oxidase (MAO) inhibitor shortly before or after venlafaxine therapy. Therefore, concomitant use of venlafaxine and MAO inhibitors is *contraindicated*. It is recommended that at least 2 weeks elapse between discontinuance of an MAO inhibitor and initiation of venlafaxine and that an interval of at least 1 week elapse between discontinuance of venlafaxine and initiation of an MAO inhibitor.

If concurrent therapy with venlafaxine and a 5-HT$_1$ receptor agonist (triptan) is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated. Concurrent use of venlafaxine and serotonin precursors (e.g., tryptophan) is not recommended.

If signs and symptoms of serotonin syndrome or NMS develop during venlafaxine therapy, treatment with venlafaxine and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated.

For additional information on serotonin syndrome, see Drug Interactions: Serotonergic Drugs, in Fluoxetine Hydrochloride 28:16.04.20.

Risk of Suicidality and Overdosage Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Administration: Pediatric Precautions, in Dosage and Administration) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older. It is currently unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior, as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. If a decision is made to discontinue therapy, venlafaxine dosage should be tapered as rapidly as is feasible but with recognition of the risks of abrupt discontinuance. (See Discontinuance of Therapy under Dosage and Administration: Dosage.)

The results of retrospective studies indicate that venlafaxine overdosage may be associated with an increased risk of fatal outcome compared with that observed with SSRIs but lower than that associated with tricyclic antidepressants. Epidemiologic studies have shown that venlafaxine-treated patients have a higher preexisting burden of suicide risk factors than patients treated with SSRIs. The extent to which the finding of an increased risk of fatal outcomes can be attributed to the toxicity of venlafaxine in an overdosage as opposed to other characteristics of these venlafaxine-treated patients is not clear. As with other antidepressants, FDA and the manufacturer of venlafaxine recommend that the drug be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

Risk of Bipolar Disorder It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression). Venlafaxine is *not* approved for use in treating bipolar depression.

Risk of Mydriasis Mydriasis has been reported in association with venlafaxine therapy. Therefore, patients with elevated intraocular pressure or those at risk of angle-closure glaucoma should be monitored during treatment with the drug.

Pediatric Precautions Safety and efficacy of venlafaxine in children younger than 18 years of age have not been established.

Although clinical studies designed to primarily assess the effect of venlafaxine on the growth, development, and maturation of children and adolescents have not been conducted to date, the results from available studies suggest that the drug may adversely affect weight, height, and appetite. Should the decision be made to prescribe venlafaxine for unlabeled (off-label) uses in pediatric patients, the manufacturer recommends regular monitoring of height and weight during therapy, particularly during long-term administration of the drug. In addition, the manufacturer states that the long-term safety of therapy with venlafaxine extended-release capsules (beyond 6 months) has not been systematically evaluated to date. Because the results of clinical studies indicate that the occurrence of blood pressure elevations considered to be clinically important in children and adolescents was similar to that observed in adults receiving venlafaxine, the manufacturer advises that the precautions for adults also should apply to pediatric patients receiving the drug. (See Risk of Sustained Hypertension under Dosage and Administration: Administration.)

In placebo-controlled clinical studies in children and adolescents† 6–17 years of age, efficacy of venlafaxine (administered as extended-release capsules) was *not* established for major depressive disorder or generalized anxiety disorder, and there were increased reports of hostility and suicide-related adverse events such as suicidal ideation and self-harm. Hostility and suicidal ideation were the most common adverse effects leading to discontinuance of the drug in clinical studies in pediatric patients with major depressive disorder, each occurring in 2% of children and adolescents receiving venlafaxine extended-release capsules compared with less than 1 or 0% of those receiving placebo, respectively. In addition, abnormal/changed behavior was the most common adverse effect leading to discontinuance of the drug in clinical studies in pediatric patients with generalized anxiety disorder, occurring in 1% of children and adolescents receiving venlafaxine extended-release capsules compared with none of those receiving placebo. There were no suicides reported in any of these clinical studies.

FDA has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, the FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. (See Cautions: Pediatric Precautions, in Fluoxetine Hydrochloride 28:16.04.20.) Anyone considering the use of venlafaxine in a child or adolescent for any clinical use must therefore balance the potential risks with the clinical need. (See Risk of Suicidality and Overdosage under Dosage and Administration: Administration.)

■ **Dosage** Dosage of venlafaxine hydrochloride is expressed in terms of venlafaxine.

Although no overall differences in efficacy or safety were observed between

geriatrie and younger adults receiving venlafaxine, the possibility that some older patients may exhibit increased sensitivity to the drug cannot be ruled out. No age-related differences in the pharmacokinetics of venlafaxine have been identified and dosage adjustments are not necessary for geriatric patients on the basis of age alone; however, as with any drug used for the treatment of depression, generalized anxiety disorder, social phobia, or panic disorder, caution should be used when treating geriatric patients and dosage should be increased cautiously. In addition, the greater frequency of decreased hepatic and renal function observed in the elderly should be considered. (See Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Venlafaxine also should be used with caution in patients whose underlying medical condition might be compromised by increases in heart rate (e.g., patients with hyperthyroidism, heart failure, or recent myocardial infarction), particularly when the venlafaxine dosage exceeds 200 mg daily.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Risk of Suicidality and Overdosage under Dosage and Administration: Administration.)

Major Depressive Disorder For the treatment of major depressive disorder in adults, the recommended initial dosage of venlafaxine is 75 mg daily administered in 2 or 3 divided doses as conventional tablets or as a single daily dose when using the extended-release capsules. According to the manufacturer, an initial dosage of 37.5 mg daily (as extended-release capsules) for the first 4–7 days (followed by an increase to 75 mg daily) may be considered for some patients. If no clinical improvement is apparent, the dosage may be increased by increments of up to 75 mg daily at intervals of not less than 4 days. If clinically necessary, dosage can be increased up to 225 mg daily in divided doses as conventional tablets or in a single daily dose when using the extended-release capsules. Although studies with venlafaxine conventional tablets in outpatient settings did not demonstrate additional benefit from dosages exceeding 225 mg daily in moderately depressed patients, patients with more severe depression responded to a mean dosage of 350 mg daily. Whether higher dosages of venlafaxine extended-release capsules are needed for more severely depressed patients is unknown; however, the manufacturer states that experience with dosages of venlafaxine extended-release capsules exceeding 225 mg daily is very limited. The manufacturer states that venlafaxine dosage should not exceed 375 mg daily (usually administered in 3 divided doses) as conventional tablets or 225 mg daily as extended-release capsules.

If desired, patients with depression who are undergoing treatment with a therapeutic dose of conventional tablets may be switched to the extended-release capsules at the nearest equivalent daily venlafaxine dose (e.g., change 37.5 mg twice daily administered as conventional tablets to a 75-mg extended-release capsule administered once daily).

Although the optimum duration of venlafaxine therapy has not been established, the manufacturer states that acute depressive episodes require several months or longer of sustained antidepressant therapy. Results of 2 relapse prevention trials indicate that the antidepressant efficacy of venlafaxine is maintained for up to 6 months in patients receiving 75–225 mg once daily as extended-release capsules and for up to 12 months in those receiving 100–200 mg daily in 2 divided doses as conventional tablets. In these studies, the same dosage of venlafaxine was used for both acute-phase and maintenance treatment. Based on these limited data, it is not known whether the dosage required to induce remission of depression would be comparable to that required to maintain euthymia. The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Generalized Anxiety Disorder For the management of generalized anxiety disorder in adults, the initial dosage of venlafaxine as extended-release capsules recommended for most patients is 75 mg once daily. In some patients, it may be desirable to initiate therapy with a dosage of 37.5 mg daily given for the first 4–7 days, followed by an increase to 75 mg daily. Although a dose-response relationship for effectiveness in generalized anxiety disorder was not clearly established in clinical studies, certain patients not responding to a venlafaxine dosage of 75 mg daily may benefit from a higher dosage. Dosage in these patients may be increased in increments of up to 75 mg daily at intervals of not less than 4 days up to a maximum dosage of 225 mg daily.

The optimum duration of venlafaxine therapy for the management of generalized anxiety disorder has not been established. Although the drug has been used for up to 6 months in controlled clinical studies, the usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Social Phobia For the management of social phobia in adults, the recommended initial dosage of venlafaxine for most patients is 75 mg once daily as extended-release capsules. In some patients, it may be desirable to initiate therapy with a dosage of 37.5 mg daily given for the first 4–7 days, followed by an increase to 75 mg daily. Although a dose-response relationship for effectiveness in social phobia was not clearly established in clinical studies, certain patients not responding to a venlafaxine dosage of 75 mg daily may benefit from a higher dosage. Dosage in these patients may be increased in increments of up to 75 mg daily at intervals of not less than 4 days up to a maximum dosage of 225 mg daily.

The optimum duration of venlafaxine therapy for the management of social phobia has not been established. The efficacy of venlafaxine for long-term therapy (i.e., longer than 12 weeks) has not been demonstrated in controlled clinical studies to date. The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Panic Disorder For the management of panic disorder in adults, the recommended initial dosage of venlafaxine is 37.5 mg once daily as extended-release capsules for 7 days, followed by 75 mg once daily as extended-release capsules for another 7 days. In clinical trials, 37.5 mg once daily was given initially for 7 days, then 75 mg once daily for 7 days; thereafter, dosage was increased in increments of 75 mg once daily every 7 days if necessary up to a maximum dosage of 225 mg daily. Although a dose-response relationship for effectiveness in panic disorder was not clearly established in fixed-dose clinical studies, certain patients not responding to a venlafaxine dosage of 75 mg daily may benefit from a higher dosage. Dosage in these patients may be increased in increments of up to 75 mg daily at intervals of not less than 7 days up to a maximum dosage of approximately 225 mg daily.

The optimum duration of venlafaxine therapy for the management of panic disorder has not been established. The efficacy of venlafaxine for long-term therapy (i.e., longer than 12 weeks) in prolonging time to relapse in responding patients has been demonstrated in a controlled clinical trial. However, the usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Vasomotor Symptoms Although the optimum dosage for the treatment of vasomotor symptoms† in women with breast cancer and in postmenopausal women remains to be established, some clinicians suggest that venlafaxine be initiated at a dosage of 37.5 mg once daily as extended-release capsules, increasing as necessary to 75 mg once daily. In one clinical study, 75 mg once daily as extended-release capsules appeared to be optimal. Further increases in dosage do not appear to provide substantially increased benefit but are potentially more toxic.

Discontinuance of Therapy Because withdrawal effects may occur, abrupt discontinuance of venlafaxine should be avoided. When venlafaxine therapy is discontinued, dosage should be tapered gradually and the patient carefully monitored to reduce the risk of withdrawal symptoms. If intolerable symptoms occur following dosage reduction or upon discontinuance of treatment, venlafaxine therapy may be reinstituted at the previously prescribed dosage until such symptoms abate. Clinicians may resume dosage reductions at that time but at a more gradual rate.

Withdrawal symptoms reported in clinical studies in adults receiving venlafaxine for major depression or generalized anxiety disorder include agitation, anorexia, anxiety, confusion, impaired coordination, diarrhea, dizziness, dry mouth, dysphoric mood, fasciculation, fatigue, headaches, hypomania, insomnia, nausea, nervousness, nightmares, sensory disturbances (including shock-like electrical sensations), somnolence, sweating, tremor, vertigo, and vomiting. Abrupt discontinuance or dosage reduction of venlafaxine has been associated with the appearance of new symptoms, the frequency of which increased with increased dosage and longer duration of treatment.

In clinical studies, venlafaxine hydrochloride extended-release capsules were discontinued by reducing the daily dosage by 75 mg at intervals of 1 week; however, individualized tapering may be necessary.

■ **Dosage in Renal and Hepatic Impairment** Since clearance of venlafaxine is decreased and elimination half-life is increased in patients with renal impairment, the manufacturer states that dosage of the drug should be reduced by 25–50% in patients with mild-to-moderate renal impairment and by 50% in those undergoing hemodialysis and administration of the dose withheld until the dialysis period is complete (4 hours). Venlafaxine dosage also should be reduced by 50% in patients with moderate hepatic impairment. The manufacturer's labeling should be consulted for more detailed information on the dosage modifications in these patient populations.

■ **Treatment of Pregnant Women during the Third Trimester** Some neonates exposed to venlafaxine, other selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs), or selective serotonin-reuptake inhibitors late in the third trimester of pregnancy have developed complications, which have sometimes been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special care nurseries. (For additional information, see Cautions: Pregnancy, Fertility, and Lactation, in Fluoxetine Hydrochloride 28:16.04.20.) Therefore, the clinician should carefully consider the potential risks and benefits of treating a pregnant woman with venlafaxine during the third trimester of pregnancy. In addition, consideration should be given to cautiously tapering venlafaxine therapy in the third trimester prior to delivery if the drug is administered during pregnancy.

Description

Venlafaxine hydrochloride, a selective serotonin- and norepinephrine-reuptake inhibitor (SNRI), is a phenylethylamine-derivative antidepressant and anxiolytic agent. Venlafaxine differs structurally and pharmacologically from other commercially available antidepressants, including tricyclic and tetracyclic antidepressants, and also differs from other commercially available agents used to treat generalized anxiety disorder.

The exact mechanisms of antidepressant and anxiolytic actions of venlafaxine have not been fully elucidated but appear to be associated with the drug's potentiation of neurotransmitter activity in the CNS. Venlafaxine and its active metabolite, O-desmethylvenlafaxine (ODV), are potent inhibitors of neuronal serotonin and norepinephrine reuptake and weak inhibitors of dopamine reuptake. In vitro studies have demonstrated that venlafaxine and ODV do not possess any significant affinity for muscarinic cholinergic, H_1-histaminergic, or α_1-adrenergic receptors.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautious, precautions, and contraindications.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

SELECTIVE SEROTONIN-REUPTAKE INHIBITORS 28:16.04.20

Citalopram Hydrobromide

■ Citalopram hydrobromide, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant.

Uses

Citalopram hydrobromide is used in the treatment of major depressive disorder. In addition, citalopram has been used for the treatment of obsessive-compulsive disorder†, panic disorder†, social phobia† (social anxiety disorder), alcohol dependence†, premenstrual dysphoric disorder†, premature ejaculation†, eating disorders†, diabetic neuropathy†, and posttraumatic stress disorder†.

■ **Major Depressive Disorder** Citalopram hydrobromide is used in the treatment of major depressive disorder. A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized, and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features, alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response to or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, Tricyclic and Other Antidepressants under Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes, and Drug Interactions: Lithium.)

The efficacy of citalopram for the management of major depression has been established in short-term (4–6 weeks' duration), placebo-controlled studies in outpatients 18–66 years of age who met DSM-III or -III-R criteria for major depressive disorder. In a 6-week study in which patients received fixed citalopram dosages of 10, 20, 40, or 60 mg daily, the drug was effective at dosages of 40 and 60 mg daily as measured by the Hamilton Depression Rating Scale (HAM-D) Total Score, the HAM-D Depressed Mood Item (Item 1), the Montgomery Asberg Depression Rating Scale, and the Clinical Global Impression (CGI) Severity Scale. This study showed no clear antidepressant effect of the 10 or 20 mg daily dosages, and the 60 mg daily dosage was not more effective than the 40 mg daily dosage.

In a 4-week, placebo-controlled study in depressed adult patients, of whom 85% met criteria for melancholia, those who were treated with citalopram (at an initial dosage of 20 mg daily, titrated to the maximum tolerated dosage or to a maximum daily dosage of 80 mg) showed greater improvement than patients receiving placebo on the HAM-D Total Score, HAM-D Item 1, and the CGI Severity score. In 3 additional placebo-controlled depression trials, the difference in response to treatment between patients receiving citalopram and patients receiving placebo was not statistically significant, possibly due at least in part to a high spontaneous response rate, a high placebo response rate, small sample size, or, in the case of one study, too low a dosage.

In 2 placebo-controlled studies, depressed adult patients who had responded to an initial 6- to 8-week course of citalopram (fixed dosage of 20 or 40 mg daily in one study and flexible dosages ranging from 20–60 mg daily in the second study) were randomized to continue receiving citalopram or placebo for up to 6 months. In both of these studies, patients receiving citalopram experienced substantially lower relapse rates over the subsequent 6 months compared with those receiving placebo. In the fixed-dose study, the decreased rate of depression relapse was similar in patients receiving 20 or 40 mg daily of citalopram. An analysis of these data for possible age-, gender-, and race-related effects on treatment outcome did not suggest any difference in antidepressant efficacy based on the age, gender, and race of the patient. In a placebo-controlled trial, citalopram also was shown to help prevent recurrences of depression in patients with recurrent major depression receiving the drug for up to 6–18 months.

While the optimum duration of citalopram therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). In placebo-controlled studies, citalopram has been shown to be effective for the long-term (e.g., up to 18 months) management of depression. In addition, the drug has been used in some patients for longer periods (e.g., up to 28 months) without apparent loss of clinical effect or increased

Chemistry and Stability

■ **Chemistry** Caffeine, like theobromine and theophylline, is a xanthine derivative. Caffeine occurs naturally in tea and coffee, but is prepared synthetically for commercial drug use. Caffeine is present in amounts of about 100–150 mg/180 mL of brewed coffee; 60–80 mg/180 mL of instant coffee; 40–100 mg/180 mL of tea; and 17–55 mg/180 mL of cola beverage.

Caffeine occurs as a white powder or white, glistening needles that are usually matted together. The drug is odorless and has a bitter taste. Caffeine, which may contain one molecule of water or be anhydrous, is sparingly soluble in water and in alcohol. The hydrate effloresces in air.

Various synthetic mixtures of caffeine have been prepared to increase its solubility. The mixture of caffeine and sodium benzoate contains 45–52% anhydrous caffeine and occurs as a white powder with a slightly bitter taste. The mixture is freely soluble in water and soluble in alcohol. Caffeine and sodium benzoate injection has a pH of 6.5–8.5. Citrated caffeine is a white powder with a bitter taste, obtained by combining caffeine with citric acid. Citrated caffeine is freely soluble in water and soluble in alcohol and contains approximately 50% anhydrous caffeine. Commercially available caffeine citrate injection and oral solution have a pH of 4.7.

■ **Stability** Commercially available caffeine and sodium benzoate injection and caffeine citrate injection and oral solution should be stored at 15–30°C. The commercially available injections and oral solution should be inspected visually for particulate matter and discoloration prior to administration. Vials containing discolored solution or visible particulate matter should be discarded.

Based on compatibility studies, the commercially available caffeine citrate injection is chemically stable for 24 hours at room temperature when mixed with any of the following solutions: 5% dextrose injection; 50% dextrose injection; Intralipid® 20% emulsion; Aminosyn® 20% solution; dopamine hydrochloride injection (diluted to 0.6 mg/mL with 5% dextrose injection); calcium gluconate 10% injection; heparin sodium injection (diluted to 1 unit/mL with 5% dextrose injection); fentanyl citrate injection (diluted to 10 mcg/mL with 5% dextrose injection).

Dexmethylphenidate Hydrochloride

■ Dexmethylphenidate hydrochloride, the *d-threo* enantiomer of racemic methylphenidate hydrochloride, is a CNS stimulant that has pharmacologic actions that are qualitatively similar to those of amphetamines.

Uses

Dexmethylphenidate hydrochloride is used alone or combined with behavioral treatment as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD).

■ **Attention Deficit Hyperactivity Disorder** Dexmethylphenidate hydrochloride is used alone or combined with behavioral treatment as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in carefully selected children 6 years of age and older, adolescents, and adults.

Efficacy of dexmethylphenidate hydrochloride conventional tablets for this indication was established in 2 placebo-controlled clinical trials in patients 6–17 years of age who met DSM-IV criteria for ADHD. In the first controlled clinical trial, improvement in symptom scores from baseline to study end (4 weeks) was greater in children receiving dexmethylphenidate hydrochloride conventional tablets than in those receiving placebo. In the second trial, children who had responded to dexmethylphenidate hydrochloride as conventional tablets in a 6-week open-label trial were randomized to receive this formulation of the drug for an additional 2 weeks or to receive placebo. Treatment failure occurred in 63% of patients receiving placebo compared with 17% of those receiving dexmethylphenidate.

Efficacy of dexmethylphenidate hydrochloride extended-release tablets for this indication was established in clinical trials in children 6 years of age and older, adolescents, and adults who met DSM-IV criteria for ADHD. In a controlled clinical trial in pediatric patients 6–17 years of age, improvement in symptoms from baseline to study end (7 weeks) was greater in children receiving dexmethylphenidate hydrochloride extended-release capsules than in those receiving placebo. Because a limited number of adolescents were enrolled in the trial, data from the trial were insufficient to adequately assess efficacy of the extended-release capsules in adolescents; however, efficacy of dexmethylphenidate hydrochloride extended-release capsules in adolescents is supported by pharmacokinetic data and by evidence of the efficacy of conventional tablets of the drug in this population. In a controlled clinical trial in adults 18–60 years of age, improvement in signs and symptoms of ADHD from baseline to study end (5 weeks) was greater in adults receiving dexmethylphenidate hydrochloride extended-release capsules than in those receiving placebo.

For further information on the management of ADHD, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate Hydrochloride 28:20.92.

Dosage and Administration

■ **Administration** Dexmethylphenidate hydrochloride conventional tablets are administered orally twice daily without regard to meals; the manufacturer recommends that doses be administered at least 4 hours apart.

Dexmethylphenidate hydrochloride extended-release capsules are administered orally once daily in the morning, with or without food. The capsules should be swallowed intact and should *not* be crushed, chewed, or divided. Alternatively, the entire contents of the extended-release capsule(s) may be sprinkled onto a small amount (e.g., a spoonful) of applesauce immediately prior to administration. The entire sprinkle/applesauce mixture should be taken immediately and should not be stored for use at a later time.

■ **Dosage** The recommended initial dosage of dexmethylphenidate hydrochloride as conventional tablets, in patients 6 years of age and older who currently are not receiving racemic methylphenidate or are receiving stimulants other than methylphenidate is 2.5 mg twice daily. In patients 6 years of age and older who are being transferred from racemic methylphenidate to dexmethylphenidate therapy, the initial dexmethylphenidate hydrochloride dosage is one-half the current methylphenidate hydrochloride dosage. Dosage of dexmethylphenidate hydrochloride may be increased by 2.5–5 mg daily at weekly intervals, up to a maximum dosage of 20 mg daily.

The recommended initial dosage of dexmethylphenidate hydrochloride as extended-release capsules in patients who currently are not receiving dexmethylphenidate or racemic methylphenidate or who are receiving stimulants other than methylphenidate is 5 mg once daily for pediatric patients 6 years of age and older or 10 mg once daily for adults. Patients currently receiving dexmethylphenidate hydrochloride conventional tablets may be switched to the extended-release capsules at the same total daily dosage. In patients being transferred from racemic methylphenidate to dexmethylphenidate therapy, the initial dexmethylphenidate hydrochloride dosage is one-half the current methylphenidate hydrochloride dosage. Dosage of dexmethylphenidate hydrochloride may be increased by 5 mg daily in pediatric patients or by 10 mg daily in adults at weekly intervals, up to a maximum dosage of 20 mg daily.

Dosage of dexmethylphenidate must be carefully adjusted according to individual requirements and response. The patient should be observed for a sufficient duration at a given dosage to ensure that maximum benefit has been achieved before dosage adjustment is considered. If a beneficial effect is not

attained after appropriate dosage adjustment over a 1-month period, dexmethylphenidate therapy should be discontinued. If paradoxical aggravation of symptoms or other adverse effects occur during dexmethylphenidate therapy, dosage should be reduced or the drug discontinued if necessary.

The long-term efficacy (i.e., exceeding 6 weeks for conventional tablets or 7 weeks for extended-release capsules) has not been evaluated systematically in controlled studies; therefore, the long-term usefulness of the drug should be reevaluated periodically in patients receiving dexmethylphenidate for extended periods. In patients who have responded to dexmethylphenidate therapy, the drug should be discontinued periodically to assess the patient's condition; improvement may be maintained temporarily or permanently after the drug is discontinued. For children or adolescents whose symptoms are not severe outside the school setting, drug holidays may be attempted for all or part of the summer to assess continuing efficacy and need for such therapy as well as to minimize adverse effects.

■ **Special Populations** No special population dosage recommendations at this time.

Cautions

■ **Contraindications** Marked anxiety, tension, and agitation, since dexmethylphenidate may aggravate these symptoms. Glaucoma. Motor tics or a family history or a diagnosis of Tourette's syndrome; however, the American Academy of Pediatrics (AAP) states that the presence of tics before or during medical management of ADHD is *not* an absolute contraindication to stimulant drug use. (See the opening discussion in Cautions, in Methylphenidate Hydrochloride 28:20.92.) Recent (within 14 days) administration of monoamine oxidase (MAO) inhibitors, since hypertensive crisis could result.

Known hypersensitivity to dexmethylphenidate, methylphenidate, or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** Dexmethylphenidate hydrochloride shares the toxic potentials of racemic methylphenidate, and the usual precautions of racemic methylphenidate therapy should be observed.

Abuse Potential. Tolerance and psychologic dependence with varying degrees of abnormal behavior can occur with chronic abuse of dexmethylphenidate. Psychotic episodes can occur, particularly with parenteral abuse. Dexmethylphenidate should be used with caution in patients with a history of drug or alcohol dependence. Caution also may be indicated in patients with comorbid conduct disorder or a chaotic family. If the risk of drug abuse by the patient or the patient's peers or family is considered high, a nonstimulant drug may be preferable.

Withdrawal. Abrupt withdrawal of dexmethylphenidate following prolonged administration may unmask severe depression. Long-term follow-up may be required.

Sudden Death and Serious Cardiovascular Events. Although a causal relationship to stimulants has not been established, sudden unexplained death, stroke, and myocardial infarction have been reported in adults receiving usual dosages of stimulants for the treatment of ADHD. Sudden unexplained death also has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of CNS stimulants. Results of one retrospective, case-control epidemiologic study showed a possible association between use of stimulant medications (e.g., methylphenidate) and sudden unexplained death in healthy children and adolescents. (See Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions.) Given the study limitations, the US Food and Drug Administration (FDA) is unable to conclude that these data affect the overall risk and benefit profile of stimulant medications used to treat ADHD in children and adolescents. Amphetamines or other stimulants should not be discontinued by parents of children or patients receiving these medications for ADHD before consulting with their clinician. Because of postmarketing reports and results of this and other epidemiologic studies, the FDA is conducting an ongoing review of safety of amphetamines and other stimulants to evaluate a possible link between use of these agents and sudden death in children. To determine whether there is a direct causal relationship between use of stimulants and serious adverse cardiovascular events, the Agency for Healthcare Research and Quality (AHRQ) and FDA announced in 2007 that they are collaborating on a large study evaluating clinical data on approximately 500,000 adults and children who received these drugs for management of ADHD during a 7-year period ending in 2005; data collection for the study is expected to be completed in 2009.

Children, adolescents, and adults who are being considered for stimulant therapy should undergo a thorough medical history review (including evaluation for a family history of sudden death or ventricular arrhythmia) and physical examination to detect the presence of cardiac disease, and should receive further cardiac evaluation (e.g., ECG, echocardiogram) if initial findings suggest such disease. Although some serious cardiac conditions are independently associated with an increased risk of sudden death, CNS stimulants generally should *not* be used in children, adolescents, or adults with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious cardiac conditions. Patients who develop exertional chest pain, unexplained syncope, or other manifestations suggestive of cardiac disease during stimulant therapy should undergo prompt cardiac evaluation.

For further information on screening for cardiac conditions, selecting appropriate candidates for stimulant therapy, and monitoring for treatment-emergent cardiac conditions, see Cardiovascular Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.

Effects on Blood Pressure and Heart Rate. Stimulants cause modest increases in average blood pressure (i.e., by about 2–4 mm Hg) and heart rate (i.e., by about 3–6 beats/minute); larger increases may occur in some patients. Although modest increases would not be expected to have short-term sequelae, all patients should be monitored for larger changes in blood pressure and heart rate. Caution is advised in patients with underlying medical conditions that might be affected by increases in blood pressure or heart rate (e.g., hypertension, heart failure, recent myocardial infarction, ventricular arrhythmia).

Psychiatric Effects. Stimulants may exacerbate symptoms of behavior disturbance and thought disorder in patients with a preexisting psychotic disorder.

Stimulants should be used with caution in the management of ADHD in patients with comorbid bipolar disorder because of the potential for precipitation of mixed or manic episodes in such patients. Prior to initiating stimulant therapy, patients with ADHD and comorbid depressive symptoms should be carefully screened to determine if they are at risk for bipolar disorder; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, or depression).

Psychotic or manic symptoms (e.g., hallucinations, delusional thinking, mania) have been reported in children and adolescents without prior history of psychotic illness or mania who received usual dosages of stimulants. In a pooled analysis of multiple short-term, placebo-controlled studies, such symptoms occurred in about 0.1% of patients receiving usual dosages of stimulants (i.e., methylphenidate, amphetamine) compared with 0% of those receiving placebo. If psychotic or manic symptoms occur during stimulant therapy, a causal relationship to stimulants should be considered, and discontinuance of therapy may be appropriate.

Aggressive behavior and hostility frequently are observed in children and adolescents with ADHD and have been reported in patients receiving drug therapy for the disorder. Although a causal relationship to stimulants has not been established, patients beginning treatment for ADHD should be monitored for the onset or worsening of aggressive behavior or hostility.

Growth Suppression. Prolonged administration of stimulants in children with ADHD has been associated with at least a temporary suppression of normal weight and/or height patterns in some patients. Results of an analysis of weight and height patterns in children 7–13 years of age suggested that treatment with methylphenidate for up to 3 years was associated with a temporary slowing in growth rate (on average, height gain was suppressed by about 2 cm and weight gain was suppressed by 2.7 kg over 3 years), without evidence of growth rebound during this period of development. In a 7-week controlled study in children and adolescents, patients receiving placebo gained a mean of 0.4 kg, while those receiving dexmethylphenidate hydrochloride extended-release capsules *lost* a mean of 0.5 kg. Published data are inadequate to determine whether long-term use of amphetamines may cause similar suppression of growth; however, it is anticipated that amphetamines, like methylphenidate, also cause temporary growth suppression. Therefore, the manufacturers of stimulant preparations state that growth should be monitored during therapy with stimulants, and children who are not growing or gaining height or weight as expected may require temporary discontinuance of therapy. However, AAP states that studies of stimulants in children generally have found little or no decrease in expected height, with any decrease in growth early in treatment being compensated for later on. (See Cautions: GI and Growth Effects, in Methylphenidate Hydrochloride 28:20.92.)

Seizures. There is some clinical evidence that stimulants may lower the seizure threshold in patients with a history of seizures, in those with prior EEG abnormalities but no history of seizures, and, very rarely, in those without a history of seizures and no prior evidence of EEG abnormalities. One patient, without a history of seizure disorder, experienced a seizure while receiving dexmethylphenidate during a controlled clinical trial. If seizures occur, the drug should be discontinued.

Visual Effects. Visual disturbances (difficulty with accommodation, blurred vision) have been reported in patients receiving stimulants.

General Precautions **Hematologic Monitoring.** The manufacturer recommends periodic monitoring of complete blood cell count (CBC), with differential, and platelet counts during prolonged therapy; however, AAP and many clinicians consider routine hematologic monitoring unnecessary in patients receiving recommended stimulants (e.g., methylphenidate, amphetamines) in the absence of clinical signs (e.g., fever, sore throat, unusual bleeding or bruising) suggestive of hematologic toxicity.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Not known whether dexmethylphenidate is distributed into milk; caution if used in nursing women.

Pediatric Use. Safety and efficacy of dexmethylphenidate not established in children younger than 6 years of age, and therefore the manufacturer states that the drug should not be used in this age group.

Therapy with stimulants may be associated with at least a temporary suppression of growth in children. (See Growth Suppression under Warnings/Precautions: Warnings, in Cautions.)

Sudden death has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of CNS stimulants. Results of one retrospective, case-control epidemio-

logic study suggested a possible association between use of stimulant medications and sudden unexplained death in healthy children and adolescents. (See Sudden Death and Serious Cardiovascular Events under Warnings/Precautions: Warnings, in Cautions.)

Renal Impairment. Safety and efficacy of dexmethylphenidate not established in patients with renal impairment.

Hepatic Impairment. Safety and efficacy of dexmethylphenidate not established in patients with hepatic impairment.

■ **Common Adverse Effects** Abdominal pain, fever, anorexia, and nausea each occurred in 5% or more of patients receiving dexmethylphenidate hydrochloride conventional tablets in clinical trials and were at least twice as frequent in patients receiving the drug as in those receiving placebo. Twitching (motor or vocal tics), anorexia, insomnia, and tachycardia each resulted in discontinuance of dexmethylphenidate hydrochloride conventional tablets in approximately 1% of patients.

Decreased appetite, headache, dyspepsia, dry mouth, anxiety, and pharyngolaryngeal pain each occurred in 5% or more of patients receiving dexmethylphenidate hydrochloride extended-release capsules in clinical trials. Twitching (motor or vocal tics), anorexia, insomnia, and tachycardia each resulted in discontinuance of dexmethylphenidate hydrochloride extended-release capsules in approximately 1% of pediatric patients. In adults, insomnia, jittery feeling, anorexia, and anxiety each resulted in discontinuance of therapy in about 1–2% of patients.

Nervousness and insomnia are the most commonly reported adverse effects in patients receiving racemic methylphenidate preparations.

Drug Interactions

The possibility that drug interactions reported with racemic methylphenidate also could occur with dexmethylphenidate should be considered.

■ **Cardiovascular Agents** Potential pharmacologic interaction (increased hypertensive effects) with concomitant use of pressor agents and dexmethylphenidate; caution advised. Pharmacodynamic interaction (decreased antihypertensive effect) reported with concomitant use of racemic methylphenidate and antihypertensive agents. Serious adverse effects have occurred rarely in patients receiving racemic methylphenidate and clonidine concomitantly; causality not established.

■ **Anticonvulsants** Potential pharmacokinetic interaction (decreased metabolism of anticonvulsant agent) with concomitant use of racemic methylphenidate and anticonvulsants (e.g., phenobarbital, phenytoin, primidone). Monitoring of plasma anticonvulsant concentrations is recommended when methylphenidate is initiated or discontinued in patients receiving anticonvulsants; adjustment of anticonvulsant dosage may be required.

■ **Anticoagulants** Potential pharmacokinetic interaction (decreased metabolism of anticoagulant) with concomitant use of racemic methylphenidate and coumarin anticoagulants. Monitoring of prothrombin time (PT)/international normalized ratio (INR) is recommended when methylphenidate is initiated or discontinued in patients receiving coumarin anticoagulants; adjustment of anticoagulant dosage may be required.

■ **Antidepressants** Pharmacologic interaction (possible hypertensive crisis) with monoamine oxidase (MAO) inhibitors. (See Cautions: Contraindications.) Pharmacokinetic interaction (decreased metabolism of antidepressant agent) reported with concomitant use of racemic methylphenidate and tricyclic antidepressants (e.g., imipramine, clomipramine, desipramine) or selective serotonin-reuptake inhibitors. Adjustment of antidepressant dosage may be required when methylphenidate is initiated or discontinued.

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Pharmacokinetic interaction unlikely.

■ **Drugs Affecting GI pH** Studies to evaluate the effects of changes in gastric pH on the absorption of dexmethylphenidate hydrochloride administered as extended-release capsules have not been performed to date. However, the potential exists for a pharmacokinetic interaction (altered release of dexmethylphenidate hydrochloride) between Focalin® XR extended-release capsules and drugs that alter gastric pH (e.g., antacids, acid suppressants).

Description

Dexmethylphenidate hydrochloride, the more pharmacologically active (*d-threo*) enantiomer of racemic methylphenidate hydrochloride, is a CNS stimulant. The mechanism of action in the treatment of attention deficit hyperactivity disorder (ADHD) has not been determined.

Dexmethylphenidate hydrochloride is well absorbed following oral administration. Because of first-pass metabolism, mean absolute bioavailability is 22–25%. When dexmethylphenidate hydrochloride is administered orally as conventional tablets in fasting patients, peak plasma concentrations are achieved within 60–90 minutes after a dose. When the drug is administered as extended-release capsules (Focalin® XR), peak plasma concentrations are attained at 1.5 hours and again at 6.5 hours after a dose. Extended-release capsules are absorbed more slowly but to the same extent as conventional tablets. Plasma concentrations of dexmethylphenidate achieved following single-dose oral administration of dexmethylphenidate hydrochloride capsules are comparable to the dexmethylphenidate concentrations achieved following single-dose oral administration of racemic methylphenidate hydrochloride capsules at equimolar doses (twice the total mg amount of dexmethylphenidate hydrochloride). Dexmethylphenidate is metabolized principally by de-esterification to form *d*-ritalinic acid, which has little or no pharmacologic activity. In vitro studies indicate that the drug does not inhibit the cytochrome P-450 (CYP) enzyme system. The mean plasma elimination half-life of dexmethylphenidate is 2–3 hours in children or 2–4.5 hours in adults.

Dexmethylphenidate hydrochloride is commercially available as conventional tablets and extended-release capsules. Each bead-filled dexmethylphenidate hydrochloride extended-release capsule (Focalin® XR) contains one-half of the dose as immediate-release beads and one-half as enteric-coated, delayed-release beads, thus providing an immediate release of dexmethylphenidate hydrochloride followed by a second delayed release of the drug.

Advice to Patients

Importance of providing patient or caregiver with a copy of the manufacturer's patient information (medication guide); discuss and answer questions about its contents (e.g., benefits and risks of stimulant therapy, appropriate use) as needed. Importance of instructing the patient or caregiver to read and understand the contents of the medication guide before initiating therapy and each time the prescription is refilled.

Importance of informing clinicians immediately of any adverse cardiovascular (e.g., chest pain, shortness of breath, fainting) or psychiatric effects (e.g., hallucinations, delusional thinking, mania).

Importance of taking the drug exactly as prescribed.

Importance of not chewing or crushing the beads contained in the capsules and of not storing the sprinkle/food mixture for later use.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs and herbal supplements, as well as any concomitant illnesses/conditions (e.g., glaucoma, cardiac/cardiovascular disease, mental/psychiatric disorder, seizures, suicidal ideation or behaviors, history of substance abuse).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Dexmethylphenidate hydrochloride is subject to control under the Federal Controlled Substances Act of 1970 as a schedule II (C-II) drug.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Dexmethylphenidate Hydrochloride

Oral		
Capsules, extended-release (containing beads)	5 mg (beads, delayed-release, enteric-coated extended-release 2.5 mg with immediate-release 2.5 mg)	Focalin® XR (C-II), Novartis
	10 mg (beads, delayed-release, enteric-coated extended-release 5 mg with immediate-release 5 mg)	Focalin® XR (C-II), Novartis
	15 mg (beads, delayed-release, enteric-coated extended-release 7.5 mg with immediate-release 7.5 mg)	Focalin® XR (C-II), Novartis
	20 mg (beads, delayed-release, enteric-coated extended-release 10 mg with immediate-release 10 mg)	Focalin® XR (C-II), Novartis

	5 mg	Focalin® (C-II), Novartis
	10 mg	Focalin® (C-II), Novartis

mended human dosage on a mg/m² basis have not revealed evidence of fetal malformation. However, risperidone has been shown to cross the placenta in rats, and an increased rate of stillborn rat pups occurred at dosages 1.5 times higher than the maximum recommended human dosage on a mg/m² basis. In 3 reproductive studies in rats, there was an increase in pup deaths during the first 4 days of lactation at dosages 0.1–3 times the human dosage on a mg/m² basis. It is not known whether these deaths resulted from a direct effect on the fetuses or pups or to effects on the dams. In a separate reproductive study in rats, an increased number of pup daths (at birth or by the day after birth) and a decrease in birth weight were observed in pups of dams treated with risperidone dosages that were 3 times the maximum recommended human dosage on a mg/m² basis. Risperidone also appeared to impair maternal behavior, as evidenced by reduced weight gain and decreased survival (from day 1–4 of lactation) in pups born to control dams but reared by risperidone-treated dams.

Although there are no adequate and controlled studies to date in humans, one case of agenesis of the corpus callosum has been reported in an infant exposed to risperidone in utero; however, a causal relationship to risperidone therapy is unknown. Reversible extrapyramidal adverse effects in the neonate also were observed following postmarketing use of risperidone during the third trimester of pregnancy. Risperidone should be used during pregnancy only when the potential benefits justify the possible risks to the fetus. The effect of risperidone on labor and delivery in humans is unknown.

Risperidone (0.16–5 mg/kg) has been shown to impair mating, but not fertility, in Wistar rats in 3 reproductive studies at dosages 0.1–3 times the maximum recommended human dosage on a mg/m² basis. The effect appeared to be in females since impaired mating behavior was not noted in the Segment I study in which males only were treated. Sperm motility and serum testosterone concentrations were decreased in beagles at dosages 0.6–10 times the human dose on a mg/m² basis. Serum testosterone and sperm parameters partially recovered but remained decreased after treatment was discontinued. A no-effect dosage was not found in these studies in either rats or dogs.

Risperidone and its principal active metabolite, 9-hydroxyrisperidone, are distributed into milk. The manufacturer states that women receiving risperidone should avoid nursing.

Description

Risperidone is a benzisoxazole-derivative antipsychotic agent and is chemically unrelated to other antipsychotic agents. While risperidone shares some of the pharmacologic actions of other antipsychotic agents, the drug has been described as an atypical or second-generation antipsychotic agent since many of its CNS effects differ from those of typical or first-generation agents (e.g., butyrophenones, phenothiazines). The exact mechanism of antipsychotic action of risperidone has not been fully elucidated but, like that of clozapine, appears to be more complex than that of most other antipsychotic agents and may involve antagonism of central type 2 serotonergic (5-HT_2) receptors and central dopamine D_2 receptors.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.

Preparations

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Ziprasidone

■ Ziprasidone has been referred to as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** *Schizophrenia* Ziprasidone is used for the symptomatic management of schizophrenia. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Because of ziprasidone's greater capacity to prolong the QT/QT_c-interval compared with that of several other antipsychotic agents, use of ziprasidone may be reserved for patients whose disease fails to respond adequately to appropriate courses of other antipsychotic agents. (See Prolongation of QT interval under Warnings/Precautions: Warnings, in Cautions.) However, it should be noted that patients with a history of resistance to antipsychotic therapy (i.e., failed to respond to adequate courses of 2 or more antipsychotic agents) usually were excluded in clinical studies of ziprasidone.

Efficacy of oral ziprasidone was evaluated in 5 placebo-controlled studies of variable duration (4 short-term [4–6 weeks] and one long-term [52 weeks]), principally in patients with schizophrenic disorders in hospital settings. Ziprasidone appears to be superior to placebo in improving both positive and negative manifestations in acute exacerbations of schizophrenia and in reducing the rate of relapse for up to 52 weeks.

Although results of a limited comparative study suggest that oral ziprasidone hydrochloride dosages of 160 mg daily may be as effective as oral haloperidol 15 mg daily in reducing positive symptoms of schizophrenia, a reliable and valid comparison of ziprasidone and oral haloperidol cannot be made at this time based solely on this study due to its relatively small sample size (90 patients), high dropout rate (51.1%), and brief duration (4 weeks). Data from one unpublished comparative study also suggest that ziprasidone hydrochloride (mean dosage of 130 mg daily) may be as effective as olanzapine (mean dosage of 11 mg daily) in the treatment of schizophrenia.

Ziprasidone is used IM for the management of acute agitation in patients with schizophrenia for whom treatment with ziprasidone is appropriate and who require an IM antipsychotic agent for rapid control of behaviors that interfere with diagnosis and care (e.g., threatening behaviors, escalating or urgently distressing behavior, self-exhausting behavior). The efficacy of IM ziprasidone for the management of acute agitation in schizophrenia was established in single-day controlled trials in hospital settings. Because there is no experience regarding the safety of administering ziprasidone IM to schizophrenic patients already receiving oral ziprasidone, concomitant use of oral and IM formulations of ziprasidone is *not* recommended.

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Ziprasidone is used for the treatment of acute manic and mixed episodes (with or without psychotic features) associated with bipolar I disorder. According to DSM-IV criteria, manic episodes are distinct periods lasting 1 week or longer (or less than 1 week if hospitalization is required) of abnormally and persistently elevated, expansive, or irritable mood accompanied by at least 3 (or 4 if the mood is only irritability) of the following 7 symptoms: grandiosity, reduced need for sleep, pressure of speech, flight of ideas, distractibility, increased goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation, and engaging in high risk behavior (e.g., unrestrained buying sprees, sexual indiscretions, foolish business investments).

Efficacy of ziprasidone in the treatment of acute manic and mixed episodes has been demonstrated in 2 short-term (3 weeks' duration), double-blind, pla-

cebo-controlled trials in patients who met the DSM-IV criteria for bipolar I disorder and who met diagnostic criteria for an acute manic or mixed episode (with or without psychotic features). The principal rating instruments used for assessing manic symptoms in these trials were the Mania Rating Scale (MRS), which is derived from the Schedule for Affective Disorders and Schizophrenia-Change Version (SADS-C) with items grouped as the Manic Syndrome subscale (e.g., elevated mood, less need for sleep, excessive energy, excessive activity, grandiosity), the Behavior and Ideation Subscale (irritability, motor hyperactivity, accelerated speech, racing thoughts, poor judgment), and impaired insight, and the Clinical Global Impression-Severity of Illness Scale (CGI-S), which was used to assess the clinical significance of treatment response.

In the first 3-week, placebo-controlled trial, ziprasidone hydrochloride was given at an initial dosage of 40 mg twice daily on the first day and 80 mg twice daily on the second day; dosage adjustment in 20-mg twice daily increments within a dosage range of 40–80 mg twice daily was then permitted for the remainder of the study. The mean daily dosage of ziprasidone hydrochloride in this study was 132 mg. In the second 3-week, placebo-controlled trial, patients also were given an initial dosage of ziprasidone hydrochloride 40 mg twice daily on the first day; subsequent dosage titration in 20-mg twice daily increments within a dosage range of 40–80 mg twice daily was permitted. The mean daily dosage of ziprasidone hydrochloride in this study was 112 mg daily. Ziprasidone was found to be superior to placebo in the reduction of the MRS total score and the CGI-S score in both of these studies.

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current American Psychiatric Association (APA) recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic such as olanzapine may be adequate. For more severe manic or mixed episodes, combination therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder in Lithium Salts 28:28.

The manufacturer states that efficacy of ziprasidone has not been systematically evaluated for long-term use (i.e., exceeding 3 weeks) or for prophylactic use in patients with bipolar disorder.

Dosage and Administration

■ **Administration** Ziprasidone hydrochloride is administered orally twice daily with food. Ziprasidone mesylate is administered only by IM injection.

The commercially available lyophilized powder of ziprasidone mesylate for injection must be reconstituted prior to administration by adding 1.2 mL of sterile water for injection to single-dose vials of ziprasidone to provide a solution containing 20 mg/mL. Other solutions should not be used to reconstitute ziprasidone mesylate injection, and the drug should not be admixed with other drugs. The vials should then be shaken vigorously to ensure complete dissolution. Strict aseptic technique must be observed since the drug contains no preservative. Following reconstitution, ziprasidone mesylate for injection is stable for 24 hours when protected from light and stored at 15–30°C or for up to 7 days when refrigerated at 2–8°C. Ziprasidone mesylate injection should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

■ **Dosage** Dosage of ziprasidone hydrochloride is expressed in terms of the hydrochloride monohydrate. Dosage of ziprasidone mesylate is expressed in terms of ziprasidone.

Schizophrenia **Oral Dosage.** For the symptomatic management of schizophrenia, the recommended initial adult dosage of ziprasidone hydrochloride is 20 mg orally twice daily. Dosage may be increased after a minimum of 2 days at each dosage up to a maximum recommended dosage of 80 mg twice daily. To ensure use of the lowest effective dosage, however, it is recommended that patients be observed for several weeks prior to upward titrations of ziprasidone dosages. While a relationship between dosage and antipsychotic effect has not been established, the effective dosage of ziprasidone hydrochloride in clinical studies generally ranged from 20–100 mg twice daily. The manufacturer states that dosages exceeding 80 mg twice daily generally are not recommended, and safety of ziprasidone hydrochloride in dosages exceeding 100 mg twice daily has not been established.

The optimum duration of ziprasidone therapy currently is not known, but maintenance therapy with ziprasidone hydrochloride 20–80 mg twice daily has been shown to be effective for up to 52 weeks. However, the manufacturer states that no additional benefit has been demonstrated for ziprasidone hydrochloride dosages beyond 20 mg twice daily. Patients responding to ziprasidone therapy should continue to receive the drug as long as clinically necessary and tolerated, but at the lowest possible effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

IM Dosage. For the prompt control of acute agitation in patients with schizophrenia, the recommended initial adult IM dose of ziprasidone is 10–20 mg given as a single dose. Depending on patient response, doses of 10 or 20 mg may be repeated every 2 or 4 hours, respectively, up to a maximum cumulative dose of 40 mg daily.

Oral therapy should replace IM therapy as soon as possible. Safety and efficacy of administering ziprasidone mesylate IM injection for longer than 3 consecutive days have not been evaluated. Because there is no experience regarding the safety of administering ziprasidone mesylate IM injection to patients with schizophrenia who already are receiving oral ziprasidone hydrochloride, the concomitant use of oral and IM formulations of ziprasidone is not recommended by the manufacturer.

Bipolar Disorder **Oral Dosage.** For the management of acute manic and mixed episodes associated with bipolar disorder (with or without psychotic features), the recommended initial adult dosage of ziprasidone hydrochloride is 40 mg orally twice daily on the first day of therapy. Dosage should then be increased to 60 or 80 mg twice daily on the second day of therapy. Subsequent dosage adjustments based on efficacy and tolerability may be made within a dosage range of 40–80 mg twice daily. In the flexible-dosage clinical trials, the mean daily dosage of ziprasidone hydrochloride was approximately 120 mg.

The optimum duration of ziprasidone hydrochloride therapy for bipolar disorder currently is not known. While it is generally agreed that pharmacologic treatment beyond an acute response in mania is desirable, both for maintenance of the initial response and for prevention of new manic episodes, there are no systematically obtained data to support the use of ziprasidone beyond 3 weeks. Therefore, the manufacturer states that clinicians who elect to use ziprasidone for extended periods should periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

■ **Special Populations** No special population dosage recommendations at this time.

Cautions

■ **Contraindications** Known history of QT prolongation (including congenital long QT syndrome), recent acute myocardial infarction, or uncompensated heart failure. (See Prolongation of QT Interval under Warnings/Precautions: Warnings, in Cautions.) Concomitant therapy with other drugs that prolong the QT interval. (See Drug Interactions: Drugs that Prolong QT Interval.) Known hypersensitivity to ziprasidone.

■ **Warnings/Precautions** ***Warnings*** **Increased Mortality in Geriatric Patients with Dementia-related Psychosis.** Geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs appear to be at an increased risk of death compared with that among patients receiving placebo. Analyses of seventeen placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6 - to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., aripiprazole, olanzapine, quetiapine, risperidone) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. The manufacturer states that ziprasidone is not approved for the treatment of patients with dementia-related psychosis. (See Geriatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

Prolongation of QT Interval. Prolongation of the QT interval can result in an occurrence of ventricular arrhythmias (e.g., torsades de pointes) and/or sudden death. In one study, oral ziprasidone prolonged the QT interval on ECG by a mean of 9–14 msec more than that observed in patients receiving risperidone, olanzapine, quetiapine, or haloperidol, but approximately 14 msec less than that observed in patients receiving thioridazine. In a study evaluating the QT/QT_c prolongation effect of IM ziprasidone, the mean increase in QT_c from baseline following 2 IM injections of ziprasidone (20 mg, then 30 mg, which is 50% higher than the recommended therapeutic dose) or haloperidol (7.5 mg, then 10 mg), given 4 hours apart, was 12.8 or 14.7 msec, respectively. Therefore, although torsades de pointes was not associated with ziprasidone therapy when the drug was administered at recommended dosages in premarketing clinical studies, experience with the drug is too limited to rule out the possibility that ziprasidone may be associated with a greater risk of sudden death than other antipsychotic agents. Patients at particular risk of torsades de pointes and/or sudden death include those with bradycardia, hypokalemia, or hypomagnesemia, those receiving concomitant therapy with other drugs that prolong the QT_c interval, and those with congenital prolongation of QT_c interval. The manufacturer states that ziprasidone should be avoided in patients with congenital prolongation of the QT interval or a history of cardiac arrhythmias and in those receiving concomitant therapy with other drugs that prolong the QT_c interval. (See Cautions: Contraindications and Drug Interactions: Drugs that Prolong QT Interval.)

Baseline serum potassium and magnesium concentrations should be determined in patients at risk for substantial electrolyte (i.e., potassium, magnesium) disturbances, particularly those receiving concomitant diuretic therapy, and hypokalemia or hypomagnesemia should be corrected prior to initiating ziprasidone. Clinical and ECG monitoring of cardiac function, including appropriate ambulatory ECG monitoring (e.g., Holter monitoring), is recommended during ziprasidone therapy in patients with symptoms that could indicate torsades de pointes (e.g., dizziness, palpitations, syncope). Ziprasidone therapy should be discontinued if the QT_c interval exceeds 500 msec.

Neuroleptic Malignant Syndrome. Although no cases have been confirmed to date in patients receiving ziprasidone, neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment, may occur in patients receiving antipsychotic agents. For additional information on NMS, see Extrapyramidal Reactions under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia. Like other antipsychotic agents, use of ziprasidone may be associated with tardive dyskinesias, a syndrome of potentially irreversible, involuntary, dyskinetic movements. Although emergence of tardive dyskinesia was not specifically evaluated in clinical studies of ziprasidone, use of the drug was associated with either no change or small reductions in the Abnormal Involuntary Movement Scale (AIMS) scores from baseline in one year-long study of the drug. However, differences among antipsychotic agents in their potential to cause tardive dyskinesia have not been established definitively. For additional information on tardive dyskinesia, see Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Hyperglycemia and Diabetes Mellitus. Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents (e.g., clozapine, olanzapine, quetiapine, risperidone). While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., clozapine, olanzapine, quetiapine, risperidone); it remains to be determined whether ziprasidone also is associated with this increased risk. Although there have been few reports of hyperglycemia or diabetes in patients receiving ziprasidone, it is not known whether the paucity of such reports is due to relatively limited experience with the drug.

Precise risk estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., clozapine, olanzapine) than with others (e.g., quetiapine, risperidone) in the class, available data are conflicting and insufficient to provide reliable estimates of relative risk associated with use of the various atypical antipsychotics.

The manufacturers of atypical antipsychotic agents state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the suspect drug; in other cases, hyperglycemia resolved with discontinuance of the antipsychotic.

For further information on managing the risk of hyperglycemia and diabetes mellitus associated with atypical antipsychotic agents, see Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications, in Clozapine 28:16.08.04.

Sensitivity Reactions **Rash.** Rash and/or urticaria, possibly related to dose and/or duration of therapy, occurred in about 5% of patients in clinical studies and have necessitated discontinuance of the drug in about 17% of these patients. Adjunctive treatment with antihistamines or steroids and/or drug discontinuance may be required. Discontinue ziprasidone if alternative etiology of rash cannot be identified.

General Precautions **Cardiovascular Effects.** Orthostatic hypotension, particularly during initial dosage titration period, has been reported. Use with caution in patients with known cardiovascular or cerebrovascular disease and/or conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy).

Nervous System Effects. Seizures occurred in about 0.4% of patients receiving ziprasidone in controlled clinical trials. Use with caution in patients with a history of seizures or with conditions known to lower the seizure threshold (e.g., Alzheimer's disease, geriatric patients).

Although not reported in clinical studies with ziprasidone, disruption of the body's ability to reduce core body temperature has been associated with use of other antipsychotic agents. Use caution when ziprasidone is administered in patients exposed to conditions that may contribute to an elevation in core body temperature (e.g., dehydration, extreme heat, strenuous exercise, concomitant use of anticholinergic agents).

GI Effects. Esophageal dysmotility and aspiration have been associated with the use of antipsychotic agents. Use with caution in patients at risk for aspiration pneumonia (e.g., geriatric patients, those with advanced Alzheimer's dementia). (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions and see Geriatric Use under Warnings/Precautions: Special Populations, in Cautions.)

Suicide. Attendant risk with psychotic illnesses; closely supervise high-risk patients. Prescribe in the smallest quantity consistent with good patient management to reduce the risk of overdosage.

Sexual Dysfunction. One case of drug-induced priapism reported in clinical studies of ziprasidone.

Other Metabolic and Endocrine Effects. Prolactin concentrations exceeding 22 ng/mL were reported in about 20% of patients receiving ziprasidone in phase II or III clinical studies compared with about 4, 46, or 89% of those receiving placebo, haloperidol, or risperidone, respectively.

Median weight gain of 0.5 kg occurred in patients receiving ziprasidone compared with no median weight change in those receiving placebo. In clinical studies, ziprasidone reportedly caused less weight gain than clozapine, olanzapine, quetiapine, or risperidone.

For additional information on metabolic effects, see Hyperglycemia and Diabetes Mellitus under Warnings/Precautions: Warnings, in Cautions.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Not known whether ziprasidone is distributed into milk; use in nursing women is not recommended.

Pediatric Use. Safety and efficacy not established in children younger than 18 years of age.

Geriatric Use. No substantial differences in safety of oral ziprasidone relative to younger adults have been observed in clinical studies. Ziprasidone mesylate IM injections have not been systematically evaluated in geriatric patients. Lower initial dosages, slower titration, and more careful monitoring during the initial dosing period may be advisable in some geriatric patients. (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions.)

Renal Impairment. Commercially available ziprasidone mesylate injections contain sulfobutylether β-cyclodextrin sodium, an excipient that is cleared by renal filtration. Therefore, ziprasidone injection should be used with caution in patients with renal impairment.

■ **Common Adverse Effects** Adverse effects occurring in more than 5% of patients with schizophrenia receiving oral ziprasidone and at least twice the frequency of placebo include somnolence (14%) and respiratory tract infection (8%).

Adverse effects occurring in more than 5% of patients with schizophrenia receiving IM ziprasidone 10 or 20 mg and at a frequency twice that reported among those receiving IM ziprasidone 2 mg include somnolence (20%), headache (13%), and nausea (12%).

Adverse effects occurring in more than 5% of patients with bipolar mania receiving oral ziprasidone and at least twice the frequency of placebo include somnolence (31%), extrapyramidal symptoms (31%), dizziness (16%), akathisia (10%), abnormal vision (6%), asthenia (6%), and vomiting (5%).

Drug Interactions

■ **Drugs that Prolong QT Interval** Potential pharmacologic interaction (additive effect on QT interval prolongation; concomitant use contraindicated) when ziprasidone is used with drugs that are known or consistently observed to prolong the QT_c interval (e.g., dofetilide, sotalol, quinidine, other Class Ia and III antiarrhythmics, mesoridazine, thioridazine, chlorpromazine, droperidol, pimozide, sparfloxacin, gatifloxacin, moxifloxacin, halofantrine, mefloquine, pentamidine, arsenic trioxide, levomethadyl acetate [no longer commercially available in the US], dolasetron mesylate, probucol, tacrolimus). Ziprasidone also is contraindicated in patients receiving drugs shown to cause QT prolongation as an effect and for which this effect is described in the full prescribing information as a contraindication or a boxed or bolded warning. (See Cautions: Contraindications and Prolongation of QT Interval under Warnings/Precautions: Warnings in Cautions.)

■ **Hypotensive Agents** Potential pharmacologic interaction (additive hypotensive effects).

■ **Other CNS Agents** Potential pharmacologic interaction (additive sedative effects).

■ **Levodopa and Dopamine Agonists** Potential pharmacologic interaction (antagonistic effects).

■ **Drugs Affecting Hepatic Microsomal Enzymes** Inhibitors or inducers of cytochrome P-450 (CYP) 3A4 isoenzyme; potential pharmacokinetic interaction (altered metabolism). Inhibitors or inducers of CYP1A2, CYP2C9, CYP2C19, or CYP2D6 isoenzymes: pharmacokinetic interaction unlikely.

■ **Protein-bound Drugs** Pharmacokinetic interaction unlikely.

Description

Ziprasidone is a benzisothiazolyl piperazine-derivative antipsychotic agent that is chemically unrelated to other currently available antipsychotic agents (e.g., butyrophenones, phenothiazines) and has been referred to as an atypical or second-generation antipsychotic agent. The exact mechanism of antipsychotic action of ziprasidone has not been fully elucidated but, like that of other atypical antipsychotic agents (e.g., olanzapine, risperidone), may involve antagonism of central type 2 serotonergic ($5\text{-}HT_2$) receptors and central dopamine D_2 receptors. As with other drugs that are effective in bipolar disorder, the precise mechanism of antimanic action of ziprasidone has not been fully elucidated. Antagonism of various other receptors (e.g., histamine H_1 receptors, α_1-adrenergic receptors) may contribute to other therapeutic and adverse effects (e.g., orthostatic hypotension, somnolence) observed with ziprasidone.

Ziprasidone is extensively metabolized in the liver principally via reduction by aldehyde oxidase with minimal excretion of unchanged drug in urine (less than 1%) or feces (less than 4%). About one-third of ziprasidone's metabolic clearance is mediated by the cytochrome P-450 (CYP) 3A4 isoenzyme. Ziprasidone did not inhibit CYP1A2, 2C9, 2C19, 2D6, or 3A4 isoenzymes in vitro.

Advice to Patients

Importance of reading manufacturer's patient information.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription (see Drug Interactions: Drugs That Prolong QT Interval) or OTC drugs, dietary supplements, and/or herbal products, as well as any concomitant illnesses (e.g., cardiovascular disease, diabetes mellitus).

Because somnolence and impairment of judgment, thinking, or motor skills may be associated with ziprasidone, avoid driving, operating machinery, or performing hazardous tasks while taking ziprasidone until gain experience with the drug's effects.

Importance of taking medication exactly as prescribed by the clinician.

Importance of women informing clinicians immediately if they are or plan to become pregnant or plan to breast-feed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview (see Users Guide). For additional information until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

BUTYROPHENONES 28:16.08.08

Haloperidol

■ Haloperidol is a butyrophenone-derivative antipsychotic agent. The drug is considered a conventional or first-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Haloperidol is used for the symptomatic management of psychotic disorders. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to improve symptoms between episodes and to minimize the risk of recurrent acute episodes. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia and generally are effective in all subtypes of the disorder and subgroups of patients. Conventional antipsychotic agents, such as haloperidol, generally are considered to exhibit similar efficacy in treating acute psychotic symptoms, although they vary in their potency and adverse effect profile. Haloperidol is a high-potency antipsychotic that has been shown to be effective in the management of acute and stable phases of schizophrenia, but is frequently associated with extrapyramidal reactions such as akathisia, dystonia, or parkinsonian symptoms, even at low dosages.

Results of short-term studies indicate that haloperidol is more effective than placebo and equally or less effective than atypical antipsychotics in the treatment of positive (e.g., delusions, hallucinations) and negative symptoms (e.g., withdrawal from social interaction, blunted emotional expression) of schizophrenia. However, in one clinical study, haloperidol was less effective than the atypical antipsychotic agent risperidone in preventing relapse in adult outpatients with clinically active schizophrenia or schizoaffective disorders who were assigned to receive either drug for a minimum of 1 year. In this study, approximately 40% of patients in the study who received usual dosages of haloperidol had relapsed by the end of the study compared with approximately 25% of those receiving usual dosages of risperidone. Because atypical antipsychotics appear to be at least as effective in the treatment of positive symptoms and possibly more effective in the treatment of negative symptoms of schizophrenia and have fewer extrapyramidal reactions, some clinicians prefer use of atypical antipsychotics rather than conventional antipsychotics, such as haloperidol, for the management of schizophrenia, except in stable patients who have had good response to conventional antipsychotics without major adverse effects, in patients who require IM therapy, which is not yet available for some atypical antipsychotics, and for the acute management of aggression/violence in some patients, particularly those requiring long-acting (depot) parenteral preparations. However, patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

The long-acting decanoate ester of haloperidol is used parenterally principally in patients requiring prolonged antipsychotic therapy (e.g., patients with chronic schizophrenic disorder). Parenteral antipsychotic therapy with a long-acting preparation may be particularly useful in patients with a history of poor compliance. In addition, long-acting antipsychotic preparations may be useful in patients with suspected GI malabsorption or variable GI absorption of the drug. The principal disadvantage of long-acting parenteral antipsychotics is the inability to terminate the drug's action when severe adverse reactions occur. Long-acting antipsychotic preparations should not be used in the acute management of severely agitated patients. Generally, patients should be stabilized on antipsychotic medication prior to conversion to haloperidol decanoate therapy and should have previously received and tolerated a shorter-acting haloperidol preparation so that the possibility of an unexpected adverse reaction that potentially could not be readily reversed following the decanoate can be minimized. For further information on the use of antipsychotic agents in the symptomatic treatment of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Tourette's Syndrome** Haloperidol is used for the control of tics and vocal utterances of Tourette's syndrome (Gilles de la Tourette's syndrome) in children and adults. Haloperidol generally has been considered the drug of choice for the management of Tourette's syndrome and pimozide has been be an effective alternative in some patients who have an inadequate response to or do not tolerate haloperidol. Because limited data suggest that pimozide may be more effective than haloperidol in reducing tics and pimozide appears to be better tolerated than haloperidol, some clinicians and experts prefer the use of pimozide in patients with Tourette's syndrome.

In children with tic disorders (e.g., Tourette's syndrome) and comorbid attention deficit hyperactivity disorder† (ADHD) in whom stimulants alone cannot control tics, haloperidol may be used concomitantly with a stimulant.

■ **Delirium** Antipsychotic agents, mainly haloperidol, have been used in the management of delirium†.

General Considerations Delirium is principally a disturbance of consciousness, attention, cognition, and perception but also may affect sleep, psychomotor activity, and emotions. It is a common psychiatric illness among medically compromised patients, particularly hospitalized patients, and may be a harbinger of substantial morbidity and mortality.

Prevalence and Course The prevalence of delirium in hospitalized medically ill patients ranges from 10–30%; in those who are elderly, delirium ranges up to 40%. Up to 25% of hospitalized cancer patients and 30–40% of hospitalized patients with acquired immunodeficiency syndrome (AIDS) develop delirium. Up to about 50% of postoperative patients develop delirium, and up to 80% of terminally ill patients develop it near death. EEG abnormalities, mainly generalized slowing, have fairly good sensitivity for aiding in the diagnosis of delirium, but the absence of such changes does not rule out the diagnosis. Prodromal manifestations may progress to full-blown delirium over 1–3 days; the duration of delirium generally ranges from less than a week to more than 2 months, but typically does not exceed 10–12 days. Symptoms persist for up to 30 days or longer in up to 15% of patients, and frequently persist for longer than 1 month in geriatric patients. Although most patients recover fully, delirium may progress to stupor, coma, seizures, and death, particularly if untreated. Full recovery is less likely in geriatric patients and patients with AIDS, possibly because of underlying dementia in both populations.

Underlying general medical conditions associated with delirium include CNS disorders (e.g., head trauma, seizures, postictal state, vascular or degenerative disease), metabolic disorders (e.g., renal or hepatic failure, anemia, hypoxia, hypoglycemia, thiamine deficiency, endocrinopathy, fluid or electrolyte imbalance, acid-base imbalance), cardiopulmonary disorder (myocardial infarction, congestive heart failure, cardiac arrhythmia, shock, respiratory failure), and systemic illness (e.g., substance intoxication or withdrawal, infection, cancer, severe trauma, sensory deprivation, temperature dysregulation, postoperative state).

Management Overview. Clinicians should undertake an essential array of psychiatric management tasks designed to provide immediate interventions for urgent general medical conditions, identify and treat the etiology of delirium, ensure safety of the patient and others in contact with the patient, and improve the patient's functioning. Environmental (e.g., varying light levels in intensive care units to heighten awareness about time of day and reduce the perception of timelessness) and supportive interventions (e.g., to deal with disorientation, to assure the patient that manifestations are temporary and reversible and do not reflect a persistent psychiatric disorder) also generally are offered to patients with delirium† and are designed to reduce factors that may exacerbate delirium, to reorient patients, and to provide support. Patients may have life-threatening medical conditions that require therapeutic intervention

even before a specific or definitive cause of the delirium is determined. The goal of diagnosis is to identify potentially reversible causes of delirium and prevent complications through prompt treatment of these specific disorders. Psychiatric management is essential and should be undertaken for all patients with delirium. Somatic interventions principally consist of drug therapy. The choice of somatic intervention will depend on the specific features of the patient's clinical condition, the underlying etiology of the delirium, and any associated comorbid conditions.

Drug Therapy. Antipsychotic agents often are the drugs of choice for the management of delirium†. Although other drugs (e.g., phenothiazines, droperidol) have been used, haloperidol generally is considered the antipsychotic of choice for most patients with delirium because of its relatively low risk of anticholinergic activity and of sedative and hypotensive effects. In addition, haloperidol has been studied most extensively, although few studies have used standardized definitions of delirium or reliable and valid delirium symptom rating measures to assess symptom severity before and after initiation of treatment. For drugs other than haloperidol, there have been no large, prospective studies that included a control. Evidence of efficacy for such alternative therapies, including second-generation antipsychotic agents (e.g., olanzapine, quetiapine, risperidone, ziprasidone), is principally from small case series, case reports, or open-label studies. In addition, interpretation of findings from many such case presentations is difficult because of use of nonstandardized delirium definitions and/or informal measures of delirium symptom severity. In general, evidence of the efficacy of antipsychotics, including haloperidol, in the management of delirium comes from numerous case reports and uncontrolled studies. However, evidence from a randomized, double-blind, comparator-drug controlled study (haloperidol, chlorpromazine, and lorazepam) in patients with AIDS that employed standardized clinical measures of delirium demonstrated clinical superiority of antipsychotic agents compared with benzodiazepines. Statistically significant improvement in the Delirium Rating Scale was evident after 2 days in patients receiving haloperidol or chlorpromazine but not in the lorazepam group (mean decreases in the score [i.e., improvement] were 8, 8.5, and 1, respectively). The symptomatic improvement in delirium occurred quickly among patients receiving antipsychotic therapy, usually before initiation of interventions directed at the medical etiologies of delirium.

Although various antipsychotic agents may be given orally, IM, or IV, IV administration is considered most effective in emergency situations or where oral access is limited. In addition, some evidence indicates that IV administration of antipsychotic agents may be associated with less severe extrapyramidal effects.

Special Precautions. Antipsychotic agents, particularly IV† haloperidol, used in the management of delirium have been associated with lengthening of the QT interval, possibly leading to atypical ventricular tachycardia (torsades de pointes), ventricular fibrillation, and sudden death. The manufacturer of Haldol® and the US Food and Drug Administration (FDA) state that although injectable haloperidol is approved *only* for IM injection and *not for IV administration*, there is considerable evidence from the medical literature that IV† administration of the drug is a relatively common, unlabeled ("off-label") clinical practice, principally for the treatment of severe agitation in intensive care units, and recommend ECG monitoring in any patient receiving the drug IV. Many clinicians also recommend that baseline and periodic or continuous ECG monitoring be performed with special attention paid to the length of the QT_c interval. Prolongation of the QT_c interval to greater than 450 msec or to greater than 15–25% over that in previous ECGs may warrant telemetry, a cardiology consultation, and dose reduction or discontinuance. Serum concentrations of magnesium and potassium also should be monitored at baseline and periodically in critically ill patients, especially those with baseline QT_c intervals of 440 msec or longer, those receiving other drugs known to increase the QT interval, and those who have electrolyte disorders. Limited evidence suggests that the incidence of torsades de pointes in patients receiving haloperidol IV is about 0.4–3.6%, but may increase to greater than 10% at relatively high IV doses (e.g., 35 mg or more over 24 hours). (See Cautions: Cardiovascular Effects and also see Cautions: Precautions and Contraindications.)

■ **Disruptive Behavior Disorder and Attention Deficit Hyperactivity Disorder** Haloperidol is used for the treatment of severe behavioral problems in children marked by combativeness and/or explosive hyperexcitable behavior (out of proportion to immediate provocations), and for the short-term treatment of hyperactive children who exhibit exeessive motor activity with accompanying conduct disorders that are manifested as impulsive behavior, difficulty sustaining attention, aggression, mood lability, and/or poor frustration tolerance. However, the possible risks of tardive dyskinesia, withdrawal dyskinesia, and other extrapyramidal reactions shonld be considered. Some experts currently reeommend use of haloperidol only for the treatment of comorbid tics in children with attention deficit hyperactivity disorder (ADHD). Some clinicians recommend routine administration of the Abnormal Involuntary Movement Scale (AIMS) to all children receiving antipsychotic agents.

■ **Nausea and Vomiting** Haloperidol also has been used in the prevention and control of severe nausea and vomiting† (e.g., cancer chemotherapy-induced emesis). Based on limited data, haloperidol appears to be as effective as phenothiazines in the prevention of cancer chemotherapy-induced emesis. Additional studies are required to determine the efficacy of haloperidol in the prevention and control of severe nausea and vomiting.

Dosage and Administration

■ **Administration** Haloperidol is administered orally. Haloperidol lactate is administered orally or by IM injection, and haloperidol decanoate is administered by IM injection. Pending accumulation of further data to establish safety and efficacy, IM administration of haloperidol lactate or decanoate in children is not recommended by the manufacturers. Haloperidol *lactate* also has been administered by IV injection† or infusion†. Haloperidol decanoate injection should *not* be administered IV.

Haloperidol decanoate should be administered by deep IM injection into the gluteal region using a 21-gauge needle. The manufacturers of haloperidol decanoate state that the maximum volume of haloperidol decanoate should not exceed 3 mL per IM injection site.

Haloperidol lactate and decanoate injections should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

■ **Dosage** Dosage of haloperidol lactate and the decanoate is expressed in terms of haloperidol.

There is considerable interindividual variation in optimum dosage requirements of haloperidol, and dosage must be carefully adjusted according to individual requirements and response, using the lowest possible effective dosage. Dosage should be increased more gradually in children and in debilitated, emaciated, or geriatric patients. Because of the risk of adverse reactions associated with cumulative effects of butyrophenones, patients with a history of long-term therapy with haloperidol and/or other antipsychotic agents should be evaluated periodically to determine whether maintenance dosage could be decreased or drug therapy discontinued.

Oral Dosage For the symptomatic management of psychotic disorders or Tourette's disorder in adults with moderate symptomatology and in geriatric or debilitated patients, the usual initial oral dosage of haloperidol is 0.5–2 mg 2 or 3 times daily. Subsequent dosage should be carefully adjusted according to the patient's tolerance and therapeutic response. Dosage during prolonged maintenance therapy should be kept at the lowest effective level.

The usual initial oral dosage of haloperidol for adults with severe symptomatology and/or chronic or resistant disorders is 3–5 mg 2 or 3 times daily. To achieve prompt control, higher dosages may be required in some patients. Patients who remain severely disturbed or inadequately controlled may require dosage adjustment. Oral dosages up to 100 mg daily may be required in some severely psychotic patients. Occasionally, dosages exceeding 100 mg daily have been used for the management of severely resistant disorders in adults; however, the safety of prolonged administration of such dosages has not been demonstrated.

The usual initial oral dosage of haloperidol in children 3–12 years of age and weighing 15–40 kg is 0.5 mg daily given in 2 or 3 divided doses. Subsequent dosage may be increased by 0.5 mg daily at 5- to 7-day intervals, depending on the patient's tolerance and therapeutic response.

For the symptomatic management of psychotic disorders in children 3–12 years of age, the usual oral dosage range is 0.05–0.15 mg/kg daily given in 2 or 3 divided doses; however, severely disturbed psychotic children may require higher dosages. Dosage during prolonged maintenance therapy should be kept at the lowest possible effective level; once an adequate response has been achieved, dosage should be gradually reduced and subsequently adjusted according to the patient's therapeutic response and tolerance.

For the management of non-psychotic behavioral problems and for the control of Tourette's disorder in children 3–12 years of age, the usual oral dosage range is 0.05–0.075 mg/kg daily given in 2 or 3 divided doses. Unlike psychotic disorders for which prolonged therapy is usually required, non-psychotic or hyperactive behavioral problems in children may be acute, and short-term administration of haloperidol may be adequate. A maximum effective dosage of haloperidol for the management of behavioral problems in children has not been established; however, the manufacturers state that there is little evidence that improvement in behavior is further enhanced at dosages greater than 6 mg daily.

IM Dosage For the prompt control of acutely agitated patients with moderately severe to very severe symptoms, the usual initial adult IM dose of haloperidol lactate is 2–5 mg (of haloperidol) given as a single dose. Depending on the response of the patient, this dose may be repeated as often as every hour; however, IM administration of haloperidol lactate every 4–8 hours may be adequate to control symptoms in some patients.

Oral therapy should replace short-acting parenteral therapy as soon as possible. Depending on the patient's clinical status, the first oral dose should be given within 12–24 hours following administration of the last parenteral dose of haloperidol lactate. Since bioavailability studies to establish bioequivalence between oral and parenteral dosage forms of haloperidol have not been conducted to date; the manufacturers suggest that the parenteral dosage administered during the preceding 24 hours be used for initial approximation of the total daily oral dosage required. Since this dosage is only an initial estimate, patients being switched from parenteral haloperidol lactate therapy to oral therapy should be closely monitored, particularly for clinical signs and symptoms of efficacy, sedation, and adverse effects, for the first several days following initiation of oral therapy. Subsequent dosage may be increased or decreased according to the patient's tolerance and therapeutic response, using the lowest possible effective dosage.

For patients requiring prolonged antipsychotic therapy (e.g., patients with

Advice to Patients

Importance of reading manufacturer's patient information.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription (see Drug Interactions: Drugs That Prolong QT Interval) or OTC drugs, dietary supplements, and/or herbal products, as well as any concomitant illnesses (e.g., cardiovascular disease, diabetes mellitus).

Because somnolence and impairment of judgment, thinking, or motor skills may be associated with ziprasidone, avoid driving, operating machinery, or performing hazardous tasks while taking ziprasidone until gain experience with the drug's effects.

Importance of taking medication exactly as prescribed by the clinician.

Importance of women informing clinicians immediately if they are or plan to become pregnant or plan to breast-feed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview (see Users Guide). For additional information until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

BUTYROPHENONES 28:16.08.08

Haloperidol

■ Haloperidol is a butyrophenone-derivative antipsychotic agent. The drug is considered a conventional or first-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Haloperidol is used for the symptomatic management of psychotic disorders. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to improve symptoms between episodes and to minimize the risk of recurrent acute episodes. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia and generally are effective in all subtypes of the disorder and subgroups of patients. Conventional antipsychotic agents, such as haloperidol, generally are considered to exhibit similar efficacy in treating acute psychotic symptoms, although they vary in their potency and adverse effect profile. Haloperidol is a high-potency antipsychotic that has been shown to be effective in the management of acute and stable phases of schizophrenia, but is frequently associated with extrapyramidal reactions such as akathisia, dystonia, or parkinsonian symptoms, even at low dosages.

Results of short-term studies indicate that haloperidol is more effective than placebo and equally or less effective than atypical antipsychotics in the treatment of positive (e.g., delusions, hallucinations) and negative symptoms (e.g., withdrawal from social interaction, blunted emotional expression) of schizophrenia. However, in one clinical study, haloperidol was less effective than the atypical antipsychotic agent risperidone in preventing relapse in adult outpatients with clinically active schizophrenia or schizoaffective disorders who were assigned to receive either drug for a minimum of 1 year. In this study, approximately 40% of patients in the study who received usual dosages of haloperidol had relapsed by the end of the study compared with approximately 25% of those receiving usual dosages of risperidone. Because atypical antipsychotics appear to be at least as effective in the treatment of positive symptoms and possibly more effective in the treatment of negative symptoms of schizophrenia and have fewer extrapyramidal reactions, some clinicians prefer use of atypical antipsychotics rather than conventional antipsychotics, such as haloperidol, for the management of schizophrenia, except in stable patients who have had good response to conventional antipsychotics without major adverse effects, in patients who require IM therapy, which is not yet available for some atypical antipsychotics, and for the acute management of aggression/violence in some patients, particularly those requiring long-acting (depot) parenteral preparations. However, patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

The long-acting decanoate ester of haloperidol is used parenterally principally in patients requiring prolonged antipsychotic therapy (e.g., patients with chronic schizophrenic disorder). Parenteral antipsychotic therapy with a long-acting preparation may be particularly useful in patients with a history of poor compliance. In addition, long-acting antipsychotic preparations may be useful in patients with suspected GI malabsorption or variable GI absorption of the drug. The principal disadvantage of long-acting parenteral antipsychotics is the inability to terminate the drug's action when severe adverse reactions occur. Long-acting antipsychotic preparations should not be used in the acute management of severely agitated patients. Generally, patients should be stabilized on antipsychotic medication prior to conversion to haloperidol decanoate therapy and should have previously received and tolerated a shorter-acting haloperidol preparation so that the possibility of an unexpected adverse reaction that potentially could not be readily reversed following the decanoate can be minimized. For further information on the use of antipsychotic agents in the symptomatic treatment of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Tourette's Syndrome** Haloperidol is used for the control of tics and vocal utterances of Tourette's syndrome (Gilles de la Tourette's syndrome) in children and adults. Haloperidol generally has been considered the drug of choice for the management of Tourette's syndrome and pimozide has been be an effective alternative in some patients who have an inadequate response to or do not tolerate haloperidol. Because limited data suggest that pimozide may be more effective than haloperidol in reducing tics and pimozide appears to be better tolerated than haloperidol, some clinicians and experts prefer the use of pimozide in patients with Tourette's syndrome.

In children with tic disorders (e.g., Tourette's syndrome) and comorbid attention deficit hyperactivity disorder† (ADHD) in whom stimulants alone cannot control tics, haloperidol may be used concomitantly with a stimulant.

■ **Delirium** Antipsychotic agents, mainly haloperidol, have been used in the management of delirium†.

General Considerations Delirium is principally a disturbance of consciousness, attention, cognition, and perception but also may affect sleep, psychomotor activity, and emotions. It is a common psychiatric illness among medically compromised patients, particularly hospitalized patients, and may be a harbinger of substantial morbidity and mortality.

Prevalence and Course The prevalence of delirium in hospitalized medically ill patients ranges from 10–30%; in those who are elderly, delirium ranges up to 40%. Up to 25% of hospitalized cancer patients and 30–40% of hospitalized patients with acquired immunodeficiency syndrome (AIDS) develop delirium. Up to about 50% of postoperative patients develop delirium, and up to 80% of terminally ill patients develop it near death. EEG abnormalities, mainly generalized slowing, have fairly good sensitivity for aiding in the diagnosis of delirium, but the absence of such changes does not rule out the diagnosis. Prodromal manifestations may progress to full-blown delirium over 1–3 days; the duration of delirium generally ranges from less than a week to more than 2 months, but typically does not exceed 10–12 days. Symptoms persist for up to 30 days or longer in up to 15% of patients, and frequently persist for longer than 1 month in geriatric patients. Although most patients recover fully, delirium may progress to stupor, coma, seizures, and death, particularly if untreated. Full recovery is less likely in geriatric patients and patients with AIDS, possibly because of underlying dementia in both populations.

Underlying general medical conditions associated with delirium include CNS disorders (e.g., head trauma, seizures, postictal state, vascular or degenerative disease), metabolic disorders (e.g., renal or hepatic failure, anemia, hypoxia, hypoglycemia, thiamine deficiency, endocrinopathy, fluid or electrolyte imbalance, acid-base imbalance), cardiopulmonary disorder (myocardial infarction, congestive heart failure, cardiac arrhythmia, shock, respiratory failure), and systemic illness (e.g., substance intoxication or withdrawal, infection, cancer, severe trauma, sensory deprivation, temperature dysregulation, postoperative state).

Management Overview. Clinicians should undertake an essential array of psychiatric management tasks designed to provide immediate interventions for urgent general medical conditions, identify and treat the etiology of delirium, ensure safety of the patient and others in contact with the patient, and improve the patient's functioning. Environmental (e.g., varying light levels in intensive care units to heighten awareness about time of day and reduce the perception of timelessness) and supportive interventions (e.g., to deal with disorientation, to assure the patient that manifestations are temporary and reversible and do not reflect a persistent psychiatric disorder) also generally are offered to patients with delirium† and are designed to reduce factors that may exacerbate delirium; to reorient patients, and to provide support. Patients may have life-threatening medical conditions that require therapeutic intervention

even before a specific or definitive cause of the delirium is determined. The goal of diagnosis is to identify potentially reversible causes of delirium and prevent complications through prompt treatment of these specific disorders. Psychiatric management is essential and should be undertaken for all patients with delirium. Somatic interventions principally consist of drug therapy. The choice of somatic intervention will depend on the specific features of the patient's clinical condition, the underlying etiology of the delirium, and any associated comorbid conditions.

Drug Therapy. Antipsychotic agents often are the drugs of choice for the management of delirium†. Although other drugs (e.g., phenothiazines, droperidol) have been used, haloperidol generally is considered the antipsychotic of choice for most patients with delirium because of its relatively low risk of anticholinergic activity and of sedative and hypotensive effects. In addition, haloperidol has been studied most extensively, although few studies have used standardized definitions of delirium or reliable and valid delirium symptom rating measures to assess symptom severity before and after initiation of treatment. For drugs other than haloperidol, there have been no large, prospective studies that included a control. Evidence of efficacy for such alternative therapies, including second-generation antipsychotic agents (e.g., olanzapine, quetiapine, risperidone, ziprasidone), is principally from small case series, case reports, or open-label studies. In addition, interpretation of findings from many such case presentations is difficult because of use of nonstandardized delirium definitions and/or informal measures of delirium symptom severity. In general, evidence of the efficacy of antipsychotics, including haloperidol, in the management of delirium comes from numerous case reports and uncontrolled studies. However, evidence from a randomized, double-blind, comparator-drug controlled study (haloperidol, chlorpromazine, and lorazepam) in patients with AIDS that employed standardized clinical measures of delirium demonstrated clinical superiority of antipsychotic agents compared with benzodiazepines. Statistically significant improvement in the Delirium Rating Scale was evident after 2 days in patients receiving haloperidol or chlorpromazine but not in the lorazepam group (mean decreases in the score [i.e., improvement] were 8, 8.5, and 1, respectively). The symptomatic improvement in delirium occurred quickly among patients receiving antipsychotic therapy, usually before initiation of interventions directed at the medical etiologies of delirium.

Although various antipsychotic agents may be given orally, IM, or IV, IV administration is considered most effective in emergency situations or where oral access is limited. In addition, some evidence indicates that IV administration of antipsychotic agents may be associated with less severe extrapyramidal effects.

Special Precautions. Antipsychotic agents, particularly IV† haloperidol, used in the management of delirium have been associated with lengthening of the QT interval, possibly leading to atypical ventricular tachycardia (torsades de pointes), ventricular fibrillation, and sudden death. The manufacturer of Haldol® and the US Food and Drug Administration (FDA) state that although injectable haloperidol is approved *only* for IM injection and *not for IV administration*, there is considerable evidence from the medical literature that IV† administration of the drug is a relatively common, unlabeled ("off-label") clinical practice, principally for the treatment of severe agitation in intensive care units, and recommend ECG monitoring in any patient receiving the drug IV. Many clinicians also recommend that baseline and periodic or continuous ECG monitoring be performed with special attention paid to the length of the QT_c interval. Prolongation of the QT_c interval to greater than 450 msec or to greater than 15–25% over that in previous ECGs may warrant telemetry, a cardiology consultation, and dose reduction or discontinuance. Serum concentrations of magnesium and potassium also should be monitored at baseline and periodically in critically ill patients, especially those with baseline QT_c intervals of 440 msec or longer, those receiving other drugs known to increase the QT interval, and those who have electrolyte disorders. Limited evidence suggests that the incidence of torsades de pointes in patients receiving haloperidol IV is about 0.4–3.6%, but may increase to greater than 10% at relatively high IV doses (e.g., 35 mg or more over 24 hours). (See Cautions: Cardiovascular Effects and also see Cautions: Precautions and Contraindications.)

■ **Disruptive Behavior Disorder and Attention Deficit Hyperactivity Disorder** Haloperidol is used for the treatment of severe behavioral problems in children marked by combativeness and/or explosive hyperexcitable behavior (out of proportion to immediate provocations), and for the short-term treatment of hyperactive children who exhibit excessive motor activity with accompanying conduct disorders that are manifested as impulsive behavior, difficulty sustaining attention, aggression, mood lability, and/or poor frustration tolerance. However, the possible risks of tardive dyskinesia, withdrawal dyskinesia, and other extrapyramidal reactions should be considered. Some experts currently recommend use of haloperidol only for the treatment of comorbid tics in children with attention deficit hyperactivity disorder (ADHD). Some clinicians recommend routine administration of the Abnormal Involuntary Movement Scale (AIMS) to all children receiving antipsychotic agents.

■ **Nausea and Vomiting** Haloperidol also has been used in the prevention and control of severe nausea and vomiting† (e.g., cancer chemotherapy-induced emesis). Based on limited data, haloperidol appears to be as effective as phenothiazines in the prevention of cancer chemotherapy-induced emesis. Additional studies are required to determine the efficacy of haloperidol in the prevention and control of severe nausea and vomiting.

Dosage and Administration

■ **Administration** Haloperidol is administered orally. Haloperidol lactate is administered orally or by IM injection, and haloperidol decanoate is administered by IM injection. Pending accumulation of further data to establish safety and efficacy, IM administration of haloperidol lactate or decanoate in children is not recommended by the manufacturers. Haloperidol *lactate* also has been administered by IV injection† or infusion†. Haloperidol decanoate injection should *not* be administered IV.

Haloperidol decanoate should be administered by deep IM injection into the gluteal region using a 21-gauge needle. The manufacturers of haloperidol decanoate state that the maximum volume of haloperidol decanoate should not exceed 3 mL per IM injection site.

Haloperidol lactate and decanoate injections should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

■ **Dosage** Dosage of haloperidol lactate and the decanoate is expressed in terms of haloperidol.

There is considerable interindividual variation in optimum dosage requirements of haloperidol, and dosage must be carefully adjusted according to individual requirements and response, using the lowest possible effective dosage. Dosage should be increased more gradually in children and in debilitated, emaciated, or geriatric patients. Because of the risk of adverse reactions associated with cumulative effects of butyrophenones, patients with a history of long-term therapy with haloperidol and/or other antipsychotic agents should be evaluated periodically to determine whether maintenance dosage could be decreased or drug therapy discontinued.

Oral Dosage For the symptomatic management of psychotic disorders or Tourette's disorder in adults with moderate symptomatology and in geriatric or debilitated patients, the usual initial oral dosage of haloperidol is 0.5–2 mg 2 or 3 times daily. Subsequent dosage should be carefully adjusted according to the patient's tolerance and therapeutic response. Dosage during prolonged maintenance therapy should be kept at the lowest effective level.

The usual initial oral dosage of haloperidol for adults with severe symptomatology and/or chronic or resistant disorders is 3–5 mg 2 or 3 times daily. To achieve prompt control, higher dosages may be required in some patients. Patients who remain severely disturbed or inadequately controlled may require dosage adjustment. Oral dosages up to 100 mg daily may be required in some severely psychotic patients. Occasionally, dosages exceeding 100 mg daily have been used for the management of severely resistant disorders in adults; however, the safety of prolonged administration of such dosages has not been demonstrated.

The usual initial oral dosage of haloperidol in children 3–12 years of age and weighing 15–40 kg is 0.5 mg daily given in 2 or 3 divided doses. Subsequent dosage may be increased by 0.5 mg daily at 5- to 7-day intervals, depending on the patient's tolerance and therapeutic response.

For the symptomatic management of psychotic disorders in children 3–12 years of age, the usual oral dosage range is 0.05–0.15 mg/kg daily given in 2 or 3 divided doses; however, severely disturbed psychotic children may require higher dosages. Dosage during prolonged maintenance therapy should be kept at the lowest possible effective level; once an adequate response has been achieved, dosage should be gradually reduced and subsequently adjusted according to the patient's therapeutic response and tolerance.

For the management of non-psychotic behavioral problems and for the control of Tourette's disorder in children 3–12 years of age, the usual oral dosage range is 0.05–0.075 mg/kg daily given in 2 or 3 divided doses. Unlike psychotic disorders for which prolonged therapy is usually required, non-psychotic or hyperactive behavioral problems in children may be acute, and short-term administration of haloperidol may be adequate. A maximum effective dosage of haloperidol for the management of behavioral problems in children has not been established; however, the manufacturers state that there is little evidence that improvement in behavior is further enhanced at dosages greater than 6 mg daily.

IM Dosage For the prompt control of acutely agitated patients with moderately severe to very severe symptoms, the usual initial adult IM dose of haloperidol lactate is 2–5 mg (of haloperidol) given as a single dose. Depending on the response of the patient, this dose may be repeated as often as every hour; however, IM administration of haloperidol lactate every 4–8 hours may be adequate to control symptoms in some patients.

Oral therapy should replace short-acting parenteral therapy as soon as possible. Depending on the patient's clinical status, the first oral dose should be given within 12–24 hours following administration of the last parenteral dose of haloperidol lactate. Since bioavailability studies to establish bioequivalence between oral and parenteral dosage forms of haloperidol have not been conducted to date, the manufacturers suggest that the parenteral dosage administered during the preceding 24 hours be used for initial approximation of the total daily oral dosage required. Since this dosage is only an initial estimate, patients being switched from parenteral haloperidol lactate therapy to oral therapy should be closely monitored, particularly for clinical signs and symptoms of efficacy; sedation, and adverse effects, for the first several days following initiation of oral therapy. Subsequent dosage may be increased or decreased according to the patient's tolerance and therapeutic response, using the lowest possible effective dosage.

For patients requiring prolonged antipsychotic therapy (e.g., patients with

chronic schizophrenic disorder), the long-acting haloperidol decanoate injection may be considered. If the decanoate is used, the patient's condition should initially be stabilized with an antipsychotic agent prior to attempting conversion to haloperidol decanoate. In addition, if the patient is receiving an antipsychotic agent other than haloperidol, it is recommended that the patient initially be converted to oral haloperidol therapy in order to minimize the risk of an unexpected adverse reaction to the drug, which might not be readily reversible following use of the decanoate.

The initial IM dose of haloperidol decanoate should be based on the patient's clinical history, physical condition, and response to previous antipsychotic therapy. To determine the minimum effective dosage, haloperidol decanoate therapy has been initiated at low initial doses and gradually titrated upward as necessary. A precise formula for converting from oral haloperidol dosage to IM haloperidol decanoate has not been established, but an initial adult dose 10–20 times the previous daily dose of oral haloperidol, not exceeding 100 mg (regardless of previous antipsychotic dosage requirements), is suggested, although limited clinical experience suggests that a lower initial dosage of the decanoate may be adequate. If conversion requires an initial dosage of haloperidol decanoate higher than 100 mg daily, such dosage should be administered in 2 injections (i.e., administering a maximum initial dose of 100 mg followed by the balance in 3–7 days). However, some clinicians have converted therapy to the decanoate using a higher initial dosage.

IM haloperidol decanoate usually has been administered at monthly intervals (i.e., every 4 weeks), but individual response may dictate the need for adjusting the dosing interval as well as the dose.

Lower initial dosages (e.g., 10–15 times the previous daily dose of oral haloperidol) and more gradual upward titration are recommended for patients who are geriatric, debilitated, or stabilized on low oral dosages.

Close clinical observation is required during dosage titration in order to minimize the risk of overdosage and of emergence of psychotic manifestations prior to the next dose. If supplemental antipsychotic therapy is necessary during periods of dosage titration or for control of acute exacerbations of psychotic manifestations, a short-acting haloperidol preparation should be used. Experience with haloperidol decanoate dosages exceeding 450 mg (of haloperidol) monthly is limited.

IV Dosage The optimum dosage of haloperidol for the treatment of delirium has not been established. However, initiation of IV† haloperidol with dosages of 1–2 mg every 2–4 hours in adults has been suggested. Lower IV dosages (e.g., 0.25–0.5 mg every 4 hours) have been suggested for geriatric patients with delirium; severely agitated adults may require titration to higher dosages. Although single IV doses up to 50 mg or total daily dosages of 500 mg have been reported in adults, the risk of adverse effects, particularly prolongation of the QT interval and torsades de pointes, must be considered. (See Uses: Delirium and see also Cautions: Cardiovascular Effects and Cautions: Precautions and Contraindications.) Some evidence suggests that the risk of torsades de pointes increases at total daily dosages of 35–50 mg or more. In patients requiring multiple IV injections of the drug to control delirium (e.g., more than eight 10-mg doses in 24 hours or more than 10 mg/hour for more than 5 consecutive hours), consideration can be given to continuous IV infusion† of haloperidol; in such patients, an initial 10-mg dose followed by an infusion of 5–10 mg/hour has been suggested. If agitation persists, repeat 10-mg IV doses at 30-minute intervals, accompanied by a 5 mg/hour increase in the infusion rate, can be considered. ECG should be determined at baseline and periodically or continuously thereafter, with special attention paid to possible prolongation of the QT interval, and dosage should be reduced or the drug discontinued if clinically important QT prolongation (e.g., 15–25% or more over baseline) occurs or the QT_c exceeds 450 msec. (See Uses: Delirium and see also Cautions: Cardiovascular Effects and Cautions: Precautions and Contraindications.)

Cautions

Haloperidol shares the toxic potentials of phenothiazines, and the usual precautions of phenothiazine therapy should be observed. The total incidence of adverse effects associated with haloperidol is similar to that associated with piperazine-derivative phenothiazines. (See Cautions in the Phenothiazines General Statement 28:16.08.24.)

Geriatric patients with dementia-related psychosis treated with antipsychotic agents are at an increased risk of mortality. (See Cautions: Geriatric Precautions.)

■ **Nervous System Effects** The most frequent adverse effects of haloperidol involve the CNS.

Extrapyramidal Reactions Extrapyramidal reactions occur frequently with haloperidol, especially during the first few days of therapy. In most patients, these reactions consist of parkinsonian symptoms (e.g., marked drowsiness and lethargy, drooling or hypersalivation, fixed stare), which are mild to moderate in severity and are usually reversible following discontinuance of the drug. Other adverse neuromuscular reactions have been reported less frequently, but are often more severe, and include feelings of motor restlessness (i.e., akathisia), tardive dystonia, and dystonic reactions (e.g., hyperreflexia, opisthotonos, oculogyric crisis, torticollis, trismus). Generally, the occurrence and severity of most extrapyramidal reactions are dose related, since they occur at relatively high dosages and disappear or become less severe following a reduction in dosage; however, severe extrapyramidal reactions have reportedly occurred at relatively low dosages. Most patients respond rapidly to treatment with an anticholinergic antiparkinsonian drug (e.g., benztropine, trihexyphenidyl). If persistent extrapyramidal reactions occur, haloperidol therapy may have to be discontinued.

Neuroleptic malignant syndrome (NMS) may occur in patients receiving haloperidol or other antipsychotic therapy. NMS is potentially fatal and requires immediate discontinuance of the drug and initiation of intensive symptomatic and supportive care. For additional information on NMS, see Extrapyramidal Reactions in Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia Like other antipsychotic agents (e.g., phenothiazines), haloperidol has been associated with persistent dyskinesias. Tardive dyskinesia may occur in some patients during long-term administration of haloperidol or it may occur following discontinuance of the drug. The risk of developing tardive dyskinesia appears to be greater in geriatric patients receiving high dosages of the drug, especially females. The symptoms are persistent, and in some patients appear to be irreversible. Tardive dyskinesia is characterized by rhythmic involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of the tongue, puffing of cheeks, chewing movements, puckering of the mouth), which sometimes may be accompanied by involuntary movements of the extremities and/or trunk. Although not clearly established, the risk of developing the syndrome and the likelihood that it will become irreversible may increase with the duration of therapy and total cumulative dose of antipsychotic agent(s) administered; however, the syndrome may occur, although much less frequently, after relatively short periods of treatment with low dosages. There is no proven or uniformly effective treatment for tardive dyskinesia; antiparkinsonian agents do not alleviate and tend to exacerbate the symptoms of this syndrome. If possible, antipsychotic agents should be discontinued if signs or symptoms of tardive dyskinesia occur. The syndrome may partially or completely remit if antipsychotic agents are discontinued, although some patients may require many months for improvement. Tardive dyskinesia may be masked if therapy is reinstituted, dosage is increased, or therapy with another antipsychotic agent is initiated. The effect that masking of the symptoms may have on the long-term course of the syndrome is not known. Fine vermicular movement of the tongue may be an early sign of the syndrome; prompt discontinuance of haloperidol after this sign occurs may prevent development of the syndrome.

In general, abrupt withdrawal of antipsychotic agents following short-term administration is not associated with adverse effects; however, transient dyskinetic signs have occurred following abrupt withdrawal in patients receiving prolonged maintenance therapy with haloperidol. In some patients, the dyskinetic movements are indistinguishable, except on the basis of their duration, from tardive dyskinesia. It is not known whether gradual withdrawal of antipsychotic agents reduces the incidence of withdrawal-emergent neurologic signs; however, if haloperidol therapy must be discontinued, gradual withdrawal of the drug is recommended, if possible, pending further accumulation of data.

Other Nervous System Effects Tardive dystonia, not associated with tardive dyskinesia, has occurred in patients receiving haloperidol. Tardive dystonia is characterized by delayed onset of choreic or dystonic movements, often is persistent, and potentially can become irreversible.

Other adverse nervous system effects of haloperidol include insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, and tonic-clonic seizures. Exacerbation of psychotic symptoms (including hallucinations and catatonic-like behavior), which may subside following discontinuance of therapy or treatment with anticholinergic agents, has also been reported.

Adverse anticholinergic effects of haloperidol include dry mouth (xerostomia), blurred vision, constipation, urinary retention, and diaphoresis. Priapism has also occurred.

■ **Hematologic Effects** Mild and usually transient leukopenia/neutropenia and leukocytosis have been reported in patients receiving antipsychotic agents, including haloperidol. Agranulocytosis (including fatal cases) has also been reported rarely in patients receiving haloperidol, but only when combined with other drugs. Possible risk factors for leukopenia and neutropenia include preexisting low leukocyte count and a history of drug-induced leukopenia or neutropenia. (See Cautions: Precautions and Contraindications.) Other adverse hematologic effects associated with haloperidol include anemia, minimal decreases in erythrocyte count, and a tendency toward lymphomonocytosis.

■ **Endocrine and Metabolic Effects** Moderate engorgement of the breast with lactation has occurred in some females receiving haloperidol. Galactorrhea, mastalgia, gynecomastia, increased libido, impotence, hyperglycemia, hypoglycemia, and hyponatremia have also occurred in some patients. Antipsychotic agents increase serum prolactin concentrations. (See Cautions: Mutagenicity and Carcinogenicity.) Although not reported to date with haloperidol, the manufacturers caution that decreases in serum cholesterol concentration have occurred in patients receiving chemically related drugs.

■ **Cardiovascular Effects** Tachycardia, hypotension, hypertension, ECG changes (including those compatible with QT-interval prolongation and the polymorphous configuration of torsades de pointes), and sudden death have been reported in patients receiving haloperidol. The US Food and Drug Administration (FDA) states that there have been at least 28 case reports of QT-interval prolongation and torsades de pointes, including some that were fatal, in patients receiving the drug IV†. In addition, FDA states that case-control

studies have demonstrated a dose-dependent relationship between IV haloperidol dosage and subsequent development of torsades de pointes. A postmarketing analysis of a worldwide safety database revealed 229 reports of QT-interval prolongation and torsades de pointes with oral or parenteral haloperidol; many of these cases were confounded by concomitant administration of drugs known to prolong the QT interval or medical conditions associated with QT-interval prolongation. The reports included 73 cases of torsades de pointes, 11 of which were fatal. In 8 out of 11 fatal cases, haloperidol was administered IV in various dosages. In another postmarketing analysis of adverse cardiovascular events associated with haloperidol decanoate, 13 cases of torsades de pointes, QT-interval prolongation, ventricular arrhythmias, and/or sudden death were identified.

FDA states that it is not possible to estimate the frequency with which QT-interval prolongation or torsades de pointes occurs following administration of haloperidol based on these case reports alone. However, use of higher than recommended doses of any haloperidol formulation and IV administration of the drug appear to be associated with an increased risk of these effects. Many of the reported cases of QT-interval prolongation and torsades de pointes have occurred in patients receiving relatively high dosages of IV haloperidol (e.g., exceeding 35 mg daily); however, such effects also have been reported in patients receiving lower IV dosages or oral therapy. Although cases of sudden death, torsades de pointes, and QT-interval prolongation have been reported even in the absence of predisposing factors, FDA, the manufacturer of Haldol®, and some clinicians state that particular caution is advised when using any formulation of haloperidol in patients who have other QT-interval prolonging conditions, including electrolyte imbalance (particularly hypokalemia and hypomagnesemia), underlying cardiac abnormalities, hypothyroidism, or familial long QT syndrome, or those who are concomitantly taking medications known to prolong the QT interval. (See Uses: Delirium, Cautions: Precautions and Contraindications, and Acute Toxicity: Manifestations.) FDA states that clinicians should consider this new cardiovascular risk information when making individual treatment decisions for their patients.

Cases of sudden and unexpected death have been reported in haloperidol-treated patients. The nature of the evidence makes it impossible to determine definitively what role, if any, haloperidol played in the outcome of the cases reported to date. Although the possibility that haloperidol played a causative role in these deaths cannot be excluded, it should be kept in mind that sudden and unexpected death may occur in psychotic patients when they remain untreated or when they are treated with other antipsychotic medications.

■ **Other Adverse Effects** Impaired liver function and/or jaundice, maculopapular and acneiform dermatologic reactions, photosensitivity, alopecia, anorexia, diarrhea, hypersalivation, dyspepsia, nausea, vomiting, cataracts, retinopathy, and visual disturbances have also been reported.

Hyperpyrexia and heat stroke, not associated with neuroleptic malignant syndrome (see Extrapyramidal Reactions in Cautions: Nervous System Effects), have been reported in some patients receiving haloperidol.

Laryngospasm, bronchospasm, and increased depth of respiration have occurred in patients receiving haloperidol. Bronchopneumonia, resulting in fatalities in some patients, has occurred following the use of antipsychotic agents, including haloperidol. It has been suggested that lethargy and decreased thirst, resulting from central inhibition, may cause dehydration, hemoconcentration, and reduced pulmonary ventilation.

Hyperammonemia following haloperidol treatment has been reported in at least one child with citrullinemia, an inherited disorder of ammonia excretion.

■ **Precautions and Contraindications** Haloperidol shares the toxic potentials of other antipsychotic agents (e.g., phenothiazines), and the usual precautions associated with therapy with these agents should be observed. (See Cautions in the Phenothiazines General Statement 28:16.08.24.)

Geriatric patients with dementia-related psychosis treated with antipsychotic agents are at an increased risk of mortality. (See Cautions: Geriatric Precautions.)

Patients should be warned that haloperidol may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle). Patients also should be warned that haloperidol may enhance their response to alcohol, barbiturates, or other CNS depressants.

Because of the possibility of transient hypotension and/or precipitation of angina, haloperidol should be used with caution in patients with severe cardiovascular disorders. If hypotension occurs, metaraminol, norepinephrine, or phenylephrine may be used; epinephrine should *not* be used since haloperidol causes a reversal of epinephrine's vasopressor effects and a further lowering of blood pressure.

Since haloperidol may lower the seizure threshold, the drug should be used with caution in patients receiving anticonvulsant agents and in those with a history of seizures or EEG abnormalities. Adequate anticonvulsant therapy should be maintained during administration of haloperidol.

The manufacturers state that haloperidol should be used with caution in patients with known allergies or with a history of allergic reactions to drugs.

When concomitant therapy with an antiparkinsonian drug is necessary to manage haloperidol-induced extrapyramidal symptoms, it may be necessary to continue the antiparkinsonian drug for a period of time after discontinuance of haloperidol in order to prevent emergence of these symptoms.

The manufacturers caution that when haloperidol is used to control mania in patients with bipolar disorder, there may be a rapid mood swing to depression.

Haloperidol should be used with caution in patients with thyrotoxicosis since severe neurotoxicity (e.g., rigidity, inability to walk or talk) may occur in these patients during therapy with an antipsychotic agent.

Cases of leukopenia and neutropenia have been reported in patients receiving antipsychotic agents, including haloperidol; agranulocytosis (including fatal cases) has also been reported. (See Cautions: Hematologic Effects.) Patients with a preexisting low leukocyte count or a history of drug-induced leukopenia or neutropenia should have their complete blood count monitored frequently during the first few months of therapy and haloperidol should be discontinued at the first sign of a decline in the leukocyte count in the absence of other causative factors. Haloperidol-treated patients with neutropenia should be carefully monitored for fever or other signs or symptoms of infection and be treated promptly should such signs and symptoms occur. Patients with severe neutropenia (absolute neutrophil count less than 1000/mm^3) should discontinue haloperidol and have their leukocyte count followed until recovery.

Care should be taken to avoid skin contact with haloperidol lactate oral solution and injection, since contact dermatitis has occurred rarely.

Cases of sudden death, QT-interval prolongation, and torsades de pointes have been reported in patients receiving haloperidol. (See Uses: Delirium and see also Cautions: Cardiovascular Effects.) Use of higher than recommended doses of any haloperidol formulation and IV† administration of the drug appear to be associated with an increased risk of QT-interval prolongation and torsades de pointes. Although these effects have been reported in the absence of predisposing factors, haloperidol should be used with particular caution in patients with other conditions that prolong the QT interval, including electrolyte imbalance (particularly hypokalemia and hypomagnesemia), underlying cardiac abnormalities, hypothyroidism; and familial long QT syndrome, as well as in those concurrently receiving other drugs known to prolong the QT interval. In addition, ECG monitoring is recommended whenever haloperidol is administered IV. (See Uses: Delirium.)

Haloperidol is contraindicated in patients with severe toxic CNS depression or in those who are comatose from any cause. Haloperidol also is contraindicated in patients who are hypersensitive to the drug and in those with parkinsonian syndrome.

■ **Pediatric Precautions** Safety and efficacy of haloperidol decanoate injection in children have not been established, and safety and efficacy of other haloperidol preparations in children younger than 3 years of age have not been established. Hyperammonemia was reported during postmarketing surveillance in a 5.5-year-old child with citrullinemia, an inherited disorder of ammonia excretion, following haloperidol therapy.

■ **Geriatric Precautions** Clinical studies of haloperidol did not include sufficient numbers of geriatric patients 65 years of age and older to determine whether this age group responds differently from younger adults. Other reported clinical experience has not consistently identified differences in responses between geriatric and younger patients. However, the prevalence of tardive dyskinesia appears to be highest among geriatric patients, particularly elderly women. In addition, the pharmacokinetics of haloperidol generally warrant the use of reduced dosages in geriatric patients. (See Dosage and Administration: Dosage.)

Geriatric patients with dementia-related psychosis treated with either conventional or atypical antipsychotic agents are at an increased risk of mortality. Analyses of 17 placebo-controlled trials (modal duration of 10 weeks) in geriatric patients mainly receiving atypical antipsychotic agents revealed an approximate 1.6- to 1.7-fold increase in mortality compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in those receiving placebo. Although the causes of death were varied in these trials, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. Subsequently, 2 observational, epidemiologic studies have indicated that, similar to atypical antipsychotic agents, treatment with conventional antipsychotic agents may increase mortality; the causes of death were not reported in the first study, and cancer and cardiac disease were the causes of death with the highest relative risk in the second study. However, the extent to which these findings of increased mortality in observational studies may be attributed to the antipsychotic agent as opposed to certain patient characteristics remains unclear.

The US Food and Drug Administration (FDA) currently advises clinicians that antipsychotic agents, including haloperidol, are *not* approved for the treatment of dementia-related psychosis. The FDA further advises clinicians that no drugs currently are approved for the treatment of dementia-associated psychosis and that other management options should be considered in patients with this disorder. The decision whether to prescribe antipsychotic agents "off-label" in the treatment of dementia symptoms is left to the discretion of the clinician. Clinicians who prescribe antipsychotic agents for geriatric patients with dementia-related psychosis should discuss the increased mortality risk with patients, their families, and their caregivers. In addition, patients currently receiving antipsychotic agents for dementia-associated symptoms should not abruptly stop taking the drugs; caregivers and patients should discuss any possible concerns with their clinician. For additional information on the use of antipsychotic agents for dementia-associated psychosis and other behavioral disturbances, see Geriatric Considerations under Psychotic Disorders: Schizophrenia and Other Psychotic Disorders, in Uses and see also Cautions: Geriatric Precautions, in the Phenothiazines General Statement 28:16.08.24.

■ **Mutagenicity and Carcinogenicity** Negative or inconsistent positive findings have been reported in vitro and in vivo in studies on the effects of conventional preparations of haloperidol on chromosome structure and number. However, the available cytogenetic evidence is considered too inconsistent to be conclusive at this time.

Although an increase in mammary neoplasms has been found in rodents following long-term administration of prolactin-stimulating antipsychotic agents, no clinical or epidemiologic studies conducted to date have shown an association between long-term administration of these drugs and mammary tumorigenesis in humans. Current evidence is considered too limited to be conclusive, and further study is needed to determine the clinical importance in most patients of elevated serum prolactin concentrations associated with antipsychotic agents. Since in vitro tests indicate that approximately one-third of human breast cancers are prolactin dependent, haloperidol should be used with caution in patients with previously detected breast cancer.

■ **Pregnancy, Fertility, and Lactation** Although there are no adequate and controlled studies to date in humans, 2 cases of limb malformations (e.g., phocomelia) have occurred in offspring of women who were given haloperidol concurrently with other potentially teratogenic drugs during the first trimester of pregnancy; these teratogenic effects have not been directly attributed to haloperidol. Haloperidol has been shown to be teratogenic and fetotoxic in animals at dosages 2–20 times the usual maximum human dosage. Haloperidol should be used during pregnancy or in women likely to become pregnant only when the potential benefits justify the possible risks to the fetus.

The effect of haloperidol on fertility in humans is not known. Impotence, increased libido, priapism, and menstrual irregularities have occurred in some individuals during haloperidol therapy.

Haloperidol is distributed into milk. The manufacturers warn that nursing should not be undertaken by women receiving haloperidol.

Drug Interactions

■ **CNS Depressants** Haloperidol may be additive with, or may potentiate the action of, other CNS depressants such as opiates or other analgesics, barbiturates or other sedatives, anesthetics, or alcohol. When haloperidol is used concomitantly with other CNS depressants, caution should be used to avoid excessive sedation.

■ **Lithium** Although most patients receiving lithium and an antipsychotic agent (e.g., haloperidol, phenothiazines) concurrently do not develop unusual adverse effects, an acute encephalopathic syndrome occasionally has occurred, especially when high serum lithium concentrations were present. Patients receiving such combined therapy should be observed for evidence of adverse neurologic effects; treatment should be promptly discontinued if such signs or symptoms appear. (See Drug Interactions: Antipsychotic Agents, in the monograph on Lithium Salts 28:28.)

■ **Anticoagulants** Haloperidol has been reported to antagonize the anticoagulant activity of phenindione in one patient. Further study is needed to determine the clinical importance of this interaction.

■ **Rifampin** Concomitant oral therapy with rifampin and haloperidol in schizophrenic patients resulted in a mean 70% decrease in plasma haloperidol concentrations and decreased antipsychotic efficacy. Following discontinuance of rifampin in other schizophrenic patients treated with oral haloperidol, mean haloperidol concentrations increased 3.3-fold. Careful monitoring of clinical status and appropriate dosage adjustment are warranted whenever rifampin is initiated or discontinued in patients stabilized on haloperidol.

■ **Drugs with Anticholinergic Effects** The manufacturers caution that increases in intraocular pressure may occur in patients receiving anticholinergic drugs, including antiparkinsonian agents, concurrently with haloperidol.

■ **Drugs that Prolong QT Interval** Cases of QT-interval prolongation and torsades de pointes have been reported in patients receiving haloperidol. Patients receiving higher than recommended dosages of any haloperidol preparation and those receiving the drug IV appear to be at a higher risk of developing these adverse effects. Particular caution is advised when oral or parenteral haloperidol is used in patients concurrently receiving other drugs that prolong the QT interval.

■ **Methyldopa** Dementia has reportedly occurred in several patients who received haloperidol and methyldopa concomitantly. Although the clinical importance of this possible interaction has not been determined, patients should be carefully observed for adverse psychiatric symptoms if the drugs are used concurrently.

Acute Toxicity

■ **Manifestations** In general, overdosage of haloperidol may be expected to produce effects that are extensions of common adverse reactions; severe extrapyramidal reactions, hypotension, and sedation have been the principal effects reported. Coma with respiratory depression and hypotension (sometimes shock-like) may occur.

Substantial prolongation of the QT interval and atypical ventricular tachycardia (torsades de pointes) have occurred following haloperidol overdosage. The possibility of ECG changes associated with torsades de pointes should be considered following haloperidol overdosage, and ECG and vital signs should be monitored for signs of QT prolongation or dysrhythmias, continuing such monitoring until the ECG is normal.

Following accidental overdosage in a 2-year-old child, hypertension, rather than hypotension, reportedly occurred. Extrapyramidal reactions may consist of muscular weakness or rigidity and a generalized or localized tremor. Manifestations of overdosage with haloperidol decanoate injection may be prolonged.

■ **Treatment** Treatment of haloperidol overdosage generally involves symptomatic and supportive care. There is no specific antidote for haloperidol intoxication; however, anticholinergic or antiparkinsonian drugs may be useful in controlling extrapyramidal reactions associated with haloperidol overdosage.

Following acute ingestion of the drug, the stomach should be emptied by inducing emesis or by gastric lavage. If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of gastric contents. Activated charcoal should be administered after gastric lavage and/or emesis.

ECG and vital signs should be monitored, particularly for signs of QT prolongation or dysrhythmias. Severe arrhythmias should be treated with appropriate antiarrhythmic measures. Appropriate therapy should be instituted if hypotension or excessive sedation occurs; epinephrine should *not* be used (see Cautions: Precautions and Contraindications).

Pharmacology

The principal pharmacologic effects of haloperidol are similar to those of piperazine-derivative phenothiazines. The precise mechanism of antipsychotic action of haloperidol is unclear, but the drug appears to depress the CNS at the subcortical level of the brain, midbrain, and brain stem reticular formation. Haloperidol appears to inhibit the ascending reticular activating system of the brain stem (possibly through the caudate nucleus), thereby interrupting the impulse between the diencephalon and the cortex. The drug may antagonize the actions of glutamic acid within the extrapyramidal system. Inhibition of catecholamine receptors may also be important in the mode of action of haloperidol; the drug may also inhibit the reuptake of various neurotransmitters in the midbrain. Haloperidol appears to have strong central antidopaminergic and weak central anticholinergic activity. Like phenothiazines, haloperidol produces catalepsy and inhibits spontaneous motor activity and conditioned avoidance behaviors in animals. Haloperidol inhibits the central and peripheral effects of apomorphine, produces ganglionic blockade, and reduces affective responses. The precise mechanism of antiemetic action of haloperidol is unclear, but like some phenothiazines (e.g., chlorpromazine, prochlorperazine), haloperidol has been shown to directly affect the chemoreceptor trigger zone (CTZ), apparently by blocking dopamine receptors in the CTZ.

Like other dopamine receptor antagonists (e.g., phenothiazines), haloperidol may cause extrapyramidal reactions, and there appears to be a very narrow range between the effective therapeutic dosage for the management of acute psychotic disorders and that causing extrapyramidal symptoms.

Haloperidol produces less sedation, hypotension, and hypothermia than chlorpromazine.

Pharmacokinetics

■ **Absorption** Haloperidol is well absorbed from the GI tract following oral administration, but appears to undergo first-pass metabolism in the liver. Oral bioavailability of the drug has been reported to average 60%. The drug may undergo some enterohepatic circulation. Peak plasma concentrations of haloperidol occur within 2–6 hours following oral administration. Following IM administration of haloperidol lactate, peak plasma haloperidol concentrations occur within 10–20 minutes and peak pharmacologic action occurs within 30–45 minutes; in acutely agitated patients, control of psychotic manifestations may become apparent within 30–60 minutes, with substantial improvement often occurring within 2–3 hours. Haloperidol concentrations are detectable in plasma for several weeks following administration of a single dose of the drug.

Esterification of haloperidol results in slow and gradual release of haloperidol decanoate from fatty tissues, thus prolonging the duration of action; administration of the ester in a sesame oil vehicle further delays the rate of release. Following IM administration of haloperidol decanoate, plasma haloperidol concentrations are usually evident within 1 day and peak concentrations generally occur within about 6–7 days (range: 1–9 days). Steady-state plasma haloperidol concentrations are usually reached in approximately 3 months following once-monthly IM injection of the decanoate. In one group of patients receiving 20–400 mg monthly, data adjusted to 100-mg monthly doses suggested mean trough plasma haloperidol concentrations of 2 ng/mL after the first dose and of 4 ng/mL at steady state; accumulation during 24 months of therapy was not apparent. Within the usual dosage range, plasma haloperidol concentrations following IM administration of the decanoate are approximately proportional and linearly related to dosage; however, there is considerable interindividual and intraindividual variation in plasma concentrations attained with a given dosage.

■ **Distribution** Distribution of haloperidol into human body tissues and fluids has not been fully characterized. Following administration of haloperidol in animals, the drug is distributed mainly into the liver, with lower concentrations being distributed into the brain, lungs, kidneys, spleen, and heart.

Haloperidol is about 92% bound to plasma proteins.

Haloperidol is distributed into milk.

■ **Elimination** Although the exact metabolic fate has not been clearly established, it appears that haloperidol is principally metabolized in the liver. The drug appears to be metabolized principally by oxidative *N*-dealkylation of the piperidine nitrogen to form fluorophenylcarbonic acids and piperidine metabolites (which appear to be inactive), and by reduction of the butyrophenone carbonyl to the carbinol, forming hydroxyhaloperidol. Limited data suggest that the reduced metabolite, hydroxyhaloperidol, has some pharmacologic activity, although its activity appears to be less than that of haloperidol. Urinary metabolites in rats include *p*-fluorophenaceturic acid, *β*-*p*-fluorobenzoylpropionic acid, and several unidentified acids.

Haloperidol and its metabolites are excreted slowly in urine and feces. Approximately 40% of a single oral dose of haloperidol is excreted in urine within 5 days. About 15% of an oral dose of the drug is excreted in feces via biliary elimination. Small amounts of the drug are excreted for about 28 days following oral administration.

Following IM administration of haloperidol decanoate, the esterified compound is initially distributed into fatty tissue stores, from which the drug is then slowly and gradually released and subsequently undergoes hydrolysis by plasma and/or tissue esterases to form haloperidol and decanoic acid. Subsequent distribution, metabolism, and excretion of haloperidol appears to be similar to those of orally administered drug. Following IM administration of the decanoate, the drug has an apparent half-life of approximately 3 weeks.

Chemistry and Stability

■ **Chemistry** Haloperidol is a butyrophenone-derivative antipsychotic agent. The drug is structurally similar to droperidol. Haloperidol is commercially available as the base, decanoic acid ester (decanoate), and lactate salt.

Haloperidol occurs as a white to faintly yellowish, amorphous or microcrystalline powder and has solubilities of less than 0.1 mg/mL in water and of approximately 16.7 mg/mL in alcohol at 25°C. The drug has a pK_a of 8.3.

Haloperidol decanoate occurs as a clear, light amber, oily liquid and is soluble in fixed oils (e.g., sesame oil) and in most organic solvents. The decanoate has a solubility of approximately 0.01 mg/mL in water. Haloperidol decanoate injection is commercially available as a sterile solution of the drug in sesame oil and contains benzyl alcohol as a preservative.

Haloperidol injection is prepared with the aid of lactic acid and contains the drug as the lactate salt; the injection is a sterile solution of the drug in water for injection. Commercially available injections are adjusted to pH 3–3.8 with lactic acid and also *may* contain parabens as preservatives. Haloperidol oral solution also is prepared with the aid of lactic acid and contains the drug as the lactate salt. The commercially available oral solution has a pH of 2.75–3.75.

■ **Stability** Commercially available haloperidol preparations should be stored in tight, light-resistant containers at controlled room temperature between 15–30°C; freezing of the oral solution and injections and refrigeration of the decanoate injection should be avoided.

Haloperidol lactate injection may be compatible with some drugs for a short period of time after mixing, but at least one manufacturer recommends that the lactate not be mixed with other drugs. Haloperidol decanoate injection is incompatible with sterile water for injection or sodium chloride injection and with other aqueous injections. Specialized references should be consulted for specific compatibility information.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Haloperidol

Oral

PHENOTHIAZINES 28:16.08.24

Phenothiazines General Statement

■ Phenothiazines are conventional (prototypical, first-generation) antipsychotic agents.

Uses

Phenothiazines mainly are used for the management of various psychoneurologic disorders and for the prevention and control of nausea and vomiting. The efficacy of individual phenothiazines varies in different neuropsychiatric and other conditions, and some phenothiazines are not used as antipsychotic agents. Promethazine is used as an antihistamine (see 4:04) and as a sedative (see 28:24.92) and thiethylperazine as an antiemetic. For further information, see the individual monographs on these derivatives.

■ **Psychotic Disorders** ***Schizophrenia and Other Psychotic Disorders*** Phenothiazines are used principally for the symptomatic management of psychotic disorders, especially those characterized by excessive psychomotor activity. The drugs produce substantial improvement in most schizophrenic patients. Phenothiazines are particularly effective in reducing hallucinations and motor and autonomic hyperactivity in patients with schizophrenic disorder; thought disorders, change in affect, and autism are also reduced during phenothiazine therapy. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

General Considerations. Schizophrenia, a major psychotic disorder, is a chronic condition that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of the disorder involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The behavioral and psychologic characteristics of schizophrenia are associated with a variety of impairments in social and occupational functioning. Although marked deterioration associated with impairments in multiple areas of functioning (e.g., learning, self-care, working, interpersonal relationships, living skills) can occur, the disorder is characterized by great interindividual heterogeneity and by intraindividual variability over time.

The principal manifestations of schizophrenia usually are described in terms of positive and negative (deficit) symptoms and, more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention. Subtypes of schizophrenia include the paranoid, disorganized, catatonic, undifferentiated, and residual types.

Management of schizophrenia usually involves a variety of interventions (e.g., psychiatric management, psychosocial interventions, drug therapy, electroconvulsive therapy [ECT]) aimed at reducing or eliminating symptoms, maximizing quality of life and adaptive functioning, and enabling recovery by assisting patients in attaining personal life goals (e.g., in work, housing, relationships). The long-term outcome of schizophrenia varies along a continuum between reasonable recovery and complete incapacity. Most patients display exacerbations and remissions in the context of experiencing clinical deterioration, although approximately 10–15% of patients are free of further episodes after recovery from a first psychotic episode, and another 10–15% remain chronically severely psychotic.

Disease Phase Overview. Schizophrenia is a disorder that has been described as developing in phases, which have been characterized as premorbid, prodromal, and psychotic. The premorbid phase consists of a period of normal functioning, although certain events (e.g., complications in pregnancy and delivery during the prenatal and perinatal periods, trauma, family stress during

Olanzapine for IM injection should not be combined with diazepam injection in a syringe because precipitation occurs when these drugs are mixed. Olanzapine for injection should not be combined in a syringe with haloperidol injection because the resulting pH has been shown to degrade olanzapine over time. Specialized references should be consulted for additional specific compatibility information.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Olanzapine

Oral		
Tablets, film-coated	2.5 mg	Zyprexa®, Lilly
	5 mg	Zyprexa®, Lilly
	7.5 mg	Zyprexa®, Lilly

Paliperidone

9-Hydroxyrisperidone

■ Paliperidone is considered an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Paliperidone is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia Paliperidone is used orally for the acute and maintenance treatment of schizophrenia. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

The short-term efficacy of paliperidone in the acute treatment of schizophrenia was established in 3 placebo-controlled and active comparator (olanzapine)-controlled, fixed-dose clinical trials of 6 weeks' duration in 1665 adult patients with schizophrenia. In these 3 studies, patients receiving paliperidone (3–15 mg daily as extended-release tablets) demonstrated substantially greater improvement in the Positive and Negative Syndrome Scale (PANSS) than did patients receiving placebo. The mean effects at all dosages (3, 6, 9, 12, and 15 mg daily) were fairly similar, although higher dosages produced numerically superior results. Paliperidone also was found to be superior to placebo in improving scores on the Personal and Social Performance (PSP) scale in these trials.

In a longer-term study, adult outpatients with schizophrenia who had clinically responded to oral paliperidone and who had received a stable fixed dosage of the drug for 2 weeks entered a 6-week, open-label, stabilization phase where they received a paliperidone dosage from 3–15 mg once daily as extended-release tablets. After the stabilization phase, patients were randomized in a double-blind manner to either continue receiving paliperidone at their stable dosage or to receive placebo until they experienced a relapse of schizophrenia symptoms. The median treatment exposure during this double-blind phase was 45 days for extended-release paliperidone and 29 days for placebo; the mean paliperidone dosage was approximately 11 mg daily throughout the phases of this trial. An interim analysis of the data showed a significantly longer time to relapse in the paliperidone-treated patients compared with those receiving placebo. In addition, 52% of the paliperidone-treated patients experienced a relapse compared with 22% of those receiving placebo. The study was stopped early because maintenance of efficacy was demonstrated. If paliperidone is used for extended periods, the need for continued therapy should be reassessed periodically on an individualized basis. (See Dosage and Administration: Dosage.)

The American Psychiatric Association (APA) considers most atypical antipsychotic agents first-line drugs for the management of the acute phase of schizophrenia (including first psychotic episodes), principally because of the decreased risk of adverse extrapyramidal effects and tardive dyskinesia, with the understanding that the relative advantages, disadvantages, and cost-effectiveness of conventional and atypical antipsychotic agents remain controversial. The APA states that, with the possible exception of clozapine for the management of treatment-resistant symptoms, there currently is no definitive evidence that one atypical antipsychotic agent will have superior efficacy compared with another agent in the class, although meaningful differences in response may be observed in individual patients. Conventional antipsychotic agents may be considered first-line therapy in patients who have been treated successfully in the past with or who prefer conventional agents. The choice of an antipsychotic agent should be individualized, considering past response to therapy, adverse effect profile (including the patient's experience of subjective effects such as dysphoria), and the patient's preference for a specific drug, including route of administration.

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

Dosage and Administration

■ **Administration** Paliperidone is administered orally once daily in the morning with or without food.

Paliperidone extended-release tablets should be swallowed whole with fluids and should *not* be chewed, divided, or crushed. Patients should be advised *not* to become concerned if they notice a tablet-like substance in their stools; this is normal since the tablet is designed to remain intact and slowly release the drug from a nonabsorbable shell during passage through the GI tract.

■ **Dosage** ***Schizophrenia*** For the management of schizophrenia, the usual recommended dosage of paliperidone in adults is 6 mg once daily in the morning; dosage titration is not required. Although it remains to be systematically evaluated whether dosages exceeding 6 mg once daily provide additional clinical benefit, a general trend for greater clinical effects with higher dosages has been observed. However, the potential for increased clinical efficacy at higher dosages must be weighed against the potential for a dose-related increase in adverse effects. Some patients may benefit from higher dosages of up to 12 mg once daily, while a lower dosage of 3 mg once daily may be sufficient for other patients. The manufacturer states that increases beyond a dosage level of 6 mg once daily should be made only after clinical reassessment and generally should be made at intervals of more than 5 days. When dosage increases are necessary, increments of 3 mg daily are recommended. The maximum recommended dosage is 12 mg once daily.

The optimum duration of oral paliperidone therapy in patients with schizophrenia currently is not known, but maintenance therapy with paliperidone 3–15 mg daily as extended-release tablets has been shown to be effective in preventing relapse. Patients responding to paliperidone therapy should continue to receive the drug as long as clinically necessary and tolerated but at the lowest possible effective dosage, and the need for continued therapy with the drug should be reassessed periodically. The American Psychiatric Association (APA) states that prudent long-term treatment options in patients with schizo-

phrenia with remitted first- or multiple-episodes include either indefinite maintenance therapy or gradual discontinuance of the antipsychotic agent with close follow-up and a plan to reinstitute treatment upon symptom recurrence. Discontinuance of antipsychotic therapy should be considered only after a period of at least 1 year of symptom remission or optimal response while receiving the antipsychotic agent. In patients who have had multiple previous psychotic episodes or 2 psychotic episodes within 5 years, indefinite maintenance antipsychotic treatment is recommended.

■ **Special Populations** Dosage adjustment is not necessary in patients with mild to moderate hepatic impairment (Child-Pugh class A and B). (See Hepatic Impairment under Warnings/Precautions: Specific Populations, in Cautions.)

In patients with renal impairment, the maximum recommended dosage of paliperidone is 6 mg once daily in those with mild renal impairment (creatinine clearance of 50–79 mL/minute) and 3 mg once daily in those with moderate to severe renal impairment (creatinine clearance of 10–49 mL/minute). (See Renal Impairment under Warnings/Precautions: Specific Populations, in Cautions.)

Because geriatric patients may have reduced renal function, dosage adjustment may be required based on renal function status. Geriatric patients with normal renal function generally may receive the same dosage recommended for younger adults with normal renal function. In geriatric patients with moderate to severe renal impairment, the maximum recommended paliperidone dosage is 3 mg once daily. (See Renal Impairment under Warnings/Precautions: Specific Populations, in Cautions.)

No dosage adjustment is necessary based on gender or race.

Cautions

■ **Contraindications** Known hypersensitivity to paliperidone, risperidone, or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** **Increased Mortality in Geriatric Patients with Dementia-related Psychosis.** Geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs appear to be at an increased risk of death compared with that among patients receiving placebo. Analysis of 17 placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6- to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., aripiprazole, olanzapine, quetiapine, risperidone) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled study, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. In addition, an increased incidence of cerebrovascular adverse effects (e.g., stroke, transient ischemic attack), including fatalities, has been observed in geriatric patients treated with aripiprazole, olanzapine, and risperidone in placebo-controlled studies of dementia-related psychosis. The manufacturer states that paliperidone is not approved for the treatment of patients with dementia-related psychosis. (See Dosage and Administration: Special Populations and see also Geriatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

Prolongation of QT Interval. Paliperidone causes a modest increase in the corrected QT (QT_c) interval. The risk of torsades de pointes in association with drugs that prolong the QT_c interval may be increased in patients with bradycardia, hypokalemia, or hypomagnesemia; patients receiving other drugs that prolong the QT_c interval; and in those with congenital prolongation of the QT interval. Therefore, the manufacturer states that paliperidone should be avoided in patients concurrently receiving other drugs known to prolong the QT_c interval, patients with congenital long QT syndrome, and those with a history of cardiac arrhythmias. (See Drugs that Prolong QT Interval under Drug Interactions.)

Neuroleptic Malignant Syndrome. Neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment, has been reported in patients receiving antipsychotic agents, including paliperidone. If a patient requires antipsychotic therapy following recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. If antipsychotic therapy is reintroduced, the dosage generally should be increased gradually and an antipsychotic agent other than the agent believed to have precipitated NMS generally should be chosen. In addition, such patients should be carefully monitored since recurrences of NMS have been reported in some patients. For additional information on NMS, see Neuroleptic Malignant Syndrome under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia. Because use of antipsychotic agents may be associated with tardive dyskinesia, a syndrome of potentially irreversible, involuntary, dyskinetic movements, paliperidone should be prescribed in a manner that is most likely to minimize the occurrence of this syndrome. Chronic antipsychotic treatment generally should be reserved for patients who suffer from a chronic illness that is known to respond to antipsychotic agents, and for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought, and the need for continued treatment should be reassessed periodically. The American Psychiatric Association (APA) currently recommends that patients receiving second-generation antipsychotic agents be assessed clinically for abnormal involuntary movements every 12 months and that patients considered to be at increased risk for tardive dyskinesia be assessed every 6 months. For additional information on tardive dyskinesia, see Tardive Dyskinesia under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Hyperglycemia and Diabetes Mellitus. Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients treated with all atypical antipsychotic agents. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with atypical antipsychotic agents. Because paliperidone was not marketed at the time these studies were performed, it is unknown if the drug is associated with this increased risk; however, there have been 2 cases of hyperglycemia or diabetes reported to date in paliperidone-treated patients in clinical trials.

The manufacturers of atypical antipsychotic agents state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia (e.g., polydipsia, polyphagia, polyuria, weakness) during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the suspect drug; in other cases, hyperglycemia resolved with discontinuance of the antipsychotic.

For further information on managing the risk of hyperglycemia and diabetes mellitus associated with atypical antipsychotic agents, see Cautions: Endocrine and Metabolic Effects and see also Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications, in Clozapine 28:16.08.04.

GI Effects. As with other nondeformable material, extended-release paliperidone tablets do not appreciably change in shape in the GI tract. Therefore, the drug generally should not be administered to patients with severe, preexisting GI narrowing (either pathological or iatrogenic). Rare cases of obstructive symptoms in patients with known strictures have been reported in association with the ingestion of drugs in nondeformable, controlled-release formulations. Because of the extended-release design of paliperidone tablets, the drug should only be used in patients who are able to swallow the tablet whole.

Decreased bioavailability of paliperidone extended-release tablets would be expected in patients with a decreased GI transit time (e.g., those with diarrhea) while an increased bioavailability would be expected in patients with an increased GI transit time (e.g., those with GI neuropathy, diabetic gastroparesis, or due to other causes). Such changes in bioavailability are more likely when changes in transit time occur in the upper GI tract.

General Precautions **Orthostatic Hypotension and Syncope.** Orthostatic hypotension and syncope have been reported. Syncope occurred in about 0.8% of patients receiving paliperidone in controlled clinical trials. Use with caution in patients with known cardiovascular disease (e.g., heart failure, history of myocardial infarction or ischemia, conduction abnormalities) or cerebrovascular disease and/or conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy). Consider monitoring of orthostatic vital signs in patients who may be vulnerable to hypotension (e.g., geriatric patients).

Seizures. Seizures have occurred in approximately 0.2% of patients receiving paliperidone in controlled clinical studies. Use with caution in patients with a history of seizures or other conditions that may lower the seizure threshold (e.g., dementia of the Alzheimer's type, geriatric patients).

Hyperprolactinemia. Similar to other antipsychotic agents, paliperidone causes elevated prolactin concentrations, which may persist during chronic administration. Paliperidone's prolactin-elevating effects are similar to those seen with risperidone, which appears to be associated with a higher level of prolactin elevation than other currently available antipsychotic agents. Clinical disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been associated with prolactin-elevating drugs. In addition, chronic hyperprolactinemia when associated with hypogonadism may lead to decreased bone density in males and females. However, the clinical importance of elevated prolactin concentrations is unknown for most patients.

Dysphagia. Esophageal dysmotility and aspiration have been associated with the use of antipsychotic agents. Use with caution in patients at risk for aspiration pneumonia (e.g., patients with advanced Alzheimer's dementia). (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions and see Geriatric Use under Warnings/Precautions: Special Populations, in Cautions.)

Suicide. Attendant risk with psychotic illnesses; closely supervise high-risk patients. Prescribe in the smallest quantity consistent with good patient management to reduce the risk of overdosage.

Somnolence. Somnolence and sedation have been reported in patients receiving paliperidone therapy.

Sexual Dysfunction. Although priapism has not been reported in clinical trials of paliperidone, the drug possesses α-adrenergic blocking activity and may therefore be associated with this risk.

Hematologic Effects. Thrombotic thrombocytopenic purpura (TTP) has not been reported in clinical trials of paliperidone. TTP has been reported in association with risperidone therapy; however, the relationship of this adverse event to risperidone is unknown.

Body Temperature Regulation. Disruption of the body's ability to reduce core body temperature has been associated with the use of antipsychotic agents. Use caution when paliperidone is administered in patients exposed to conditions that may contribute to an elevation in core body temperature (e.g., dehydration, extreme heat, strenuous exercise, concomitant use of anticholinergic agents).

Antiemetic Effects. Antiemetic effects were observed in preclinical studies with paliperidone; these effects also may occur in humans and mask signs of overdosage of other drugs or obscure cause of vomiting in various disorders (e.g., intestinal obstruction, Reye's syndrome, brain tumor).

Patients with Concomitant Illness. Clinical experience with paliperidone in patients with certain concomitant illnesses is limited.

Patients with parkinsonian syndrome or dementia with Lewy bodies who receive antipsychotics, including paliperidone, reportedly have an increased sensitivity to antipsychotic agents. Clinical manifestations of this increased sensitivity have been reported to include confusion, obtundation, postural instability with frequent falls, extrapyramidal symptoms, and features consistent with NMS. (For additional information on extrapyramidal adverse effects and NMS, see Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.)

Paliperidone has not been adequately evaluated in patients with a recent history of myocardial infarction or unstable cardiovascular disease to date and patients with these conditions were excluded from premarketing clinical trials. Because of the risk of orthostatic hypotension associated with paliperidone, the manufacturer states that the drug should be used with caution in patients with cardiovascular disease. (See Orthostatic Hypotension and Syncope under Warnings/Precautions/General Precautions, in Cautions.)

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Paliperidone is distributed into milk in animals. Both risperidone and 9-hydroxyrisperidone, which is the major active metabolite of risperidone and the same drug as paliperidone, distribute into milk following risperidone administration in humans. The manufacturer states that women receiving paliperidone should not breast-feed.

Pediatric Use. Safety and effectiveness not established in pediatric patients younger than 18 years of age.

Geriatric Use. In clinical studies, approximately 7% of nearly 1800 patients were 65 years of age or older. In addition, the short-term efficacy and safety of paliperidone have been demonstrated in a placebo-controlled trial of 6 weeks' duration in 114 geriatric patients with schizophrenia. While no substantial differences in efficacy or safety relative to younger adults were observed in these studies or in other clinical experience with the drug, increased sensitivity cannot be ruled out.

Because geriatric patients may have reduced renal function, dosage adjustment may be required based on renal function status; consider monitoring renal function. (See Dosage and Administration: Special Populations.)

Geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs appear to be at an increased risk of death compared with that among patients receiving placebo. Paliperidone is *not* approved for the treatment of dementia-related psychosis. (See Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions.)

Hepatic Impairment. Patients with moderate hepatic impairment (Child-Pugh class B) exhibited similar plasma concentrations of free paliperidone as healthy individuals, although total paliperidone exposure decreased because of decreased protein binding. Dosage adjustment is not necessary in patients with mild to moderate hepatic impairment (Child-Pugh class A and B). The effect of severe hepatic impairment on paliperidone pharmacokinetics is not known. (See Dosage and Administration: Special Populations.)

Renal Impairment. Clearance decreased by an average of 32, 64, and 71% in patients with mild, moderate, and severe renal impairment, respectively. Dosage adjustment is recommended in patients with moderate or severe renal impairment. (See Dosage and Administration: Special Populations.)

■ **Common Adverse Effects** Adverse effects reported in 5% or more of patients receiving paliperidone include tremor, headache, orthostatic hypotension, tachycardia, somnolence, akathisia, insomnia, anxiety, extrapyramidal reaction, dizziness, dystonia, QT_c interval prolongation, nausea, dyspepsia, and weight gain.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes** Inhibitors or inducers of cytochrome P-450 (CYP) isoenzymes 2D6, 3A4, 1A2, 2A6, 2C9, and 2C19: pharmacokinetic interaction unlikely.

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Substrates of CYP1A2, CYP2A6, CYP2C8/9/10, CYP2D6, CYP2E1, CYP3A4, or CYP3A5: pharmacokinetic interaction unlikely.

■ **Drugs Inhibiting P-glycoprotein Transport System** At therapeutic concentrations, paliperidone did not inhibit P-glycoprotein; clinically relevant interactions unlikely.

■ **Drugs that Prolong QT Interval** Potential pharmacologic interaction (additive effect on QT-interval prolongation); avoid concomitant use of other drugs known to prolong the QT interval (e.g., amiodarone, quinidine, procainamide, sotalol; other Class Ia and III antiarrhythmics, chlorpromazine, thioridazine, gatifloxacin, moxifloxacin).

■ **Protein-bound Drugs** Pharmacokinetic interaction unlikely.

■ **Alcohol** Potential pharmacologic interaction (additive sedative effects). Avoid alcoholic beverages during paliperidone therapy.

■ **Hypotensive Agents** Potential pharmacologic interaction (additive hypotensive effects).

■ **Levodopa and Dopamine Agonists** Potential pharmacologic interaction (antagonistic effects).

■ **Paroxetine** Concomitant administration of paroxetine (20 mg daily) and a single dose of paliperidone (3 mg as extended-release tablets) caused a small, clinically insignificant increase in paliperidone area under the concentration-time curves (AUCs) compared with paliperidone administration alone. Therefore, dosage adjustment of paliperidone is not neeessary.

■ **Risperidone** Concurrent use of paliperidone with risperidone has not been studied to date. However, because paliperidone is the prineipal active metabolite of risperidone, consideration should be given to additive paliperidone exposure if risperidone and paliperidone are coneomitantly administered.

■ **Other CNS Agents** Potential pharmacologic interaction (additive sedative effeets). Use with caution.

■ **Smoking** Pharmacokinetic interaction unlikely. Dosage adjustment in patients who smoke is not necessary.

Description

Paliperidone is a benzisoxazole-derivative antipsyehotic agent that differs chemieally from other currently available first-generation (typical) antipsychotic agents (e.g., butyrophenones, phenothiazines) and has been referred to as an atypical or second-generation antipsychotie agent. The drug is the major active metabolite of risperidone, another atypical antipsychotic agent.

The exact mechanism of paliperidone's antipsychotic action, like that of other antipsychotic agents, has not been fully elucidated, but may involve antagonism of central dopamine type 2 (D_2) and serotonin type 2 (5-hydroxytryptamine [$5\text{-}HT_{2A}$]) receptors. Antagonism at α_1- and α_2-adrenergic and histamine (H_1) receptors may contribute to other therapeutic and adverse effects observed with the drug. Paliperidone possesses no affinity for eholinergic muscarinic and β_1- and β_2-adrenergic receptors.

In vitro studies have suggested a role for cytochrome P-450 (CYP) isoenzymes 2D6 and 3A4 in the metaholism of paliperidone; however, the results of in vivo studies indicate that these isoenzymes play a limited role in the overall elimination of the drug from the body.

Approximately 80% and 11% of a single 1-mg oral dose of radiolabeled, immediate-release paliperidone is recovered in urine and feces, respectively, within 1 week. About 59% of the administered dose is recovered as unchanged drug and 32% recovered as metabolites. Following single-dose oral administration as extended-release tablets, paliperidone appears to have a mean terminal elimination half-life of about 23 hours.

Advice to Patients

Importance of reading manufacturer's patient information.

Risk of orthostatic hypotension, particularly during initial dosage titration and at times of reinitiation of therapy or increases in dosage. Importance of advising patients who experience dizziness or fainting during therapy to get up slowly when sitting or lying down.

Because somnolenee and impairment of judgment, thinking, or motor skills may be associated with paliperidone, patients should be cautioned about driving, operating machinery, or performing hazardous tasks while taking paliperidone until they gain experience with the drug's effects. Importance of avoiding alcohol during paliperidone therapy.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription (see Drug Interactions: Drugs that Prolong QT Interval) and OTC drugs, dietary supplements, and/or herbal products, as well as any concomitant illnesses (e.g., cardiovascular disease, diabetes mellitus, seizures).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of avoiding overheating or dehydration.

Importance of informing patients that paliperidone tablets should be swallowed whole with the aid of liquids, and should not be chewed, divided or crushed. Patients should not be concerned if they notice a tablet-like substance in their stool.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[a] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufac-

turer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Quetiapine Fumarate

■ Quetiapine is considered an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Quetiapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia Short-term efficacy of quetiapine for the management of schizophrenia has been established by placebo-controlled studies of 6 weeks' duration principally in hospitalized patients with schizophrenia. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

In clinical studies in patients with schizophrenia, quetiapine was more effective than placebo in reducing the severity of symptoms associated with this disorder. Quetiapine appears to improve both positive and negative manifestations of schizophrenia. Results from comparative clinical studies and meta-analyses suggest that quetiapine is at least as effective as chlorpromazine or haloperidol in reducing positive and negative symptoms of schizophrenia.

The American Psychiatric Association (APA) considers certain atypical antipsychotic agents (i.e., quetiapine, aripiprazole, olanzapine, risperidone, ziprasidone) first-line drugs for the management of the acute phase of schizophrenia (including first psychotic episodes), principally because of the decreased risk of adverse extrapyramidal effects and tardive dyskinesia, with the understanding that the relative advantages, disadvantages, and cost-effectiveness of conventional and atypical antipsychotic agents remain controversial. The APA states that, with the possible exception of clozapine for the management of treatment-resistant symptoms, there currently is no definitive evidence that one atypical antipsychotic agent will have superior efficacy compared with another agent in the class, although meaningful differences in response may be observed in individual patients. Conventional antipsychotic agents may be considered first-line therapy in patients who have been treated successfully in the past with or who prefer conventional agents. The choice of an antipsychotic agent should be individualized, considering past response to therapy, adverse effect profile (including the patient's experience of subjective effects such as dysphoria), and the patient's preference for a specific drug, including route of administration.

Although the efficacy of quetiapine for long-term use has not been established in controlled studies, the manufacturer states that beneficial effects of the drug were maintained for up to 4 years in some patients during an open-label extension study in patients who achieved an initial response to treatment during double-blind clinical studies. If quetiapine is used for extended periods, the need for continued therapy should be reassessed periodically on an individualized basis. (See Dosage and Administration: Dosage.)

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Quetiapine is used alone or in conjunction with lithium or divalproex sodium for the management of acute manic episodes associated with bipolar I disorder. Efficacy of quetiapine monotherapy in the treatment of acute manic episodes has been demonstrated in 2 placebo-controlled studies of 12 weeks' duration in patients who met the DSM-IV criteria for bipolar disorder and who met diagnostic criteria for an acute manic episode (with or without psychotic features). Patients with rapid cycling and mixed episodes were excluded from these studies. The principal rating instrument used for assessing manic symptoms in these studies was the Young Mania Rating Scale (YMRS) score, an 11-item clinician rated scale traditionally used to assess the degree of manic symptomatology in a range from 0 (no manic features) to 60 (maximum score). In these studies, quetiapine was shown to be superior to placebo in reduction of the YMRS total score after 3 and 12 weeks of treatment.

Efficacy of quetiapine when used in combination with lithium or divalproex sodium in the management of acute manic episodes has been demonstrated in a placebo-controlled study of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder with acute manic episodes (with or without psychotic features). Patients with rapid cycling and mixed episodes were excluded from enrollment and patients included in the study may or may not have received an adequate course of therapy with lithium or divalproex sodium prior to randomization. Quetiapine was shown to be superior to placebo when added to lithium or divalproex sodium alone in the reduction of YMRS total score. However, in a similarly designed study, quetiapine was associated with an improvement of YMRS scores but did not demonstrate superiority to placebo.

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current APA recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic (e.g., olanzapine) may be adequate. For more severe manic or mixed episodes, combination therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Quetiapine also is used for the treatment of depressive episodes associated with bipolar disorder. Efficacy of quetiapine in the treatment of depressive episodes has been demonstrated in 2 randomized, double-blind, placebo-controlled studies of 8 weeks' duration in patients with bipolar I or II disorder (with or without a rapid cycling course). Patients in these studies received fixed daily quetiapine dosages of 300 or 600 mg once daily. The principal rating instrument used for assessing depressive symptoms in these studies was the Montgomery-Asberg Depression Rating Scale (MADRS), a 10-item clinician-rated scale with scores ranging from 0 to 60. In both studies, quetiapine was found to be superior to placebo in reduction of MADRS scores at week 8, with improvements in scores evident within one week of treatment. In addition, patients receiving 300 mg of quetiapine daily demonstrated significant improvements compared to placebo recipients in overall quality of life and satisfaction related to various areas of functioning.

Dosage and Administration

■ **Administration** Quetiapine is administered orally. While food reportedly can marginally increase the peak concentration and oral bioavailability of quetiapine, the drug generally can be administered without regard to meals.

Dispensing and Administration Precautions Because of similarity in spelling between Seroquel® (the trade name for quetiapine fumarate) and Serzone® (the former trade name for nefazodone hydrochloride, an antidepressant agent; no longer commercially available in the US under this trade name), dispensing errors have been reported to the US Food and Drug Administration (FDA) and the manufacturer of Seroquel® (AstraZeneca). According to the medication error reports, the overlapping strengths (100 and 200 mg), dosage forms (tablets), and dosing intervals (twice daily) and the fact that these 2 drugs were stored closely together in pharmacies also were critical in causing these errors. Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Seroquel® and Serzone®. Although the Serzone brand was discontinued in June 2004, clinicians may continue to refer to nefazodone by the former brand name in prescribing. Some experts recommend that pharmacists assess the measures of avoiding dispensing errors and implement them as appropriate (e.g., by verifying all orders for these agents by spelling both the trade and generic names to prescribers, using computerized name alerts, attaching reminders to drug containers and pharmacy shelves, separating the drugs on pharmacy shelves, counseling patients). (See Dispensing and Administration Precautions under Warnings/Precautions: General Precautions in Cautions.)

■ **Dosage** Dosage of quetiapine fumarate is expressed in terms of quetiapine and must be carefully adjusted according to individual requirements and response, using the lowest possible effective dosage.

in vitro studies have identified a novel gabapentin binding site in the neocortex and hippocampus of rat brain, additional studies are required to fully elucidate the identity and function of this binding site.

In animal test systems, gabapentin exhibits anticonvulsant activity similar to that of other commonly used anticonvulsant drugs. The drug protects against seizures induced in animals by electrical stimulation or pentylenetetrazole, suggesting that it may be effective in the management of tonic-clonic (grand mal) and partial seizures or absence (petit mal) seizures, respectively. However, available data in animals and humans are conflicting regarding the effect of gabapentin on EEG spike and wave activity associated with absence (petit mal) seizures. Gabapentin also prevents seizures in some animals with congenital epilepsy and protects against audiogenic tonic extensions and clonic seizures in mice.

Although the mechanism of action is unknown as yet, gabapentin also has demonstrated analgesic activity. In animals, gabapentin has been shown to prevent allodynia (pain-related behavior in response to normally innocuous stimuli) and hyperalgesia (exaggerated response to painful stimuli) in several models of neuropathic pain. Gabapentin also has been shown to decrease pain-related responses after peripheral inflammation in animals; however, the drug has not altered immediate pain-related behaviors. The clinical relevance of these findings is not known.

Gabapentin does not bind to plasma proteins, is not appreciably metabolized, does not induce hepatic enzyme activity, and does not appear to alter the pharmacokinetics of commonly used anticonvulsant drugs (e.g., carbamazepine, phenytoin, valproate, phenobarbital, diazepam) or oral contraceptives. In addition, the pharmacokinetics of gabapentin are not altered substantially by concomitant administration of other anticonvulsant drugs.

Children younger than 5 years of age have a higher clearance of gabapentin normalized for weight compared with those 5 years of age and older; clearance of the drug in children 5 years of age and older is consistent with that in adults after a single dose. Therefore, a higher daily dosage is required in children 3–5 years of age to achieve average plasma concentrations similar to those in patients 5 years of age and older. (See Dosage and Administration: Dosage.) Infants younger than 1 year of age have a highly variable clearance.

SumMon* (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.

Lamotrigine

■ Lamotrigine is a phenyltriazine anticonvulsant.

Uses

■ **Seizure Disorders** ***Partial Seizures*** Lamotrigine is used in combination with other anticonvulsant agents in the management of partial seizures in adults and children. Lamotrigine also is used as monotherapy in patients converting from monotherapy with a hepatic enzyme-inducing anticonvulsant agent (e.g., phenytoin, carbamazepine, phenobarbital, primidone) in the management of partial seizures in adults.

In controlled clinical studies, adjunctive therapy with lamotrigine was effective in reducing seizure frequency in patients with simple and/or complex partial seizures refractory to therapy with one or more conventional anticonvulsant drugs (e.g., phenytoin, carbamazepine, phenobarbital); the median reduction in seizure frequency was 24–36%. In a controlled clinical study in children 2–16 years of age with partial seizures, the median reduction in frequency of all partial seizures was 36 or 7% in patients receiving lamotrigine or placebo, respectively, in addition to their current therapy (up to 2 conventional anticonvulsant drugs).

The effectiveness of lamotrigine monotherapy in adults with partial seizures who are converting from monotherapy with a hepatic enzyme-inducing anticonvulsant drug (e.g., phenytoin, carbamazepine, phenobarbital, primidone) was established in a controlled clinical study of patients who experienced at least 4 simple or complex partial seizures, with or without secondary generalization, during each of 2 consecutive 4-week baseline periods; during the baseline periods, patients were receiving either phenytoin or carbamazepine monotherapy. Patients were randomized either to lamotrigine (target dose: 500 mg daily) or valproic acid (1000 mg daily) therapy, which was added to their baseline regimen over a 4-week period. Patients were then converted to either lamotrigine or valproic acid monotherapy over another 4-week period and monotherapy continued for another 12-week period. Study end points were either successful completion of the 12-week monotherapy period or meeting a study "escape" criterion, relative to baseline. Escape criteria were defined as doubling of the mean monthly seizure count; doubling of the highest consecutive 2-day seizure frequency; emergence of a new seizure type (defined as a seizure that did not occur during the 8-week baseline period) that was more severe than the other seizure types occurring during the study period; or clinically important prolongation of generalized tonic-clonic seizures. The proportion of lamotrigine- or valproic acid-treated patients meeting escape criteria was 42 or 69%, respectively; no differences in efficacy were detected based on age, race, or gender. It was noted that the patients in the valproic acid control arm were treated intentionally with a relatively low valproic acid dosage because the intent of the study was to establish the effectiveness of lamotrigine monotherapy, and that the study results cannot be interpreted to imply the superiority of lamotrigine therapy to adequate valproic acid therapy. In addition, the manufacturer states that the use of lamotrigine therapy for the management of partial seizures has not been established as initial monotherapy; for conversion from monotherapy with anticonvulsant drugs that do *not* induce hepatic enzymes (e.g., valproate); or for simultaneous conversion to monotherapy from 2 or more concomitant anticonvulsant drugs.

Primary Generalized Tonic-Clonic Seizures Lamotrigine is used in combination with other anticonvulsant agents in the management of primary generalized tonic-clonic seizures in adults and children 2 years of age and older. Efficacy of the drug as adjunctive therapy was established in a placebo-controlled trial in adult and pediatric patients at least 2 years of age who had experienced at least 3 primary generalized tonic-clonic seizures during an 8-week baseline phase. Patients were randomized to receive either placebo or lamotrigine in a fixed-dose regimen (target dosages of 200–400 mg daily in adults and 3–12 mg/kg daily in children) for 19–24 weeks, which was added to their current anticonvulsant regimen of up to 2 anticonvulsant drugs. Patients receiving lamotrigine experienced a substantially greater median reduction in seizure frequency compared with baseline than did patients receiving placebo (66 and 34%, respectively).

Seizures Associated with Lennox-Gastaut Syndrome Lamotrigine also is used in combination with other anticonvulsant agents in the management of generalized seizures associated with Lennox-Gastaut syndrome in pediatric patients and adults. In a controlled clinical trial in patients with Lennox-Gastaut syndrome, adjunctive therapy with lamotrigine resulted in a 32, 34, and 36% decrease in major motor seizures, drop attacks, and tonic-clonic seizures, respectively.

■ **Bipolar Disorder** Lamotrigine is used in the maintenance therapy of bipolar I disorder to prevent or attenuate recurrences of bipolar episodes in patients who remain at high risk of relapse following treatment of an acute depressive or manic episode. The American Psychiatric Association (APA) currently recommends use of lamotrigine as an alternative to first-line maintenance therapies (e.g., lithium, valproic acid, or divalproex). The APA also states that both lamotrigine and lithium are effective in the maintenance treatment of bipolar I disorder; however, the results of two randomized, double-blind, placebo-controlled studies of 18 months' duration indicate that lamotrigine may be more effective in preventing depressive episodes while lithium may be more effective in preventing manic episodes.

Although efficacy of the drug in the acute treatment of mood episodes has yet to be fully established, lamotrigine is considered a first-line agent by the APA for the management of acute depressive episodes in patients with bipolar disorder†. The APA also recommends the use of lamotrigine as an alternative to lithium, valproic acid, or divalproex in the management of patients with rapid cycling bipolar disorder†, particularly in those with the bipolar 2 form of rapid cycling.

For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Dosage and Administration

■ **Administration** Lamotrigine is administered orally. The drug may be administered without regard to meals.

Lamotrigine conventional tablets should be swallowed whole. Lamotrigine chewable/dispersible tablets may be swallowed whole, chewed (and consumed with a small amount of water or diluted fruit juice to aid swallowing), or dispersed in water or diluted fruit juice. To disperse the tablets, they should be added to a small volume (i.e., 5 mL or enough to cover the tablet) of liquid and allowed to disperse completely (over approximately 1 minute); the solution then should be swirled and consumed immediately. Administration of partial quantities of the dispersed tablets should *not* be attempted; calculated doses that do not correspond to available strengths of whole tablets should be rounded down to the nearest whole tablet. Lamotrigine orally disintegrating tablets should be placed on the tongue and moved around in the mouth, where the tablet disintegrates rapidly in saliva, and then subsequently can be swallowed with or without water.

Patients who are currently receiving or beginning therapy with lamotrigine and/or any other anticonvulsant for any indication should be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. (See Cautions: Precautions and Contraindications.)

Dispensing and Administration Precautions Dispensing errors have occurred because of the similarity in spelling between Lamictal® (the trade name for lamotrigine) and Lamisil® (terbinafine hydrochloride), lamivudine, labetalol hydrochloride, Lomotil® (the fixed combination of atropine sulfate and diphenoxylate hydrochloride), and Ludiomil® (the former trade name for maprotiline hydrochloride; no longer commercially available under this trade name in the US). Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Lamictal® and these other drugs. The manufacturer recommends that clinicians consider including the intended use of the particular drug on the prescription, in addition to alerting patients to carefully check the drug they receive and promptly bring any question or concern to the attention of the dispensing pharmacist. The manufacturer also recommends that pharmacists assess various measures of avoiding dispensing errors and implement them as appropriate (e.g., by computerized filling and handling of prescriptions, patient counseling). (See Cautions: Precautions and Contraindications.)

■ **Dosage** Because of the possibility of increasing seizure frequency, anticonvulsant drugs, including lamotrigine, should *not* be discontinued abruptly, particularly in patients with preexisting seizure disorders. Discontinuance of lamotrigine therapy should be done gradually over at least 2 weeks, in a stepwise fashion (e.g., achieving a 50% reduction in the daily dosage of lamotrigine each week). However, concerns for patient safety with continued use of lamotrigine may require more rapid withdrawal of the drug.

The dosage regimen of lamotrigine used in combination with other anticonvulsant drugs depends on whether valproic acid or hepatic enzyme-inducing anticonvulsant drugs, or a combination of these, is administered concomitantly. Addition to lamotrigine therapy of an anticonvulsant drug that induces hepatic microsomal enzymes (e.g., carbamazepine, phenobarbital, phenytoin, primidone) may be expected to increase the clearance (i.e., reduce plasma concentrations) of lamotrigine; conversely, discontinuance of such a concomitantly administered anticonvulsant drug may result in decreased clearance (i.e., increased plasma concentrations) of lamotrigine. Addition of valproate sodium to lamotrigine therapy also decreases the clearance (i.e., increases plasma concentrations) of lamotrigine. Therefore, clinicians should be aware that addition of hepatic enzyme-inducing anticonvulsant drugs or valproic acid to, or their discontinuance from, an anticonvulsant regimen including lamotrigine may require modification of the dosage of lamotrigine and/or the other anticonvulsant agent(s). Exceeding the recommended initial dosage and subsequent dosage escalations of lamotrigine may increase the risk of developing a rash and is *not* recommended.

According to the manufacturer, the effect of anticonvulsants other than hepatic enzyme-inducing anticonvulsant drugs or valproic acid on the pharmacokinetics of lamotrigine has not been fully established, and specific dosing recommendations for patients receiving such drugs cannot be made at this time. Conservative initial dosages and dose escalations (as with concomitant valproic acid) are recommended, and an appropriate maintenance dosage probably would be greater than the maintenance dosage with valproic acid and lower than the maintenance dosage with a hepatic enzyme-inducing anticonvulsant drug.

Seizure Disorders **Adjunctive Therapy for Partial Seizures, Primary Generalized Tonic-Clonic Seizures, or Lennox-Gastaut Syndrome.** For adjunctive therapy in the management of partial seizures, primary generalized tonic-clonic seizures, or Lennox-Gastaut syndrome in adults and children older than 12 years of age who are receiving hepatic enzyme-inducing anticonvulsant drugs *without* concomitant valproic acid therapy, the usual initial dosage of lamotrigine is 50 mg once daily for 2 weeks, then 100 mg daily in 2 divided doses for 2 weeks. The daily dosage may then be increased by 100 mg every 1–2 weeks until an effective maintenance dosage of 300–500 mg daily given in 2 divided doses is reached.

For adjunctive therapy in the management of partial seizures, primary generalized tonic-clonic seizures, or Lennox-Gastaut syndrome in adults and children older than 12 years of age who are receiving an anticonvulsant regimen containing valproic acid, the usual initial dosage of lamotrigine is 25 mg every other day for 2 weeks, followed by 25 mg once daily for 2 weeks. The initial dosage of lamotrigine in patients also receiving valproic acid should not exceed 25 mg every other day because of an increased incidence of rash with concomitant lamotrigine and valproic acid therapy. After the initial 4 weeks of therapy, the daily dosage of lamotrigine may be increased by 25–50 mg every 1–2 weeks until an effective maintenance dosage of 100–400 mg daily given in 1 or 2 divided doses is reached. The usual maintenance dosage of lamotrigine when added to valproic acid alone in adults and children older than 12 years of age is 100–200 mg daily.

Although maintenance dosages of lamotrigine as high as 700 mg daily have been used in anticonvulsant drug regimens that included hepatic enzyme-inducing anticonvulsants but *not* valproic acid or as high as 200 mg daily in drug regimens that included valproic acid alone, dosages exceeding 300–500 mg daily (in regimens *not* containing valproic acid) or exceeding 200 mg daily (in regimens containing valproic acid alone) have not been evaluated in controlled studies.

For adjunctive therapy in the management of partial seizures, primary generalized tonic-clonic seizures, or Lennox-Gastaut syndrome in patients 2–12 years of age who are receiving hepatic enzyme-inducing anticonvulsant drugs *without* concomitant valproic acid therapy, the usual initial dosage of lamotrigine is 0.6 mg/kg daily (rounded down to the nearest whole tablet) in 2 divided doses for 2 weeks. During the subsequent 2 weeks of therapy, the usual dosage is 1.2 mg/kg daily (rounded down to the nearest whole tablet) in 2 divided doses. Subsequent daily doses should be increased every 1–2 weeks by 1.2 mg/kg (rounded down to the nearest whole tablet) until an effective daily maintenance dosage of 5–15 mg/kg (maximum of 400 mg/day in 2 divided doses) is reached. In patients weighing less than 30 kg, increases in maintenance dosages of up to 50% may be required based on the response and tolerance of the patient.

For adjunctive therapy in the management of partial seizures, primary generalized tonic-clonic seizures, or Lennox-Gastaut syndrome in patients 2–12 years of age who are receiving an anticonvulsant regimen containing valproic acid, the usual initial dosage of lamotrigine is 0.15 mg/kg daily (rounded down to the nearest whole tablet) in 1 or 2 divided doses for 2 weeks. During the subsequent 2 weeks of therapy, the usual dosage is 0.3 mg/kg daily (rounded down to the nearest whole tablet) in 1 or 2 divided doses. Subsequent daily doses should be increased every 1–2 weeks by 0.3 mg/kg (rounded down to the nearest whole tablet) until an effective daily maintenance dosage of 1–5 mg/kg (maximum of 200 mg/day in 1 or 2 divided doses) is reached. Usual maintenance dosages range from 1–3 mg/kg daily in patients receiving lamotrigine and valproic acid alone. In patients weighing less than 30 kg, increases in maintenance dosages of up to 50% may be required based on the response and tolerance of the patient.

Monotherapy for Partial Seizures. For subsequent monotherapy in the management of partial seizures in patients converted from monotherapy with a hepatic enzyme-inducing anticonvulsant drug, the usual lamotrigine maintenance dosage in adults and children 16 years of age or older is 500 mg daily given in 2 divided doses. The transition regimen for converting patients from monotherapy with a hepatic enzyme-inducing anticonvulsant drug to lamotrigine monotherapy is a 2-step process; the goal of the transition regimen is to ensure adequate seizure control while minimizing the possibility of developing a serious rash associated with the rapid titration of lamotrigine.

In the first step of the process, lamotrigine therapy is added to the current drug regimen (which should be maintained at a fixed dose) at a dosage of 50 mg once daily for 2 weeks, followed by 100 mg daily in 2 divided doses for 2 weeks; the daily dosage is then increased by 100 mg every 1–2 weeks until the maintenance dosage of 500 mg daily (in 2 divided doses) is reached. Once the maintenance lamotrigine dosage is reached, the concomitant hepatic enzyme-inducing anticonvulsant drug can then be withdrawn gradually over a period of 4 weeks; based on experience from the controlled clinical trial, the concomitant drug was withdrawn by 20% decrements each week over a 4-week period.

Bipolar Disorder For monotherapy in the maintenance treatment of bipolar disorder, the recommended initial adult dosage of lamotrigine is 25 mg once daily for 2 weeks, followed by 50 mg once daily for 2 weeks. After the initial 4 weeks of therapy, the daily dosage of lamotrigine may be doubled at weekly intervals until an effective maintenance dosage of 200 mg daily is reached. Because 400-mg daily dosages were shown to be no more effective than 200-mg daily dosages in clinical studies of lamotrigine monotherapy, the manufacturer recommends that daily dosages not exceed 200 mg daily.

For adjunctive therapy in the maintenance treatment of bipolar disorder in patients who are receiving carbamazepine or other hepatic enzyme-inducing drugs *without* concomitant valproic acid therapy, the usual initial adult dosage of lamotrigine is 50 mg once daily for 2 weeks, followed by 100 mg daily in 2 divided doses for 2 weeks; the daily dosage is then increased in 100-mg increments at weekly intervals until the maintenance dosage of 400 mg daily (in 2 divided doses) is reached.

For adjunctive therapy in the maintenance treatment of bipolar disorder in adults who are receiving valproic acid, the usual initial dosage of lamotrigine is 25 mg every other day for 2 weeks, followed by 25 mg once daily for 2 weeks. After the initial 4 weeks of therapy, the daily dosage of lamotrigine may be doubled at weekly intervals until an effective maintenance dosage of 100 mg daily is reached. To minimize the risk of potentially serious rash in patients receiving lamotrigine in conjunction with valproic acid, the recommended initial dosages and subsequent dose escalations of lamotrigine should not be exceeded.

Addition of hepatic enzyme-inducing drugs (e.g., carbamazepine) or hepatic enzyme-inhibiting drugs (e.g., valproic acid) to a regimen including lamotrigine may require modification of the dosage of lamotrigine and/or the hepatic enzyme-inducing or -inhibiting drug. In pivotal clinical studies, dosages of lamotrigine were halved immediately following the addition of valproic acid to treat an acute mood episode and maintained at that dosage as long as valproic acid was administered concomitantly with lamotrigine. Following addition of carbamazepine or other hepatic enzyme-inducing drugs to treat an acute mood episode, dosages of lamotrigine were gradually doubled (e.g., over a period of at least 3 weeks) and maintained at that dosage as long as these drugs were administered concomitantly with lamotrigine. Following the addition of other psychotropic agents with no known clinical pharmacokinetic interactions with lamotrigine, patients were maintained at current maintenance dosages of lamotrigine.

Discontinuance of hepatic enzyme-inducing drugs (e.g., carbamazepine) or hepatic enzyme-inhibiting drugs (e.g., valproic acid) from a regimen including lamotrigine may require modification of the dosage of lamotrigine. For patients discontinuing carbamazepine or other enzyme-inducing agents following resolution of the acute mood episode and achievement of a maintenance lamotrigine dosage, lamotrigine dosage should remain constant for the first week and then should be decreased in 100-mg daily increments at weekly intervals until an effective maintenance dosage of 200 mg daily is reached. For patients discontinuing valproic acid following resolution of the acute mood episode and achievement of a maintenance lamotrigine dosage, lamotrigine dosage should be increased in 50-mg daily increments at weekly intervals until an effective maintenance dosage of 200 mg daily is reached.

The optimum duration of lamotrigine therapy for the management of bipolar disorder has not been established, and the usefulness of the drug during prolonged therapy (i.e., longer than 18 months) should be reevaluated periodically.

■ **Dosage in Renal and Hepatic Impairment** Because clinical experience with lamotrigine is limited in patients with concomitant illness, the drug should be used with caution in patients with conditions (e.g., renal, hepatic, cardiac impairment) that may affect metabolism and elimination of the drug.

The manufacturer states that lamotrigine should be used with caution in patients with severe renal impairment because there is insufficient information from controlled clinical studies to establish the safety and efficacy of therapy with the drug in such patients. The initial dosage of lamotrigine in patients with renal impairment should be based on the patient's existing anticonvulsant drug regimen (see Dosage and Administration: Dosage). The manufacturer states that a reduced maintenance dosage of lamotrigine may be effective and generally should be used in patients with substantial renal impairment; however, the manufacturer currently makes no specific recommendation for dosage adjustment in such patients.

The manufacturer states that experience with lamotrigine therapy in patients with hepatic impairment is limited. Based on a clinical pharmacology study of the drug in a small number of patients with moderate to severe hepatic dysfunction, the manufacturer makes the general recommendation that initial, escalation, and maintenance doses of lamotrigine therapy should be decreased by approximately 50% in patients with moderate (e.g., Child-Pugh class B) and 75% in patients with severe (e.g., Child-Pugh class C) hepatic impairment. Escalation and maintenance dosages should be adjusted according to clinical response.

Cautions

Lamotrigine generally is well tolerated. However, there have been rare reports of serious dermatologic reactions (including some fatalities) in adults and children receiving lamotrigine. Nervous system and dermatologic effects are among the most frequently reported adverse effects of lamotrigine and among those most frequently requiring discontinuance of the drug. The most frequently occurring adverse effects associated with lamotrigine as adjunctive therapy in adults in controlled clinical trials include dizziness, ataxia, somnolence, headache, diplopia, blurred vision, nausea, vomiting, and rash. Discontinuance of lamotrigine because of adverse effects was required in about 11% of adult patients receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials; the adverse effects most frequently associated with discontinuance of lamotrigine in these trials were rash (3% of patients), dizziness (2.8% of patients), and headache (2.5% of patients). In children receiving lamotrigine as adjunctive therapy in controlled clinical trials, the most commonly reported adverse effects were infection, vomiting, rash, fever, somnolence, accidental injury, dizziness, diarrhea, abdominal pain, nausea, ataxia, tremor, asthenia, bronchitis, flu syndrome, and diplopia. Approximately 11.5% of pediatric patients receiving lamotrigine as adjunctive therapy in clinical trials discontinued the drug because of an adverse effect; the adverse effects most frequently associated with discontinuance of lamotrigine therapy in these patients were rash (4.4% of patients), reaction aggravated (1.7% of patients), and ataxia (0.6% of patients).

The most common adverse effects associated with lamotrigine as monotherapy in adults in the controlled clinical trial were vomiting, coordination abnormality, dyspepsia, nausea, dizziness, rhinitis, anxiety, insomnia, infection, pain, weight decrease, chest pain, and dysmenorrhea; during the conversion period (i.e., when lamotrigine was initially added on to an existing monotherapy regimen consisting of a hepatic enzyme-inducing anticonvulsant drug), the most commonly reported adverse effects were dizziness, headache, nausea, asthenia, coordination abnormality, vomiting, rash, somnolence, diplopia, ataxia, accidental injury, tremor, blurred vision, insomnia, nystagmus, diarrhea, lymphadenopathy, pruritus, and sinusitis. The adverse effects most commonly associated with discontinuance of the drug in this trial were rash (4.5% of patients), headache (3.1% of patients), and asthenia (2.4% of patients).

The adverse effect profiles in males and females in clinical trials of lamotrigine were similar and were independent of age; the rates of discontinuance of lamotrigine for individual adverse effects also were similar for males and females. In general, females receiving adjunctive therapy with lamotrigine or placebo in controlled trials were more likely to report adverse effects than were males; however, dizziness was the only adverse effect reported with at least 10% greater frequency (i.e., 16.5% greater frequency) in females than in males (without a corresponding difference by gender with placebo) in controlled trials.

Because clinical trials of lamotrigine therapy involved specific patient populations and use of the drug as adjunctive therapy or monotherapy following conversion from therapy with another single hepatic enzyme-inducing anticonvulsant drug, it is difficult to determine whether a causal relationship exists for many reported adverse effects, to compare adverse effect frequencies with those in other clinical reports, and/or to extrapolate the adverse effects experience from controlled clinical trials to usual clinical practice.

■ **Nervous System Effects** Nervous system effects were among the most frequent adverse effects reported in patients receiving lamotrigine as adjunctive therapy in controlled clinical trials. Dizziness, headache, and ataxia were the most frequent adverse nervous system effects, occurring in 38, 29, and 22% of adults, respectively, in controlled trials of lamotrigine adjunctive therapy. The frequency of dizziness and ataxia and the rate of discontinuance of lamotrigine because of these adverse effects were dose related in clinical trials; in a dose-response study, dizziness occurred in 54, 31, or 27% of patients receiving lamotrigine 500 mg/day, lamotrigine 300 mg/day, or placebo, respectively, while ataxia occurred in 28, 10, or 10% of those receiving these respective regimens. Limited data also suggest an increased incidence of adverse nervous system effects in patients receiving carbamazepine concomitantly with lamotrigine. (See Cautions: Precautions and Contraindications.)

Somnolence or insomnia occurred in 14 or 6%, respectively, of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Incoordination or tremor was reported in 6 or 4%, respectively, of lamotrigine-treated adults; limited evidence suggests that incoordination and tremor may be dose related, and tremor may occur more frequently with concomitant administration of valproic acid and lamotrigine. Depression occurred in 4%, anxiety in 4%, irritability in 3%, speech disorder in 3%, and concentration disturbance in 2% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Seizure or seizure exacerbation has been reported in 3 or 2% of adults, respectively, receiving lamotrigine as adjunctive therapy in controlled trials; an increase in seizure frequency also has been reported with lamotrigine therapy. Treatment-emergent seizures diagnosed unequivocally as status epilepticus were reported in 7 of 2343 adults receiving adjunctive therapy with lamotrigine in clinical trials; however, the manufacturer states that valid estimates of the incidence of treatment-emergent status epilepticus are difficult to obtain because of variations in the definitions used by different investigators to identify such cases.

Coordination abnormality, dizziness, anxiety, and insomnia occurred in 7, 7, 5, and 5%, respectively, of adults receiving lamotrigine as monotherapy in a controlled trial; amnesia, ataxia, asthenia, depression, hypesthesia, libido increase, decreased or increased reflexes, nystagmus, and irritability, each occurred in 2% of such patients. Paresthesia or asthenia occurred in more than 1% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials but with equal or greater frequency in those receiving placebo.

Somnolence occurred in 17%, dizziness in 14%, ataxia in 11%, tremor in 10%, and asthenia in 8% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Emotional lability, gait abnormality, thinking abnormality, seizures, nervousness, and vertigo each occurred in 2–4% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials.

Amnesia, confusion, hostility, decreased memory, nervousness, nystagmus, thinking abnormality, or vertigo was reported in at least 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Abnormal dreams, abnormal gait, agitation, akathisia, apathy, aphasia, CNS depression, depersonalization, dysarthria, dyskinesia, dysphoria, emotional lability, euphoria, faintness, grand mal seizures, hallucinations, hyperkinesia, hypertonia, hypesthesia, increased libido, mind racing, myoclonus, panic attack, paranoid reaction, personality disorder, psychosis, migraine, sleep disorder, or stupor occurred in at least 0.1% but in less than 1% of such patients. Cerebellar syndrome, choreoathetosis, CNS stimulation, delirium, delusions, dystonia, hypoesthesia, hypotonia, hemiplegia, hyperalgesia, hyperesthesia, hypokinesia, hypomania, decreased libido, manic-depressive reaction, movement disorder, neuralgia, neurosis, or paralysis occurred in less than 0.1% of patients.

Suicidal ideation has been reported in 2–5% of adult patients receiving lamotrigine monotherapy for partial seizures in a controlled clinical trial and in less than 1% of pediatric and adult patients receiving the drug in uncontrolled and controlled clinical trials; suicide and/or suicide attempt has been reported rarely. The Food and Drug Administration (FDA) has analyzed suicidality reports from placebo-controlled studies involving 11 anticonvulsants, including lamotrigine, and found that patients receiving anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%). (See Cautions: Precautions and Contraindications.)

Exacerbation of parkinsonian manifestations in patients with preexisting parkinsonian syndrome and the occurrence of tics have been reported during postmarketing experience with lamotrigine and/or in worldwide uncontrolled clinical trials; however, the manufacturer states that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to lamotrigine.

■ **GI Effects** GI effects were among the most frequent adverse effects reported in adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Nausea was the most frequent adverse GI effect, occurring in 19% of adults in controlled clinical trials; vomiting was reported in 9% of patients in these trials. The frequency of nausea and vomiting appears to be dose related; in a dose-response study, nausea occurred in 25, 18, or 11% of patients receiving lamotrigine 500 mg daily, lamotrigine 300 mg daily, or placebo, respectively, while vomiting occurred in 18, 11, or 4% of those receiving these respective regimens. Diarrhea occurred in 6%, dyspepsia in 5%, abdominal pain in 5%, constipation in 4%, tooth disorder in 3%, and anorexia in 2% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Flatulence was reported in more than 1% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials but occurred with equal or greater frequency in patients receiving placebo. Vomiting, dyspepsia, and nausea occurred in 9, 7, and 7%, respectively, of adults receiving lamotrigine as monotherapy in a controlled trial; anorexia, dry mouth, rectal hemorrhage, and peptic ulcer each occurred in 2% of such patients.

Vomiting occurred in 20%, diarrhea in 11%, abdominal pain in 10%, and nausea in 10% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Constipation, dyspepsia, and tooth disorder each occurred in 2–4% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials.

Halitosis, dry mouth, dysphagia, gingivitis, glossitis, gum hyperplasia, increased appetite, increased salivation, mouth ulceration, stomatitis, taste perversion, thirst, or tooth disorder occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Eructation, gastritis, GI hemorrhage, gum hemorrhage, hematemesis, hemorrhagic colitis, melena, gastric ulcer, taste loss, or tongue edema was reported in less than 0.1% of patients.

Esophagitis and pancreatitis have been reported during postmarketing experience with lamotrigine and/or in worldwide uncontrolled clinical trials; however, the manufacturer states that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to lamotrigine.

■ **Dermatologic and Sensitivity Reactions** Serious dermatologic reactions (including some fatalities) have been reported in adults and children receiving lamotrigine therapy. Rash occurred in 10% of adults and 14% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. The incidence of severe rash associated with lamotrigine also appears to be higher in pediatric patients than in adults; the manufacturer states that severe rash, including Stevens-Johnson syndrome, has been reported in 0.8% of children younger than 16 years of age and in 0.3% of adults receiving lamotrigine as adjunctive therapy in clinical trials. There is evidence that most cases of rash associated with lamotrigine therapy are associated with transiently high plasma concentrations of the drug occurring during the initial weeks of therapy or with high plasma concentrations occurring during concomitant valproic acid therapy. Cases of life-threatening rashes associated with lamotrigine almost always have occurred within 2–8 weeks of treatment initiation; however, severe rashes rarely have presented following prolonged treatment (e.g., 6 months). Lamotrigine-associated rashes do not appear to have distinguishing features. Because it is not possible to distinguish benign rashes from those that may become severe and/or life-threatening, lamotrigine generally should be discontinued at the first sign of rash (unless the rash is known not to be drug related). However, a rash may become life-threatening or permanently disabling or disfiguring despite discontinuance of the drug. Discontinuance of lamotrigine because of rash was required in 3% of adults receiving the drug as adjunctive therapy and 4.5% of adults receiving the drug as monotherapy in controlled clinical trials; 4.4% of pediatric patients receiving lamotrigine in controlled clinical trials discontinued the drug because of the development of rash. The potential for development of a rash at the beginning of lamotrigine therapy may be decreased by employing low initial doses and by gradual escalation of dosage to avoid initially high plasma concentrations of the drug.

Rash, including serious and potentially life-threatening rash, appears to be more likely to occur in patients receiving concomitant valproic acid. Valproic acid can decrease clearance and increase plasma concentrations of lamotrigine more than twofold; exceeding the recommended reduced initial dosage of lamotrigine or the subsequent recommended schedule for escalation of lamotrigine dosage (see Dosage and Administration: Dosage and see Cautions: Precautions and Contraindications), particularly in patients receiving valproic acid, may increase the incidence of rash, including serious rash, in such patients. In clinical trials, 1% of adults and 1.2% of children receiving a drug regimen including lamotrigine concomitantly with valproic acid experienced a rash requiring hospitalization, while 0.16% of adults and 0.6% of children receiving a drug regimen of lamotrigine without valproic acid were hospitalized because of rash.

Rashes severe enough to cause hospitalization, including Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme, angioedema, and a hypersensitivity syndrome (usually consisting of fever, rash, facial swelling, and hematologic, hepatic, and/or lymphatic involvement), occurred in 0.3% of adults receiving lamotrigine in premarketing controlled and uncontrolled clinical trials and in about 0.8% of pediatric patients receiving the drug in clinical trials; death associated with rash has been reported rarely in postmarketing use of lamotrigine. Erythema multiforme has been reported in patients receiving lamotrigine in premarketing controlled and uncontrolled clinical trials in the US, while lupus-like syndrome and vasculitis have been reported during postmarketing experience with the drug and/or in worldwide uncontrolled clinical trials.

Pruritus occurred in 3% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Contact dermatitis, dry skin, peripheral edema, and sweating each occurred in 2% of adults receiving lamotrigine as monotherapy in a controlled trial. Eczema, facial edema, photosensitivity, and pruritus each were reported in 2% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Acne, alopecia, facial edema, dry skin, erythema, hirsutism, maculopapular rash, peripheral edema, skin discoloration, Stevens-Johnson syndrome, sweating, urticaria, or vesiculobullous rash occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Angioedema, erythema multiforme, fungal dermatitis, herpes zoster, leukoderma, petechial rash, pustular rash, seborrhea, or photosensitivity occurred in less than 0.1% of patients.

Hypersensitivity reactions, which can be fatal or life-threatening, have been reported in patients treated with lamotrigine. In some cases, manifestations of these reactions have included multiorgan dysfunction (including hepatic abnormalities) and disseminated intravascular coagulation (see Cautions: Hepatic Effects). Early signs of a possible hypersensitivity reaction, such as fever and lymphadenopathy, should prompt immediate evaluation of the patient; a rash may or may not be present. Unless another cause for the signs or symptoms is found, lamotrigine should be discontinued.

■ **Cardiovascular Effects** Hemorrhage was reported in 2% of pediatric patients receiving lamotrigine as adjunctive therapy in controlled clinical trials. Chest pain occurred in more than 1% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials but occurred with equal or greater frequency in patients receiving placebo. Chest pain also occurred in 5% of adults receiving lamotrigine as monotherapy in a controlled clinical trial. Flushing, hot flushes, palpitations, postural hypotension, syncope, tachycardia, or vasodilation occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Cerebrovascular accident, cerebral sinus thrombosis, deep thrombophlebitis, myocardial infarction, atrial fibrillation, angina pectoris, hemorrhage, or hypertension occurred in less than 0.1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials.

■ **Respiratory Effects** Rhinitis occurred in 14%, pharyngitis in 10%, increased cough in 8%, and flu-like syndrome in 7% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Respiratory disorder was reported in more than 1% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials but occurred with equal or greater frequency in patients receiving placebo. Rhinitis occurred in 7% of adults receiving lamotrigine as monotherapy in a controlled trial; epistaxis, bronchitis, and dyspnea each occurred in 2% of such patients. Pharyngitis, bronchitis, and increased cough occurred in 14, 7, and 7%, respectively, of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Sinusitis and bronchospasm each were reported in 2% of children in these trials. Dyspnea, epistaxis, or hyperventilation occurred in at least 0.1% but in less than 1% of patients in uncontrolled and controlled clinical trials, and bronchospasm, hiccups, or sinusitis occurred in less than 0.1% of patients. Apnea has been reported during postmarketing experience with lamotrigine and/or in worldwide uncontrolled clinical trials; however, the manufacturer states that data are insufficient to provide an estimate of the incidence of this adverse effect or to establish a causal relationship to lamotrigine.

■ **Ocular and Otic Effects** Ocular effects were among the most frequent adverse effects reported in patients receiving lamotrigine as adjunctive therapy in controlled clinical trials. Diplopia was the most frequent adverse ocular effect reported in adults receiving lamotrigine as adjunctive therapy in controlled trials, occurring in 28% of such patients, and blurred vision occurred in 16% of patients. The frequency of diplopia and blurred vision appears to be dose related; in a dose-response study, diplopia occurred in 49, 24, or 8% of patients receiving lamotrigine 500 mg daily, lamotrigine 300 mg daily, or placebo, respectively, while blurred vision occurred in 25, 11, or 10% of patients receiving these respective regimens. Limited data also indicate an increased incidence of some adverse effects, including diplopia and blurred vision, in patients receiving carbamazepine concomitantly with lamotrigine. (See Cautions: Precautions and Contraindications.)

Vision abnormality occurred in 3% of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials and in 2% of adults receiving lamotrigine as monotherapy in a controlled trial. Diplopia, blurred vision, or vision abnormality occurred in 5, 4, or 2%, respectively, of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Abnormality of accommodation, conjunctivitis, oscillopsia, or photophobia occurred in at least 0.1% but in less than 1% of patients in uncontrolled and controlled clinical trials, and dry eyes, lacrimation disorder, strabismus, ptosis, or uveitis occurred in less than 0.1% of patients.

Ear disorder was reported in 2% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Otic pain or tinnitus occurred in at least 0.1% but in less than 1% of patients in uncontrolled and controlled

clinical trials. Deafness was reported in less than 0.1% of patients in uncontrolled and controlled clinical trials.

■ **Musculoskeletal Effects** Neck pain and arthralgia each occurred in 2% of adults receiving lamotrigiuc as adjunctive therapy in controlled clinical trials. Back pain or myalgia occurred in more than 1% of patients receiving lamotrigine as adjunctive therapy in controlled trials but with equal or greater frequency in patients receiving placebo. Joint disorder, myasthenia, muscle spasm, or twitching occurred in at least 0.1% but in less than 1% of patients in uncontrolled and controlled trials, and arthritis, bursitis, leg cramps, tendinous contracture, or pathological fracture occurred in less than 0.1% of patients. Rhabdomyolysis has been observed in patients experiencing hypersensitivity reactions during postmarketing experience with lamotrigine and/or in worldwide uncontrolled trials; however, the manufacturer states that data are insufficient to provide an estimate of the incidence of this adverse effect or to establish a causal relationship to lamotrigine.

■ **Genitourinary Effects** Dysmenorrhea occurred in 7%, vaginitis in 4%, and amenorrhea in 2% of women receiving lamotrigine as adjunctive therapy in controlled clinical trials. Dysmenorrhea occurred in 5% of women receiving lamotrigine as monotherapy in a controlled trial. Menstrual disorder or urinary tract infection occurred in more than 1% of adults receiving adjunctive lamotrigine therapy in controlled trials but with equal or greater frequency in patients receiving placebo. Urinary tract infection occurred in 3% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials; penis disorder was reported in 2% of male pediatric patients receiving lamotrigine in these trials.

Lactation (in females), vaginal candidiasis, hematuria, polyuria, urinary frequency, urinary incontinence, or urinary retention occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine therapy in uncontrolled and controlled clinical trials. Abnormal ejaculation, impotence, epididymitis, cystitis, urine abnormality, dysuria, kidney pain, kidney failure, acute kidney failure, or menorrhagia occurred in less than 0.1% of patients in uncontrolled and controlled clinical trials.

■ **Endocrine and Metabolic Effects** Goiter or hyperthyroidism occurred in less than 0.1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Weight decrease occurred in 5% of adults receiving lamotrigine as monotherapy in a controlled trial. Weight loss or weight gain occurred in at least 0.1% but in less than 1% of patients in uncontrolled and controlled clinical trials. Edema occurred in 2% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Edema or hyperglycemia occurred in less than 0.1% of patients in uncontrolled and controlled clinical trials.

■ **Hepatic Effects** Fatalities associated with multiorgan failure and various degrees of hepatic failure have been reported rarely during premarketing trials of lamotrigine as adjunctive therapy. A young woman receiving concomitant valproic acid and carbamazepine developed a possible hypersensitivity syndrome consisting of headache, fever, and a maculopapular rash 3 weeks following addition of lamotrigine to therapy; fulminant hepatic failure and hepatic coma developed within 3 days, and despite subsequent clinical improvement, the patient died of a massive pulmonary embolus 2 months later. Multiorgan (including renal and/or hepatic) failure and disseminated intravascular coagulation associated with frequent generalized seizures or status epilepticus have been reported in several patients receiving lamotrigine; it has been suggested that this syndrome may have resulted from rhabdomyolysis caused by uncontrolled generalized seizures. The majority of these cases of hepatic and/or multiorgan failure occurred in association with other serious medical events (e.g., status epilepticus, overwhelming sepsis), making it difficult to identify the initiating cause. However, disseminated intravascular coagulation, rhabdomyolysis, renal failure, maculopapular rash, ataxia, and increased liver enzymes (e.g., AST [SGOT]) in the absence of generalized seizures also have been reported rarely with lamotrigine as adjunctive therapy. Abnormal liver function test results occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials, and hepatitis, increased alkaline phosphatase, or bilirubinemia occurred in less than 0.1% of patients.

■ **Hematologic Effects** Blood dyscrasias that may or may not be associated with hypersensitivity reactions, including neutropenia, leukopenia, anemia, thrombocytopenia, pancytopenia, and rarely, aplastic anemia and pure red cell aplasia (PRCA), have been reported with lamotrigine. Lymphadenopathy occurred in 2% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Anemia, ecchymosis, petechiae, leukocytosis, leukopenia, or lymphadenopathy occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Eosinophilia, fibrin decrease, fibrinogen decrease, iron deficiency anemia, lymphocytosis, macrocytic anemia, or thrombocytopenia occurred in less than 0.1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials.

Disseminated intravascular coagulation has been reported rarely in conjunction with multiorgan (e.g., renal and/or hepatic) failure in patients receiving lamotrigine as adjunctive therapy. (See Cautions: Hepatic Effects.) Agranulocytosis, aplastic anemia, hemolytic anemia, neutropenia, pancytopenia, red cell aplasia, and progressive immunosuppression have been reported during postmarketing experience with lamotrigine and/or in worldwide uncontrolled clinical trials; however, the manufacturer states that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to lamotrigine.

■ **Other Adverse Effects** Flu syndrome or fever occurred in 7 or 6%, respectively, of adults receiving lamotrigine as adjunctive therapy in controlled clinical trials. Pain and infection each occurred in 5% and fever in 2% of adults receiving lamotrigine as monotherapy in a controlled trial. Infection occurred in 20%, fever in 15%, accidental injury in 14%, flu syndrome in 7%, and pain in 5% of children receiving lamotrigine as adjunctive therapy in controlled clinical trials. Pain occurred in at least 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Accidental injury, infection, chills, and malaise occurred in at least 0.1% but in less than 1% of patients receiving lamotrigine in uncontrolled and controlled clinical trials. Breast pain, breast abscess, breast neoplasm, enlarged abdomen, increase in serum creatinine concentration, parosmia, or alcohol intolerance occurred in less than 0.1% of patients.

■ **Precautions and Contraindications** Because of the possibility of increased seizure frequency, anticonvulsant drugs, including lamotrigine, should not be discontinued suddenly, particularly in patients with preexisting seizure disorders. Unless safety concerns dictate a more rapid withdrawal of the drug, discontinuance of lamotrigine should be done gradually over a period of 2 weeks. (See Dosage and Administration: Dosage.) Seizure exacerbation and/or status epilepticus have been reported in patients receiving lamotrigine as adjunctive therapy in the management of seizure disorders, although the incidence of these adverse effects has been difficult to determine conclusively. (See Cautions: Nervous System Effects.) The use and dosage of all anticonvulsant drugs in a regimen including lamotrigine should be reevaluated if there is a change in seizure control or appearance or worsening of adverse effects, and patients should be instructed to report immediately any worsening of seizure control.

The US Food and Drug Administration (FDA) has informed healthcare professionals about an increased risk of suicidality (suicidal behavior or ideation) observed in an analysis of studies using various anticonvulsants compared with placebo. FDA's analysis included 199 randomized, placebo-controlled studies of 11 anticonvulsants (carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, and zonisamide) involving over 43,000 patients 5 years of age or older; the studies evaluated the effectiveness of the anticonvulsants in epilepsy, psychiatric disorders (e.g., bipolar disorder, depression, anxiety), and other conditions (e.g., migraine, neuropathic pain). The analysis revealed that patients receiving these anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%); this increased suicidality risk was observed as early as one week after beginning therapy and continued through 24 weeks. The results were generally consistent among the 11 drugs studied. In addition, patients who were treated for epilepsy, psychiatric disorders, and other conditions were all found to be at increased risk for suicidality when compared with placebo; there did not appear to be a specific demographic subgroup of patients to which the increased risk could be attributed. However, the relative risk for suicidality was found to be higher in patients with epilepsy compared with patients who were given one of the drugs for psychiatric or other conditions.

Based on the current analysis of the available data, FDA recommends that all patients who are currently receiving or beginning therapy with any anticonvulsant for any indication be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or unusual changes in mood or behavior. Symptoms such as anxiety, agitation, hostility, mania, and hypomania may be precursors to emerging suicidality. Clinicians should inform patients, their families, and caregivers of the potential for an increased risk of suicidality so that they are aware and able to notify their clinician of any unusual behavioral changes. Patients, family members, and caregivers also should be advised not to make any changes to the anticonvulsant regimen without first consulting with the responsible clinician. They should pay close attention to any day-to-day changes in mood, behavior, and actions; since changes can happen very quickly, it is important to be alert to any sudden differences. In addition, patients, family members, and caregivers should be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). If these or any new and worrisome behaviors occur, the responsible clinician should be contacted immediately. FDA also recommends that clinicians who prescribe lamotrigine or any other anticonvulsant balance the risk for suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician must consider whether the emergence of these symptoms in any given patient may be related to the illness being treated.

During the premarketing development of lamotrigine, 20 sudden and unexplained deaths were reported among a cohort of 4700 patients with epilepsy receiving adjunctive therapy with the drug (5747 patient-years of exposure). Although the rate of these deaths exceeds that expected to occur in a healthy (nonepileptic) population matched for age and gender, this rate was similar to that occurring in a similar population of epileptic patients receiving a chemically unrelated anticonvulsant agent. This evidence suggests, but does not prove, that the incidence of sudden, unexplained death observed with lamotrigine adjunctive therapy may be reflective of the population itself rather than the effects of lamotrigine.

Some evidence suggests that use of lamotrigine concomitantly with valproic acid increases the risk of serious rash. The incidence of rash also appears to increase with the magnitude of the initial dose of lamotrigine and the subsequent rate of dosage escalation; exceeding the recommended dosage of lamotrigine at initiation of therapy appears to increase the risk of rash requiring withdrawal of therapy. (See Dosage and Administration: Dosage.) A benign initial appearance of a rash in a patient receiving lamotrigine therapy cannot predict an entirely benign outcome. Patients receiving lamotrigine, especially in conjunction with valproic acid, should be cautioned that rash, in some cases potentially life-threatening, may occur, and that any occurrence of rash should immediately be reported by the patient to their clinician.

The concomitant use of valproic acid and/or hepatic enzyme-inducing anticonvulsant drugs (e.g., phenobarbital, primidone, carbamazepine, phenytoin) can increase or decrease the metabolism and elimination of lamotrigine, requiring dosage adjustments to maintain efficacy and/or avoid toxicity. (See Dosage and Administration: Dosage.) Addition of valproic acid to lamotrigine therapy reduces lamotrigine clearance and increases steady-state plasma lamotrigine concentrations by slightly more than 50% whether or not hepatic enzyme-inducing anticonvulsant drugs are given concomitantly. Conversely, steady-state plasma concentrations of lamotrigine are decreased by about 40% when phenobarbital, primidone, or carbamazepine is added to lamotrigine therapy and by about 45–54% when phenytoin is added to lamotrigine therapy; the magnitude of the effect with phenytoin is dependent on the total daily dosage of phenytoin (from 100–400 mg daily). Discontinuance of an enzyme-inducing anticonvulsant drug can be expected to increase, and discontinuance of valproic acid can be expected to decrease, the elimination half-life and plasma concentrations of lamotrigine. Although the manufacturer states that a therapeutic plasma concentration range has not been established for lamotrigine and that dosage should be based on therapeutic response, the change in plasma lamotrigine concentrations resulting from addition or discontinuance of enzyme-inducing anticonvulsant drugs or valproic acid should be considered when these drugs are added to or withdrawn from an existing anticonvulsant drug regimen that includes lamotrigine.

Addition of lamotrigine to existing therapy with phenytoin or carbamazepine generally does *not* appreciably alter the steady-state plasma concentrations of these concomitantly administered drugs. Addition of lamotrigine to carbamazepine therapy reportedly has resulted in increased plasma concentrations of a pharmacologically active metabolite of carbamazepine (carbamazepine-10,11-epoxide) and an increased incidence of some adverse effects (e.g., dizziness, headache, diplopia, blurred vision, ataxia, nausea, nystagmus). However, elevations in carbamazepine-10,11-epoxide plasma concentrations and/or increased toxicity have not been consistently observed with concomitant administration of lamotrigine and carbamazepine, and the mechanism of the interaction between these drugs remains unclear.

Addition of lamotrigine to valproic acid therapy in healthy individuals resulted in a 25% reduction in trough steady-state plasma concentrations of valproic acid over a 3-week period, followed by stabilization of these concentrations.

The manufacturer states that the effects of adding lamotrigine to an existing regimen including valproic acid, phenytoin, and/or carbamazepine may be expected to be similar to those associated with addition of each drug independently (i.e., valproic acid concentrations decrease, phenytoin and carbamazepine concentrations do not change).

Lamotrigine is a weak inhibitor of dihydrofolate reductase. Although clinically important alterations in blood folate concentrations or hematologic parameters have not been documented in clinical studies of lamotrigine therapy of at least 5 years duration, the manufacturer states that clinicians should be aware of this effect when prescribing other drugs that inhibit folate metabolism.

Multiorgan failure and various degrees of hepatic failure, in some cases fatal, have been reported rarely with lamotrigine as adjunctive therapy. (See Cautions: Hepatic Effects.) The possibility of such potentially fatal adverse effects should be considered in patients who exhibit signs and symptoms associated with multiorgan and/or hepatic impairment following initiation of lamotrigine as adjunctive therapy.

Lamotrigine can produce drowsiness and dizziness, and patients should be cautioned that the drug may impair their ability to perform hazardous activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle).

Limited information indicates that the elimination half-life of lamotrigine is prolonged in patients with severe chronic renal failure (mean creatinine clearance of 13 mL/minute) not receiving other anticonvulsant drugs. In a study of a limited number of patients and healthy individuals receiving a single 100-mg dose of lamotrigine, the mean plasma half-life of the drug was 42.9 hours in patients with chronic renal failure, 57.4 hours between treatments in dialysis patients, and 26.2 hours in healthy individuals. The mean plasma half-life of lamotrigine was decreased to 13 hours during hemodialysis; an average of 20% (range: 5.6–35.1%) of the total body load of lamotrigine was eliminated during a 4-hour hemodialysis treatment. The manufacturer states that a reduced maintenance dosage of lamotrigine generally should be used in patients with substantial renal impairment; however, the manufacturer currently makes no specific recommendations for dosage adjustment in such patients. (See Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

The manufacturer states that experience with use of lamotrigine in patients with impaired liver function is limited. Following a single 100-mg dose of lamotrigine, the median half-life of the drug in patients with mild, moderate, or severe hepatic impairment (Child-Pugh class A, B, or C, respectively) was 36, 60, or 100 hours, respectively, compared with 32 hours in healthy individuals. The manufacturer recommends reduction of initial, escalation, and maintenance dosages of lamotrigine in patients with moderate or severe hepatic impairment. (See Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Because lamotrigine is transformed in the liver principally to glucuronide metabolites, that are eliminated renally, the drug should be used with caution in patients with diseases or conditions (e.g., renal, hepatic, or cardiac impairment) that could affect metabolism and/or elimination of the drug. In dogs, lamotrigine is extensively metabolized to its 2-*N*-methyl metabolite, which has caused dose-dependent prolongations of the PR interval, widening of the QRS complex, and at high dosages, complete AV block. There have been no consistent effects of lamotrigine metabolites on cardiac conduction in humans. Trace amounts of the 2-*N*-methyl metabolite of lamotrigine have been found in urine, but not in plasma, with chronic dosing of lamotrigine in humans. However, the manufacturer states that it is possible that increased plasma concentrations of the 2-*N*-methyl metabolite could occur in patients with hepatic disease who have decreased ability to glucuronidate lamotrigine.

Lamotrigine binds to melanin-containing ocular tissue in pigmented rats and cynomolgus monkeys, but evidence of this manifestation has not been reported in humans. Although ophthalmologic testing was conducted in one controlled clinical trial of lamotrigine therapy, the manufacturer states that it was inadequate to detect subtle effects or injury resulting from long-term administration of lamotrigine and that the ability of available tests to detect potentially adverse effects associated with the binding of lamotrigine to melanin is unknown. The manufacturer further states that while no specific recommendations for periodic ophthalmologic monitoring of patients receiving long-term lamotrigine therapy can be provided, prolonged administration of the drug could potentially result in its accumulation and possible toxic effects in melanin-rich tissues, including those of the eye, and that clinicians should be aware of possible adverse ophthalmologic effects occurring as a result of binding of the drug to melanin.

Because of similarity in spelling between Lamictal® (the trade name for lamotrigine) and labetalol, Lamisil® (terbinafine hydrochloride), lamivudine, Lomotil® (the fixed combination of atropine sulfate and diphenoxylate hydrochloride), and Ludiomil® (no longer commercially available under this trade name in the US; maprotiline hydrochloride), dispensing errors have been reported to the manufacturer of Lamictal® (GlaxoSmithKline). These medication errors may be associated with serious adverse events either due to lack of appropriate therapy for seizures (e.g., in patients not receiving the prescribed anticonvulsant, lamotrigine, which may lead to status epilepticus) or, alternatively, to the risk of developing adverse effects (e.g., serious rash) associated with the use of lamotrigine in patients for whom the drug was not prescribed and consequently was not properly titrated. Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Lamictal® and these other drugs. When appropriate, clinicians might consider including the intended use of the particular drug on the prescription in addition to alerting patients to carefully check the drug they receive and promptly bring any question or concern to the attention of the dispensing pharmacist. The manufacturer also recommends that pharmacists assess various measures of avoiding dispensing errors and implement them as appropriate (e.g., by computerized filling and handling of prescriptions, patient counseling). Medication errors also may occur between the different formulations of lamotrigine. Depictions of Lamictal® conventional tablets, chewable/dispersible tablets, and orally disintegrating tablets may be found in the medication guide; patients are strongly advised to visually inspect their tablets to verify that they are Lamictal® as well as the correct formulation of Lamictal® each time they fill their prescription.

Lamotrigine is contraindicated in patients with known hypersensitivity to the drug or any ingredient in the formulation.

■ **Pediatric Precautions** Safety and efficacy of lamotrigine have not been established in pediatric patients younger than 2 years of age. Safety and efficacy in children 2–16 years of age have not been established for uses other than adjunctive therapy of partial seizures, primary generalized tonic-clonic seizures, or seizures associated with Lennox-Gastaut syndrome.

Safety and efficacy of lamotrigine for the management of bipolar disorder in patients younger than 18 years of age have not been established.

The incidence of severe rashes requiring hospitalization and discontinuance of the drug appears to be higher in pediatric patients compared with adults (about 0.8% versus 0.3%).

Analyses of population pharmacokinetic data for children 2–18 years of age demonstrated that lamotrigine clearance is influenced mainly by total body weight and concomitant anticonvulsant therapy. Oral clearance of lamotrigine is higher in children than adults when calculated on the basis of body weight; patients weighing less than 30 kg have a higher clearance on a weight-adjusted basis than patients weighing more than 30 kg and may require increases in maintenance dosage. (See Dosage and Administration: Dosage.)

■ **Geriatric Precautions** The manufacturer states that clinical trials of lamotrigine did not include sufficient numbers of patients older than 65 years of age to determine whether they respond differently than younger patients. Because of the greater frequency of decreased hepatic, renal, and/or cardiac function and of concomitant diseases and drug therapy in geriatric patients, the manufacturer suggests that patients in this age group receive initial dosages of the drug in the lower end of the usual range.

■ **Mutagenicity and Carcinogenicity** No evidence of mutagenicity was demonstrated by lamotrigine in vitro in the Ames *Salmonella* microbial mutagen test or the mammalian mouse lymphoma assay. Lamotrigine also did not increase the incidence of structural or numerical chromosomal abnormalities in the in vitro human lymphocyte assay and the in vivo rat bone marrow assay.

No evidence of carcinogenicity was demonstrated by lamotrigine in studies in mice receiving 30 mg/kg daily and in rats receiving 10–15 mg/kg daily for up to 2 years. Steady-state plasma lamotrigine concentrations produced by these dosages ranged from 1–4 mcg/mL in mice and from 1–10 mcg/mL in rats. In humans receiving the recommended lamotrigine dosage of 300–500 mg daily, plasma lamotrigine concentrations generally are in the range of 2–5 mcg/mL, although plasma concentrations up to 19 mcg/mL have been reported.

■ **Pregnancy, Fertility, and Lactation** The safety of lamotrigine when used during pregnancy in humans is unknown, and the drug should be used during pregnancy only when the potential benefits justify the possible risks to the fetus. Patients should be advised to notify their clinician if they become pregnant or intend to become pregnant. The manufacturer, in collaboration with the US Centers for Disease Control and Prevention (CDC), maintains a lamotrigine pregnancy registry to monitor fetal outcomes of pregnant women exposed to lamotrigine. Clinicians aware of patients who have received lamotrigine at any time during their pregnancy and who wish to register these cases before fetal outcome is known (e.g., through ultrasound, amniocentesis, birth) may obtain information by calling the Lamotrigine Pregnancy Registry at 800-336-2176. Patients can enroll themselves in the North American Antiepileptic Drug (NAAED) Pregnancy Registry by calling 888-233-2334; registry information also is available on the website at http://www.aedpregnancyregistry.org/.

Preliminary information from the NAAED Pregnancy Registry suggests a possible association between exposure to lamotrigine monotherapy during the first trimester of pregnancy and an increased incidence of cleft lip or cleft palate in infants. Of 564 pregnant women listed in the NAAED Pregnancy Registry who received lamotrigine monotherapy during the first trimester, 5 cases of oral clefts (2 cases of isolated cleft lips, 3 cases of isolated cleft palate) occurred, yielding a total prevalence of 8.9 cases per 1000 exposures compared with a prevalence of 0.5–2.16 reported among infants of nonepileptic women who were not receiving lamotrigine. However, other pregnancy registries of similar size have not replicated this observation, and the validity of this association cannot be established until additional data are collected in NAAED Pregnancy Registry, in other pregnancy registries, or by additional research. The US Food and Drug Administration (FDA) states that the clinical importance of this preliminary report remains uncertain pending further data collection and more research is needed. FDA recommends that women who are pregnant should not begin or discontinue lamotrigine therapy without first talking to their clinician.

Although there are no adequate and controlled studies to date in humans, lamotrigine has been shown to produce maternal toxicity and secondary fetal toxicity (e.g., reduced fetal weight and/or delayed ossification) in mice and rats receiving oral dosages up to 1.2 or 0.5 times (on a mg/m² basis), respectively, the maximum usual human maintenance dosage of 500 mg daily during the period of organogenesis. However, no evidence of teratogenicity was found in mice, rats, or rabbits receiving the drug orally in dosages up to 1.2, 0.5, or 1.1 times (on a mg/m² basis), respectively, the maximum usual human daily maintenance dosage. Maternal toxicity and fetal death occurred in rats receiving lamotrigine orally during late gestation (days 15–20) in dosages of 0.1, 0.14, or 0.3 times (on a mg/m² basis) the maximum usual human daily maintenance dosage; food consumption and weight gain were reduced in dams, and the gestation period was slightly prolonged. Stillborn pups were found in all three groups of rats receiving lamotrigine, with the greatest number of stillborn pups in the group receiving the highest dosage. Postnatal death of pups occurred between days 1 and 20 only in the group of rats receiving 0.14 or 0.3 times (on a mg/m² basis) the maximum usual human daily maintenance dosage. Some of these deaths appeared to be drug related and not secondary to maternal toxicity. No evidence of teratogenicity was demonstrated in rats receiving lamotrigine in dosages 0.4 times (on a mg/m² basis) the maximum usual human daily maintenance dosage prior to and during mating and throughout gestation and lactation. However, the incidence of intrauterine death without signs of teratogenicity was increased in rat dams receiving lamotrigine isethionate by rapid IV injection in a dosage 0.6 times (on a mg/m² basis) the maximum usual human daily maintenance dosage. In a study designed to determine the effects of lamotrigine on postnatal development, pregnant rats received lamotrigine orally in dosages 0.1 and 0.5 times (on a mg/m² basis) the recommended human daily dosage during the period of organogenesis. At day 21 postpartum, pups born to dams receiving the lower dosage (5 mg/kg daily) exhibited a longer latent period for open field exploration and a lower frequency of rearing. Pups born to dams receiving the higher dosage (25 mg/kg daily) demonstrated an increased time to completion of a swimming maze test performed 39–44 days postpartum. No evidence of adverse effects on development of pups was demonstrated by lamotrigine in a group of rats receiving the drug in dosages 0.4 times (on a mg/m² basis) the maximum usual human daily maintenance dosage prior to and during mating, and throughout gestation and lactation.

Because lamotrigine is a dihydrofolate reductase inhibitor, it decreases fetal folate concentrations in rats, an effect known to be associated with teratogenesis in animals and humans. However, there are no adequate and well-controlled studies in pregnant women, and animal reproduction studies are not always predictive of human response. Decreased plasma folate concentrations in rats were partially returned to normal by administration of leucovorin. Clinicians should be aware of lamotrigine's dihydrofolate reductase inhibiting activity, especially when prescribing other drugs that inhibit folate metabolism.

The effect of lamotrigine on labor and delivery in humans is unknown.

Reproduction studies revealed no adverse effects on fertility in rats receiving lamotrigine in oral dosages 0.4 times (on a mg/m² basis) the maximum usual human daily maintenance dosage prior to and during mating, and throughout gestation and lactation. The effect of lamotrigine on human fertility is unknown.

Preliminary data indicate that lamotrigine is distributed into milk. Because of the potential for serious adverse reactions to lamotrigine in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Description

Lamotrigine is a phenyltriazine anticonvulsant agent. The drug differs structurally from other currently available anticonvulsant agents. Although the precise mechanism of anticonvulsant action of lamotrigine is unknown, studies in animals indicate that the drug may stabilize neuronal membranes by blocking voltage-sensitive sodium channels, which inhibits the release of excitatory amino acid neurotransmitters (e.g., glutamate, aspartate) that play a role in the generation and spread of epileptic seizures. In animal test systems, lamotrigine exhibits anticonvulsant activity similar to that of phenytoin, phenobarbital, and carbamazepine. The drug protects against seizures induced by electrical stimulation or pentylenetetrazole, suggesting that it may be effective in the management of tonic-clonic (grand mal) and partial seizures or absence (petit mal) seizures, respectively. Lamotrigine also is active in electrically evoked afterdischarge tests, indicating activity against simple and complex partial seizures, and in rat cortical kindling tests, which may indicate activity against complex partial seizures. The mechanism(s) of action of lamotrigine in bipolar disorder has not been established.

In vitro studies indicate that lamotrigine has weak inhibitory effects on type 3 serotonergic (5-HT_3) receptors, and does not exhibit high affinity for type 2 serotoninergic (5-HT_2), adenosine A_1 or A_2, α_1- or α_2-adrenergic, β-adrenergic, dopamine D_1 or D_2, γ-aminobutyric acid (GABA) A or B, histamine H_1, opiate κ, or cholinergic muscarinic receptors. The drug has weak agonist effects at opiate σ receptors. Lamotrigine apparently has no effect on dihydropyridine-sensitive calcium channels or *N*-methyl-d-aspartate (NMDA) receptors and does not inhibit the uptake of norepinephrine, dopamine, serotonin, or aspartic acid.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Lamotrigine

Oral		
Tablets	25 mg	**Lamictal®** (scored), GlaxoSmithKline
	100 mg	**Lamictal®** (scored), GlaxoSmithKline
	150 mg	**Lamictal®** (scored), GlaxoSmithKline
	200 mg	**Lamictal®** (scored), GlaxoSmithKline
Tablets, chewable/dispersible	2 mg	**Lamictal®**, GlaxoSmithKline
	5 mg	**Lamictal®**, GlaxoSmithKline
	25 mg	**Lamictal®**, GlaxoSmithKline
Tablets, orally disintegrating	25 mg	**Lamictal® ODT**, GlaxoSmithKline
	50 mg	**Lamictal® ODT**, GlaxoSmithKline
	100 mg	**Lamictal® ODT**, GlaxoSmithKline
	200 mg	**Lamictal® ODT**, GlaxoSmithKline

†Use is not currently included in the labeling approved by the US Food and Drug Administration.

■ **Elimination** The elimination half-life of citalopram averages approximately 35 hours in adults with normal renal and hepatic function.

The exact metabolic fate of citalopram has not been fully elucidated; however, metabolism of citalopram is mainly hepatic and involves *N*-demethylation. Citalopram is metabolized to demethylcitalopram, didemethylcitalopram, citalopram-*N*-oxide, and a deaminated propionic acid derivative. In vitro studies have indicated that cytochrome P-450 (CYP) 3A4 and 2C19 isoenzymes are the principal enzymes involved in the *N*-demethylation of citalopram to demethylcitalopram and that demethylcitalopram is further *N*-demethylated to didemethylcitalopram by CYP2D6. Because citalopram is metabolized by multiple enzyme systems, inhibition of a single enzyme is unlikely to appreciably decrease the clearance of citalopram. Unlike some other selective serotonin-reuptake inhibitors, the demethylated metabolites of citalopram, demethylcitalopram and didemethylcitalopram, are substantially less active than the parent compound as inhibitors of serotonin reuptake. Thus, citalopram's metabolites are unlikely to contribute to the antidepressant and other clinical actions of the drug.

In humans, unchanged citalopram is the predominant compound in plasma. At steady state, the concentrations of demethylcitalopram and didemethylcitalopram in plasma are approximately one-half and one-tenth, respectively, that of the parent drug. Following IV (parenteral dosage form not commercially available in the US) administration of citalopram, the fraction of drug recovered in urine as citalopram and demethylcitalopram was about 10 and 5%, respectively.

Following oral administration of a single, radiolabeled dose of citalopram in healthy individuals, approximately 75% of the dose was excreted in urine and approximately 10% was eliminated in feces within 17 days. An analysis of the urinary composition showed that besides the known metabolites of citalopram, 3 glucuronides were present. The relative amounts of citalopram, demethylcitalopram, didemethylcitalopram, and the *N*-oxide metabolite present in urine collected for 7 days were 26, 19, 9, and 7%, respectively, with glucuronidated metabolites accounting for the remainder.

Following IV administration, the mean systemic clearance of citalopram is approximately 330 mL/minute, with approximately 20% of that due to renal clearance.

The effect of age on the elimination of citalopram has not been fully elucidated. Studies in healthy geriatric individuals and depressed geriatric patients have found higher AUC values and longer elimination half-lives compared with younger individuals. (See Pharmacokinetics: Absorption.) In healthy geriatric individuals, the elimination half-life of citalopram was increased by 50% in a single-dose study and by 30% in a multiple-dose study. It has been suggested that these differences in pharmacokinetic parameters may reflect declining liver and kidney function. In addition, the stereoselective metabolism of the enantiomers for citalopram and demethylcitalopram in older individuals appears to differ from that reported in younger patients, suggesting possible age-associated changes in CYP2C19 activities. (See Dosage and Administration: Dosage in Geriatric Patients and see Cautions: Geriatric Precautions.)

Because citalopram is extensively metabolized in the liver, hepatic impairment can affect the elimination of the drug. Following oral administration, the clearance of citalopram in patients with impaired hepatic function was reduced by 37% and the elimination half-life was increased twofold compared with that in healthy individuals. Therefore, the manufacturer recommends that in depressed patients with hepatic impairment, citalopram therapy should be initiated at 20 mg once daily, and titrated to 40 mg once daily *only* in nonresponders. (See Dosage and Administration: Dosage in Hepatic and Renal Impairment and see Cautions: Precautions and Contraindications.)

The effect of renal impairment on the pharmacokinetics of citalopram has not been fully evaluated to date. In patients with moderate renal impairment, the renal clearance of citalopram and its 2 principal metabolites was reduced and the elimination half-life of citalopram was slightly prolonged to an average of about 50 hours. In a study comparing the pharmacokinetics of citalopram in a limited number of patients with severe renal failure undergoing hemodialysis and in healthy individuals, no substantial differences were found between the 2 groups in any of the pharmacokinetic parameters, with the exception of the renal clearance of citalopram, which was significantly lower in the renal failure group than in the control group (11.7 mL/minute versus 66 mL/minute). Therefore, moderate to severe renal failure does not appear to markedly affect the pharmacokinetics of citalopram suggesting that dosage adjustment in such patients may not be necessary. Additional studies evaluating long-term citalopram therapy in patients with severe renal impairment are necessary to confirm these findings. (See Dosage and Administration: Dosage in Hepatic and Renal Impairment.)

Limited data indicate that citalopram and demethylcitalopram are not appreciably removed by hemodialysis. In a limited number of patients, hemodialysis cleared only about 1% of an oral dose of citalopram as the parent drug and 1% as demethylcitalopram. Because of the large volume of distribution of citalopram, hemodialysis, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion also are unlikely to be effective in removing substantial amounts of citalopram from the body.

Chemistry and Stability

■ **Chemistry** Citalopram hydrobromide, a selective serotonin-reuptake inhibitor (SSRI), is a bicyclic phthalane-derivative antidepressant. The drug differs structurally from most other selective serotonin-reuptake inhibitors (e.g., fluoxetine, fluvoxamine, paroxetine, sertraline) and also differs structurally and pharmacologically from tricyclic and tetracyclic antidepressants. The commercially available drug is a 50:50 racemic mixture of the *R*- and *S*-enantiomers. The inhibition of serotonin reuptake by citalopram is principally due to the *S*-enantiomer, escitalopram (see Escitalopram Oxalate 28:16.04.20).

Citalopram hydrobromide occurs as a fine white to off-white powder that is sparingly soluble in water and soluble in ethanol. The drug has a pK_a of 9.5.

Citalopram hydrobromide is commercially available for oral administration as tablets and as an oral solution. Commercially available Celexa® (citalopram hydrobromide) oral solution is a clear, colorless to opalescent solution with a peppermint flavor and containing 10 mg of citalopram per 5 mL. Citalopram hydrobromide oral solution contains methylparahens and propylparahens as preservatives. Citalopram also is commercially available in some countries as an IV injection†; however, this dosage form currently is not available in the US.

■ **Stability** Citalopram hydrobromide tablets and oral solution should be stored at a temperature of 25°C but may be exposed to temperatures ranging from 15–30°C. When stored as directed, the tablets and oral solution have an expiration date of 2 years and 18 months, respectively, following the date of manufacture.

Preparations

Because of similarity in spelling of Celexa® (citalopram hydrobromide), Celebrex® (celecoxib), and Cerebyx® (fosphenytoin sodium), extra care should be exercised in ensuring the accuracy of prescriptions for these drugs.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Escitalopram Oxalate

■ Escitalopram, the *S*-enantiomer of citalopram, is a selective serotonin-reuptake inhibitor (SSRI) and an antidepressant.

Uses

■ **Major Depressive Disorder** Escitalopram oxalate is used for the acute and maintenance treatment of major depressive disorder in adults and adolescents 12–17 years of age.

Efficacy of escitalopram for the acute management of major depression in adults was established in 3 placebo-controlled studies of 8 weeks' duration in adult outpatients who met DSM-IV criteria for major depressive disorder. In these studies, 10- and 20-mg daily dosages of escitalopram were more effective than placebo in improving scores on the Montgomery Asberg Depression Rating Scale (MADRS), the Hamilton Rating Scale for Depression (HAM-D), and the Clinical Global Impression Improvement and Severity of Illness Scale. Escitalopram also was more effective than placebo in improving other aspects of depressive disorder, including anxiety, social functioning, and overall quality of life. Substantial improvement in MADRS and HAM-D scores was noted in patients receiving either dosage of escitalopram compared with those receiving placebo after 1–2 weeks of therapy. In addition, escitalopram dosages of 10–20 mg daily appeared to be at least as effective as racemic citalopram dosages of 20–40 mg daily. No age-, race-, or gender-related differences in efficacy were noted in these studies.

Efficacy of escitalopram for the acute management of major depressive disorder in adolescents 12–17 years of age was established in an 8-week, flexible-dose, placebo-controlled study in outpatients who met DSM-IV criteria for major depressive disorder. Escitalopram-treated patients in this study demonstrated substantially greater improvement on the Children's Depression Rating Scale–Revised (CDRS-R) compared with those receiving placebo. Efficacy of

escitalopram in the acute treatment of major depressive disorder in adolescents was also established on the basis of extrapolation from an 8-week, flexible-dose, placebo-controlled study with racemic citalopram 20–40 mg daily. In this outpatient study conducted in children and adolescents 7–17 years of age who met DSM-IV criteria for major depressive disorder, citalopram-treated patients demonstrated substantially greater improvement on the CDRS-R compared with those receiving placebo; the positive results in this trial came largely from the adolescent subgroup. Two additional flexible-dose, placebo-controlled depression studies (one for escitalopram in patients 7–17 years of age and one for citalopram in adolescents) did not demonstrate efficacy.

In a longer-term study, 274 adults with major depressive disorder who had responded to escitalopram 10 or 20 mg daily during an initial 8-week, open-label, flexible dosage treatment phase were randomized to continue escitalopram at the same dosage or receive placebo for up to 36 weeks of observation for relapse in the double-blind phase. Relapse during the double-blind phase was defined as an increase in the MADRS total score to 22 or greater or discontinuance due to insufficient clinical response. Escitalopram-treated patients experienced a substantially longer time to relapse of depression compared with those receiving placebo. In addition, more placebo recipients relapsed compared with patients receiving escitalopram (cumulative relapse rates were approximately 40 and 26%, respectively).

Although efficacy of escitalopram as maintenance therapy in adolescent patients has not been systematically evaluated, such efficacy can be extrapolated from adult data along with comparisons of escitalopram pharmacokinetic parameters in adults and adolescent patients.

The manufacturer states that if escitalopram is used for extended periods, the need for continued therapy should be reassessed periodically.

There is some evidence that escitalopram may offer some clinical advantages compared with citalopram or other selective serotonin-reuptake inhibitors (e.g., increased efficacy, more rapid onset of therapeutic effect, fewer adverse effects); however, additional studies are needed to confirm these initial findings.

Efficacy of escitalopram in hospital settings has not been established to date.

For further information on use of SSRIs in the treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant agent for a particular patient, see Uses: Major Depressive Disorder, in Citalopram Hydrobromide 28:16.04.20.

■ **Generalized Anxiety Disorder** Escitalopram is used in the management of generalized anxiety disorder in adults. Efficacy for the management of generalized anxiety disorder was established in 3 multicenter, flexible-dose, placebo-controlled studies of 8-weeks' duration in adult outpatients who met DSM-IV criteria for generalized anxiety disorder. In these studies, patients receiving 10–20 mg daily of escitalopram had substantially greater mean improvements in scores on the Hamilton Anxiety Scale (HAM-A) than those receiving placebo.

For further information on the treatment of generalized anxiety disorder, see Uses: Anxiety Disorders, in Paroxetine 28:16.04.20.

Dosage and Administration

■ **Administration** Escitalopram oxalate is administered orally once daily, in the morning or evening, without regard to meals. Commercially available escitalopram oxalate tablets and oral solution are bioequivalent.

Patients receiving escitalopram should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

The manufacturer recommends that at least 2 weeks elapse between discontinuance of a monoamine oxidase (MAO) inhibitor and initiation of escitalopram and vice versa. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions and see also Drug Interactions: Monoamine Oxidase Inhibitors.)

■ **Dosage** Dosage of escitalopram oxalate is expressed in terms of escitalopram.

Major Depressive Disorder For the acute management of major depressive disorder in adults, the recommended initial dosage of escitalopram is 10 mg once daily. Although efficacy has been established at dosages of 10 or 20 mg once daily, no additional benefit was observed with the 20-mg dosage in a fixed-dose study. If a dosage exceeding 10 mg daily is considered necessary, dosage may be increased to 20 mg daily after a minimum of 1 week.

For the acute management of major depressive disorder in adolescents 12–17 years of age, the recommended initial dosage of escitalopram is 10 mg once daily. Efficacy has been established at dosages of 10–20 mg daily in a flexible-dose study. If dosage is increased to 20 mg daily, this should occur after a minimum of 3 weeks.

While the optimum duration of escitalopram oxalate therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). Whether the dosage of escitalopram oxalate required to induce remission is identical to the dosage needed to maintain and/or sustain euthymia is unknown. Systematic evaluation of escitalopram oxalate has shown that its antidepressant efficacy is maintained for periods of up to 36 weeks in adults receiving 10–20 mg daily. Nevertheless, the manufacturer recommends that the usefulness of escitalopram be reevaluated periodically in patients receiving long-term therapy.

Generalized Anxiety Disorder For the management of generalized anxiety disorder in adults, the recommended initial dosage of escitalopram is 10 mg once daily. If no clinical improvement is apparent, dosage may be increased to 20 mg daily after a minimum of 1 week.

Although the manufacturer states that the efficacy of escitalopram for long-term therapy (i.e., longer than 8 weeks) has not been demonstrated in controlled studies to date, generalized anxiety disorder is a chronic condition. If escitalopram is used for extended periods, the need for continued therapy with the drug should be reassessed periodically.

Discontinuance of Therapy Because withdrawal effects may occur (see Withdrawal of Therapy under Warnings/Precautions: Other Warnings and Precautions, in Cautions), the manufacturer and many experts recommend that dosage of escitalopram and other SSRIs be tapered gradually (e.g., over a period of several weeks) and the patient monitored closely. Abrupt discontinuance of the drug should be avoided.

If intolerable symptoms occur following a decrease in the dosage or upon discontinuance of therapy, escitalopram therapy may be reinstituted at the previously prescribed dosage. Subsequently, the clinician may continue decreasing the dosage but at a more gradual rate.

■ **Special Populations** The recommended dosage of escitalopram in most geriatric patients and those with hepatic impairment is 10 mg daily. Dosage adjustment in patients with mild to moderate renal impairment is not necessary, but the drug should be used with caution in those with severe renal impairment.

Treatment of Pregnant Women during the Third Trimester Because some neonates exposed to escitalopram and other SSRIs or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed severe complications, consideration may be given to cautiously tapering escitalopram therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Pregnancy, under Warnings/Precautions: Specific Populations, in Cautions.)

Cautions

■ **Contraindications** Concurrent or recent (i.e., within 2 weeks) therapy with a monoamine oxidase (MAO) inhibitor. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions and see also Drug Interactions: Monoamine Oxidase Inhibitors.)

Concomitant use with pimozide. (See Drug Interactions: Antipsychotic Agents and Other Dopamine Antagonists.)

Known hypersensitivity to escitalopram, citalopram, or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** **Worsening of Depression and Suicidality Risk.** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared to placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms

that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. If a decision is made to discontinue therapy, taper escitalopram dosage as rapidly as is feasible but consider the risks of abrupt discontinuance. (See Discontinuance of Therapy, under Dosage and Administration: Dosage.) FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

Other Warnings and Precautions **Serotonin Syndrome or Neuroleptic Malignant Syndrome (NMS)-like Reactions.** Potentially life-threatening serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions have been reported with SSRIs, including escitalopram, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) alone, but particularly with concurrent use of other serotonergic drugs (including serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"]), drugs that impair the metabolism of serotonin (e.g., MAO inhibitors), or antipsychotics or other dopamine antagonists. Manifestations of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. Monitor patients receiving escitalopram for the development of serotonin syndrome or NMS-like signs and symptoms. (See Contraindications and see also Drug Interactions.)

Concurrent or recent (i.e., within 2 weeks) therapy with MAO inhibitors intended to treat depression is contraindicated. (See Contraindications and see also Drug Interactions: Monoamine Oxidase Inhibitors.)

If concurrent therapy with escitalopram and a 5-HT_1 receptor agonist (triptan) is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated.

Concomitant use of escitalopram and serotonin precursors (e.g., tryptophan) is not recommended.

If signs and symptoms of serotonin syndrome or NMS occur, immediately discontinue treatment with escitalopram and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, and initiate supportive and symptomatic treatment.

Withdrawal of Therapy. Withdrawal symptoms, including dysphoric mood, irritability, agitation, dizziness, sensory disturbances (e.g., paresthesias such as electric shock sensations), anxiety, confusion, headache, lethargy, emotional lability, insomnia, hypomania, tinnitus, and seizures, have been reported during the postmarketing surveillance period for escitalopram and other SSRIs and SNRIs, particularly upon abrupt discontinuance of these drugs. While these events are generally self-limiting, there have been reports of serious discontinuance symptoms. Therefore, patients should be monitored for these symptoms when discontinuing escitalopram therapy. A gradual reduction in the dosage rather than abrupt cessation is recommended whenever possible. (See Discontinuance of Therapy under Dosage and Administration: Dosage.)

If intolerable symptoms occur following dosage reduction or discontinuance, reinstitute the previously prescribed dosage until symptoms abate, then resume more gradual dosage reductions.

Seizures. Although anticonvulsant effects of racemic citalopram have been observed in animal studies, escitalopram has not been systematically evaluated in patients with seizure disorders. Seizures have been reported in patients receiving escitalopram in clinical trials; therefore, as with other antidepressants, initiate therapy with caution in patients with a history of seizure disorder.

Activation of Mania/Hypomania. Activation of mania and hypomania has occurred in patients receiving escitalopram or citalopram. Use with caution in patients with a history of mania.

Hyponatremia/Syndrome of Inappropriate Antidiuretic Hormone Secretion. Treatment with SNRIs and SSRIs, including escitalopram, may result in hyponatremia. In many cases, hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia. Signs and symptoms of hyponatremia include headache, difficulty concentrating, memory impairment, confusion, weakness, and unsteadiness, which may lead to falls; more severe and/or acute cases have been associated with hallucinations, syncope, seizures, coma, respiratory arrest, and death. Initiate appropriate medical intervention and consider drug discontinuance in patients with symptomatic hyponatremia.

Abnormal Bleeding. SNRIs and SSRIs, including escitalopram, may increase the risk of bleeding events. Concurrent administration of aspirin, nonsteroidal anti-inflammatory agents, warfarin, and other anticoagulants may add to this risk. Case reports and epidemiologic studies have demonstrated an association between the use of drugs that interfere with serotonin reuptake and the occurrence of GI bleeding. Bleeding events related to SNRI and SSRI use have ranged from ecchymoses, hematomas, epistaxis, and petechiae to life-threatening hemorrhages. The manufacturer recommends that patients be advised of the risk of bleeding associated with the concomitant use of escitalopram with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation. (See Drug Interactions: Drugs Affecting Hemostasis.)

Interference with Cognitive and Motor Performance. In a study in healthy volunteers, escitalopram 10 mg daily did not impair intellectual function or psychomotor performance. However, because any psychoactive drug may impair judgment, thinking, or motor skills, caution patients about operating hazardous machinery, including driving a motor vehicle, until they are reasonably certain that the drug does not affect their ability to engage in such activities.

Concomitant Illnesses. Experience with escitalopram in patients with certain concomitant diseases is limited. (See Renal Impairment and see Hepatic Impairment under Warnings/Precautions: Specific Populations, in Cautions.)

Escitalopram has not been systematically evaluated in patients with a recent history of myocardial infarction or unstable cardiovascular disease; such patients were generally excluded from clinical studies. Use with caution in patients with diseases or conditions that produce altered metabolism or hemodynamic responses.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Complications, sometimes severe and requiring prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care, have been reported in some neonates exposed to escitalopram, other SSRIs, or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester; such complications may arise immediately upon delivery. In addition, an increased risk of persistent pulmonary hypertension of the newborn (PPHN) has been observed in infants exposed to SSRIs during late pregnancy; PPHN is associated with substantial neonatal morbidity and mortality.

Clinicians should carefully consider the potential risks and benefits of escitalopram therapy when used during the third trimester of pregnancy. However, clinicians also should be aware that women who discontinued antidepressant therapy during pregnancy were more likely to experience a relapse of depression than those who remained on antidepressant therapy according to results of one longitudinal study involving women with a history of major depressive disorder who were euthymic while receiving antidepressant therapy at the beginning of pregnancy. Clinicians may consider tapering the dosage of escitalopram in women in the third trimester of pregnancy. (See Pregnancy under Cautions: Pregnancy, Fertility, and Lactation, in Citalopram Hydrobromide 28:16.04.20.)

Lactation. Like racemic citalopram, escitalopram is distributed into human milk. Potential for serious adverse effects (e.g., excessive somnolence, decreased feeding, weight loss) in nursing infants exists. Discontinue nursing or the drug, taking into account the potential risk in nursing infants and the importance of the drug to the mother.

Pediatric Use. Safety and efficacy of escitalopram have not been established in pediatric patients younger than 12 years of age with major depressive disorder. Safety and effectiveness have been established in adolescents 12–17 years of age for the acute treatment of major depressive disorder. Although efficacy of escitalopram as maintenance therapy in adolescent patients with major depressive disorder has not been systematically evaluated, such efficacy can be extrapolated from adult data along with comparisons of pharmacokinetic parameters in adults and adolescent patients. (See Uses: Major Depressive Disorder.)

Safety and efficacy of escitalopram have not been established in pediatric patients younger than 18 years of age with generalized anxiety disorder.

FDA warns that a greater risk of suicidal thinking or behavior (suicidality) occurred during first few months of antidepressant treatment compared with placebo in children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders based on pooled analyses of 24 short-term, placebo-controlled trials of 9 antidepressant drugs (SSRIs and other antidepressants). However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

Carefully consider these findings when assessing potential benefits and risks of escitalopram in a child or adolescent for any clinical use. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Geriatric Use. Approximately 6% of patients studied in clinical trials of escitalopram for major depressive disorder and generalized anxiety disorder were 60 years of age or older; geriatric patients in these trials received daily dosages of 10–20 mg daily. Experience in geriatric patients in these trials was insufficient to determine whether they respond differently from younger adults; however, increased sensitivity cannot be ruled out.

SNRIs and SSRIs, including escitalopram, have been associated with clinically important hyponatremia in geriatric patients, who may be at greater risk for this adverse effect. (See Hyponatremia/Syndrome of Inappropriate Antidiuretic Hormone Secretion under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Renal Impairment. Use with caution in patients with severe renal impairment (i.e., creatinine clearance less than 20 mL/minute). (See Dosage and Administration: Special Populations.)

Hepatic Impairment. In clinical studies, clearance of racemic citalopram was decreased by 37% and elimination half-life was doubled relative to that in patients with normal hepatic function. Dosage reduction recommended for patients with hepatic impairment. (See Dosage and Administration: Special Populations.)

■ **Common Adverse Effects** Adverse effects reported in approximately 5% or more of patients with generalized anxiety or major depressive disorder receiving escitalopram and with an incidence of at least twice that of placebo include insomnia, nausea, increased sweating, sexual dysfunction (ejaculation disorder [primarily ejaculatory delay], decreased libido, anorgasmia), fatigue, and somnolence.

Drug Interactions

■ **Drugs Affecting or Metabolized by Hepatic Microsomal Enzymes** Inhibitors or inducers of cytochrome P-450 (CYP) 3A4 (e.g., carbamazepine, ketoconazole, ritonavir, triazolam) and 2C19 isoenzymes: clinically important pharmacokinetic interaction unlikely since escitalopram is metabolized by multiple enzyme systems. However, possibility that carbamazepine may increase clearance of escitalopram should be considered.

Substrates of CYP2D6 isoenzyme (e.g., desipramine, metoprolol): potential pharmacokinetic (increased peak plasma concentrations and AUC of the substrate) interactions. Use with caution. Increased plasma concentrations of metoprolol have been associated with decreased cardioselectivity.

■ **Drugs Affecting Hemostasis** Pharmacokinetics of warfarin were not affected by racemic citalopram; however, prothrombin time increased by 5%. The effects of escitalopram have not been evaluated, and the clinical importance of this interaction is unknown.

Altered anticoagulant effects, including increased bleeding, have been reported when SSRIs or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) were concurrently administered with warfarin or other anticoagulants. The manufacturer of escitalopram recommends carefully monitoring patients receiving warfarin during initiation and discontinuance of escitalopram therapy.

Potential pharmacologic (increased risk of bleeding) interaction with aspirin or other nonsteroidal anti-inflammatory agents; use with caution.

■ **Antipsychotic Agents and Other Dopamine Antagonists** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions) if used concurrently with antipsychotic agents or other dopamine antagonists. If signs and symptoms of serotonin syndrome or NMS occur, immediately discontinue treatment with escitalopram and any concurrently administered antidopaminergic or serotonergic agents and initiate supportive and symptomatic treatment. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Pimozide In a controlled study, concurrent administration of a single, 2-mg dose of pimozide in individuals receiving citalopram (40 mg once daily for 11 days) was associated with mean increases in the corrected QT (QT_c) interval of approximately 10 msec compared with pimozide given alone. Citalopram did not substantially affect the mean area under the plasma concentration-time curve (AUC) or peak plasma concentrations of pimozide. The mechanism for this potential pharmacodynamic interaction is not known. In addition, concomitant use of citalopram and pimozide rarely may result in potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions. The manufacturer of escitalopram states that concurrent use of escitalopram and pimozide is contraindicated.

■ **5-HT_1 Receptor Agonists ("Triptans")** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions) if used concurrently with 5-HT_1 receptor agonists (e.g., almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan). If concomitant use is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, when dosage is increased, or when another serotonergic agent is initiated. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Monoamine Oxidase Inhibitors** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions). Concomitant use of monoamine oxidase (MAO) inhibitors with escitalopram is contraindicated. In addition, at least 2 weeks should elapse between discontinuance of an MAO inhibitor and initiation of escitalopram and vice versa. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Linezolid Linezolid, an anti-infective agent that is a nonselective and reversible MAO inhibitor, has been associated with drug interactions resulting in serotonin syndrome and should therefore be used with caution in patients receiving escitulopram.

Isoniazid Potential pharmacologic interaction (potentially serious serotonin syndrome) when isoniazid, an antituberculosis agent that appears to have some MAO-inhibiting activity, is used concomitantly with escitalopram.

■ **Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions); concurrent administration not recommended. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Other Serotonergic Drugs** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions) with drugs affecting serotonergic neurotransmission, including tramadol and St. John's wort (*Hypericum perforatum*); use concomitantly with caution. If signs and symptoms of serotonin syndrome or NMS occur, immediately discontinue treatment with escitalopram and any concurrently administered serotonergic or antidopaminergic agents and initiate supportive and symptomatic treatment. Concurrent administration of escitalopram and serotonin precursors (such as tryptophan) is not recommended. (See Serotonin Syndrome or Neuroleptic Malignant Syndrome [NMS]-like Reactions under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

■ **Alcohol** Concomitant use not recommended.

■ **Cimetidine** Potential pharmacokinetic interaction (increased AUC and peak plasma concentrations of citalopram have been observed); effects on escitalopram have not been evaluated. Clinical importance of this interaction is unknown.

■ **Citalopram** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions).

Because escitalopram is the more active isomer of racemic citalopram, the 2 agents should not be used concomitantly.

■ **CNS-active Drugs** Potential pharmacologic interaction when given with other centrally acting drugs; use concomitantly with caution.

■ **Digoxin** Pharmacokinetic interaction unlikely based on studies with racemic citalopram.

■ **Lithium** Concurrent administration of racemic citalopram and lithium did not substantially affect the pharmacokinetics of either drug. However, pending further accumulation of data, the manufacturer of escitalopram recommends that plasma lithium concentrations be monitored in patients concurrently receiving escitalopram and that lithium dosage be adjusted accordingly.

Potential pharmacologic interaction (enhanced serotonergic effects of escitalopram and potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions); use concomitantly with caution.

■ **Ritonavir** Combined administration of a single 600-mg dose of ritonavir, a CYP3A4 substrate and potent inhibitor of CYP3A4, and escitalopram 20 mg did not substantially affect the pharmacokinetics of either drug.

■ **Sibutramine** Potential pharmacologic interaction (potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions). Use concomitantly with caution.

■ **Theophylline** Pharmacokinetics of theophylline were not affected by racemic citalopram. The effect of theophylline on the pharmacokinetics of racemic citalopram, however, has not been evaluated.

■ **Electroconvulsive Therapy** The combined use of electroconvulsive therapy and escitalopram has not been evaluated.

Description

Escitalopram, a selective serotonin-reuptake inhibitor (SSRI), is a bicyclic phthalane-derivative antidepressant. Escitalopram is the *S*-enantiomer of citalopram, an SSRI that occurs as a 50:50 racemic mixture of the *R*- and *S*-enantiomers. Escitalopram and citalopram differ structurally from other SSRIs (e.g., fluoxetine, fluvoxamine, paroxetine, sertraline) and other currently available antidepressants (e.g., monoamine oxidase inhibitors, tricyclic and tetracyclic antidepressants). Escitalopram is at least 100-fold more potent as an inhibitor of the reuptake of serotonin (5-hydroxytryptamine [5-HT]) at the presynaptic membranes and the 5-HT neuronal firing rate than the *R*-enantiomer and is twice as potent as the racemic mixture. However, further studies are needed to determine whether these differences result in any clinical superiority of escitalopram compared with citalopram.

Like other SSRIs, escitalopram's antidepressant effect is believed to involve potentiation of serotonin activity in the CNS. Escitalopram appears to have little or no effect on reuptake of other neurotransmitters such as norepinephrine and dopamine. In vitro studies also have demonstrated that escitalopram possesses little or no affinity for α- or β-adrenergic, dopamine D_{1-5}, histamine H_{1-3}, GABA-benzodiazepine, muscarinic M_{1-5}, or 5-HT_{1-7} receptors or various ion channels (e.g., calcium, chloride, potassium, sodium channels).

Escitalopram is extensively metabolized, principally by the hepatic cytochrome P-450 (CYP) 2C19 and 3A4 isoenzymes. The principal metabolites are less potent inhibitors of serotonin reuptake, suggesting that the metabolites do not substantially contribute to the antidepressant activity of escitalopram.

Advice to Patients

Importance of providing copy of written patient information (medication guide) each time escitalopram is dispensed. Importance of advising patients to read the patient information before taking escitalopram and each time the prescription is refilled.

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Importance of informing patients of potential risk of serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions, particularly with concurrent use of escitalopram and 5-HT_1 receptor agonists (also called triptans), tramadol, tryptophan, other serotonergic agents, or antipsychotic agents. Importance of immediately contacting clinician if signs and symptoms of these syndromes develop (e.g., restlessness, hallucinations, loss of coordination, fast heart beat, increased body temperature, muscle stiffness, labile blood pressure, diarrhea, coma, nausea, vomiting, confusion).

Risk of psychomotor impairment; importance of exercising caution while operating hazardous machinery, including driving a motor vehicle, until the drug's effects on the individual are known.

Importance of patients being aware that withdrawal effects may occur when stopping escitalopram, especially with abrupt discontinuance of the drug.

Risks associated with concomitant use of escitalopram with alcohol or racemic citalopram.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs or herbal supplements, as well as any concomitant illnesses (e.g., bipolar disorder) or personal or family history of suicidality or bipolar disorder. Risk of bleeding associated with concomitant use of escitalopram with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of advising patients that, although they may notice improvement with escitalopram therapy within 1–4 weeks, they should continue therapy as directed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[r] (see Users Guide). **For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.**

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Fluoxetine Hydrochloride

■ Fluoxetine, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant.

Uses

Fluoxetine is used in the treatment of major depressive disorder, obsessive-compulsive disorder, premenstrual dysphoric disorder, and bulimia nervosa. In addition, fluoxetine has been used for the treatment of depression associated with bipolar disorder†; obesity†; anorexia nervosa†; panic disorder† with or without agoraphobia; myoclonus†; cataplexy†; alcohol dependence†; and premature ejaculation†.

■ **Major Depressive Disorder** Fluoxetine is used in the treatment of major depressive disorder. The efficacy of fluoxetine for long-term use (i.e., longer than 5–6 weeks) as an antidepressant has not been established by controlled studies, but the drug has been used in some patients for substantially longer periods (e.g., up to 4 years or longer) without apparent loss of clinical effect or increased toxicity. If fluoxetine is used for extended periods, the need for continued therapy should be reassessed periodically.

A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features), alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, see Drug Interactions: Tricyclic and Other Antidepressants, and see Drug Interactions: Lithium.)

Efficacy of fluoxetine for the management of major depression has been established principally in outpatient settings; the drug's antidepressant efficacy in hospital or institutional settings has not been adequately studied to date. Most patients evaluated in clinical studies with fluoxetine had major depressive episodes of at least moderate severity, had no evidence of bipolar disorder, and had experienced either single or recurrent episodes of depressive illness. Limited evidence suggests that mildly depressed patients may respond less well to fluoxetine than moderately depressed patients. There also is some evidence that patients with atypical depression (which usually is characterized by atypical signs and symptoms such as hypersomnia and hyperphagia), a history of poor response to prior antidepressant therapy, chronic depressive symptomatology with or without episodic worsening of depressive symptoms, a longer duration of depression in the current episode, and/or a younger age of onset of depression may be more likely to respond to fluoxetine than to tricyclic antidepressant therapy.

Considerations in Choosing Antidepressants A variety of antidepressant drugs are available for the treatment of major depressive disorder, including selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., desvenlafaxine, duloxetine, venlafaxine), tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine, tranylcypromine), and other antidepressants (e.g., bupropion, maprotiline, nefazodone, trazodone). Most clinical studies have shown that the antidepressant effect of usual dosages of fluoxetine in patients with moderate to severe depression is greater than that of placebo and comparable to that of usual dosages of tricyclic antidepressants, maprotiline, other selective serotonin-reuptake inhibitors (e.g., paroxetine, sertraline), and other antidepressants (e.g., trazodone). Fluoxetine appears to be

AHFS® DRUG INFORMATION

22 March 2010

Fluvoxamine Maleate

AHFS Class: Selective Serotonin-reuptake Inhibitors (28:16.04.20)

VA Class: CN609

Chemical Name: *O*-(2-aminoethyl)oxime 5-methoxy-1-(4-(trifluoromethyl)phenyl)-1-pentanone (*Z*)-2-butenedioate (1:1)

Molecular Formula: $C_{15}H_{21}F_3N_2O_2 \cdot C_4H_4O_4$

[Posted 11/17/2009] FDA notified healthcare professionals of new safety information concerning an interaction between clopidogrel (Plavix), an anti-clotting medication, and omeprazole (Prilosec/Prilosec OTC), a proton pump inhibitor (PPI) used to reduce stomach acid. New data show that when clopidogrel and omeprazole are taken together, the effectiveness of clopidogrel is reduced. Patients at risk for heart attacks or strokes who use clopidogrel to prevent blood clots will not get the full effect of this medicine if they are also taking omeprazole. Separating the dose of clopidogrel and omeprazole in time will not reduce this drug interaction.

Other drugs that are expected to have a similar effect and should be avoided in combination with clopidogrel include: cimetidine, fluconazole, ketoconazole, voriconazole, etravirine, felbamate, fluoxetine, fluvoxamine, and ticlopidine.

Recommendations for healthcare professionals are provided in the "Information for Healthcare Professionals" sheet. For more information visit the FDA website at: [Web] and [Web].

Introduction

Fluvoxamine maleate, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant.[1 7]

Uses

Pending revision, the material in this section should be considered in light of more recently available information in the MEDWATCH notification at the beginning of this monograph.

■ Obsessive-Compulsive Disorder

Fluvoxamine is used in the treatment of obsessive-compulsive disorder when obsessions or compulsions cause marked distress, are time-consuming, or interfere substantially with social or occupational functioning.[1 2 4 7 8 9 10 11 12 13 14] Efficacy of fluvoxamine for the management of obsessive-compulsive disorder has been established by controlled studies of 10 weeks' duration principally in outpatient settings.[1 2 14] In a limited number of clinical studies in patients with moderate to severe obsessive-compulsive disorder, fluvoxamine was more effective than placebo in reducing the severity of symptoms associated with this disorder.[1 2 4 7 8 9 10 12] In the studies used to establish efficacy, a positive clinical response (much or very much improved on the Clinical Global Impressions scale) occurred in 43 or 12% of patients receiving fluvoxamine or placebo, respectively.[1 2 14] In these studies, no age- or gender-related differences in efficacy were noted.[1] Results from a limited number of comparative studies suggest that fluvoxamine is as effective as clomipramine in the management of obsessive-compulsive disorder.[2 4 13] Like fluoxetine and clomipramine, fluvoxamine reduces but does not eliminate obsessions and compulsions.[1 2 4 7 12 14] Therapeutic response to fluvoxamine in patients with obsessive-compulsive disorder generally is evident within 2–3 weeks, but may not be maximal until several months after beginning therapy with the drug.[4 8 9 12 14] The efficacy of fluvoxamine for long-term use (i.e., longer than 10 weeks) has not been established in placebo-controlled studies,[1] but the drug has been used in some patients for prolonged periods (e.g., reportedly up to 8 years) without apparent loss of clinical effect.[4 14] If fluvoxamine is used for extended periods, the need for continued therapy should be reassessed periodically.[1]

As with other antidepressants, the possibility that fluvoxamine may precipitate hypomanic or manic attacks in patients with bipolar or other major affective disorders should be considered.[1 4 7 15 16]

■ Bulimia Nervosa

Fluvoxamine has been used in the treatment of bulimia nervosa†.[19 20] In one double-blind placebo-controlled study in patients with bulimia nervosa, maintenance therapy with fluvoxamine following an inpatient treatment program resulted in an attenuated relapse rate compared with treatment with placebo.[20] For further information on use of antidepressants in the treatment of bulimia nervosa, see Bulimia Nervosa under Uses: Eating Disorders, in Fluoxetine Hydrochloride 28:16.04.20.

Dosage and Administration

■ Administration

Pending revision, the material in this section should be considered in light of more recently available information in the MEDWATCH notification at the beginning of this monograph.

Fluvoxamine maleate is administered orally.[1 5] Dosages of 100 mg daily or less in adults or 50 mg or less in pediatric patients generally are given as a single daily dose at bedtime; higher dosages generally are given as 2 divided doses, either as equally divided doses or as unequal doses with the larger dose given at bedtime.[1 5] Since food does not appear to affect GI absorption of fluvoxamine maleate, the drug generally can be administered without regard to meals.[1 17]

Patients receiving fluvoxamine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment.[23 24 25] (See Suicidality Precautions under Dosage and Administration: Dosage.)

Fluvoxamine should *not* be used concomitantly with thioridazine.[1 22 26] In addition, fluvoxamine should *not* be used concurrently with alosetron, astemizole (no longer commercially available in the US), cisapride, pimozide, terfenadine (no longer commercially available in the US), or tizanidine.[1 34 35 36 42] For additional information on potentially serious drug interactions that may occur between selective serotonin-reuptake inhibitors such as fluvoxamine and these agents, see Drug Interactions in Fluoxetine Hydrochloride 28:16.04.20.

Risk of Serotonin Syndrome

The development of potentially life-threatening serotonin syndrome may occur with fluvoxamine therapy, particularly during concomitant administration of other serotonergic drugs such as other selective serotonin-reuptake inhibitors (SSRIs), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs), selective serotonin (5-hydroxytryptamine; 5-HT) type 1 agonists used as antimigraine agents (also called triptans), drugs that impair the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), tramadol, or tryptophan (a serotonin precursor) supplements.[1 43 44] Therefore, patients should be cautioned about the potential risk of serotonin syndrome when fluvoxamine is given concurrently with other serotonergic agents.[43] Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea).[43 44]

Serious (sometimes fatal) adverse reactions, possibly related to serotonin syndrome, have been reported in patients who received an MAO inhibitor during or after SSRI therapy.[1 44] Therefore, concomitant use of fluvoxamine and MAO inhibitors is contraindicated, and it is recommended that at least 2 weeks elapse between discontinuance of an MAO inhibitor and initiation of fluvoxamine and vice versa.[1 22]

If concurrent therapy with fluvoxamine and an SSRI, SNRI, or 5-HT_1 receptors agonist ("triptan") is clinically warranted, careful observation of the patient is recommended, particularly during treatment initiation, increases in dosage, or following the addition of another serotonergic drug.[42 43] In addition, clinicians should assess the potential risks and benefits of concurrent therapy with fluvoxamine and triptans prior to prescribing these drugs concurrently.[43] Concurrent use of SSRIs with serotonin precursors (such as tryptophan supplements) is not recommended.[44] For additional information on serotonin syndrome, see Drug Interactions: Drugs Associated with Serotonin Syndrome, in the Monoamine Oxidase Inhibitors General Statement 28:16.04.12 and see Drug Interactions: Drugs Associated with Serotonin Syndrome, in Fluoxetine Hydrochloride 28:16.04.20.

■ Dosage

Pending revision, the material in this section should be considered in light of more recently available information in the MEDWATCH notification at the beginning of this monograph.

Obsessive-Compulsive Disorder

Adult Dosage. For the management of obsessive-compulsive disorder in adults, the recommended initial dosage of fluvoxamine maleate is 50 mg at bedtime.[1] Based on the tolerance and clinical response of the patient, dosage may be increased by increments of 50 mg daily at intervals of 4–7 days up to a maximum of 300 mg daily.[1] Because fluvoxamine clearance may be reduced in geriatric patients and/or such patients may have increased sensitivity to the adverse effects of CNS-active drugs, fluvoxamine maleate therapy may be initiated with a lower dosage (i.e., 25 mg daily)[19] and subsequent dosage adjustments made.[1] While a relationship between dosage and therapeutic effect in obsessive-compulsive disorder has not been established, efficacy of fluvoxamine maleate was demonstrated in clinical trials employing 100–300 mg daily.[1] Although the optimum duration of fluvoxamine therapy has not been established, obsessive-compulsive disorder may require several months of sustained drug therapy.[1] If therapy with the drug is prolonged, the lowest possible dosage should be employed and the need for continued therapy reassessed periodically.[1]

Pediatric Dosage. For the management of obsessive-compulsive disorder in pediatric patients 8–17 years of age, the recommended initial dosage of fluvoxamine maleate is 25 mg at bedtime.[1] This dosage may be increased in increments of 25 mg every 4–7 days, as tolerated, until maximum therapeutic benefit is achieved.[1] In one clinical study, dosages for pediatric patients 8–17 years of age were titrated within a range of 50–200 mg daily.[1 21] However, in a multiple-dose, pharmacokinetic study, steady-state plasma fluvoxamine concentrations were found to be twofold to threefold higher in children 6–11 years of age than in adolescents 12–17 years of age, and the area under the plasma concentration-time curve (AUC) and peak plasma concentrations were 1.5-2.7 times higher in children than in adolescents.[1 37] Both children and adolescents exhibited nonlinear pharmacokinetics, and female children exhibited higher AUC values and peak plasma concentrations compared with male children.[1 37] Steady-state plasma concentrations were similar in adults and adolescents receiving 300 mg of fluvoxamine daily, suggesting that fluvoxamine exposure was similar in these two groups.[1 37] Clinicians should consider both age and gender differences when selecting a fluvoxamine dosage in pediatric patients.[1 37] The maximum dosage of fluvoxamine in children up to 11 years of age should not exceed 200 mg daily, and therapeutic effects of the drug in female children may be achieved with a lower dosage than in male children.[1 37] In adolescents, fluvoxamine dosage adjustment up to the maximum daily dosage of 300 mg daily used in adults may be necessary to achieve optimal therapeutic benefit.[1 37]

The optimum duration of fluvoxamine therapy in pediatric patients has not been established.[22] If therapy with the drug is prolonged (i.e., longer than 10 weeks), the lowest possible dosage should be employed and the need for continued therapy reassessed periodically.[22] (See Pediatric Precautions under Dosage and Administration: Dosage.)

Suicidality Precautions. Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Pediatric Precautions under Dosage and Administration: Dosage) patients with major depressive disorder or other psychiatric disorders, whether or not they

are taking antidepressants.[23 24 25 45] This risk may persist until clinically important remission occurs.[23] Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide.[23 24 25] However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment.[23] Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders.[23 24] An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age, and a reduced risk was observed in adults 65 years of age or older.[23 24]

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly duringinitiation of therapy (i.e., the first few months) and during periods of dosage adjustments.[23 24 25] Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior, as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.[23 25 47]

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality.[1 23 25] Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms.[23] If a decision is made to discontinue therapy, fluvoxamine dosage should be tapered as rapidly as is feasible but with recognition of the risks of abrupt discontinuance.[23] FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.[23]

Bipolar Disorder Precautions. It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder.[23] Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).[23] Fluvoxamine is *not* approved for use in treating bipolar depression.[23]

Pediatric Precautions. Safety and efficacy of fluvoxamine for the treatment of obsessive-compulsive disorder in children younger than 8 years of age have not been established.[22] In addition, the safety and efficacy of fluvoxamine in the management of pediatric patients with conditions other than obsessive-compulsive disorder have not been established.[1]

The safety and efficacy of fluvoxamine in pediatric patients with obsessive-compulsive disorder were established in a 10-week, placebo-controlled trial in children and adolescents 8–17 years of age.[1 21] The majority of these patients continued receiving fluvoxamine therapy for up to 1–3 years longer in an open-label extension of the initial study.[1] Adverse effects generally were similar to those reported in adults.[1 21] Agitation, depression, dysmenorrhea, flatulence, hyperkinesia, and rash were reported in at least 5% of the pediatric patients and with an incidence at least twice that reported with placebo.[1] In addition, abnormal thinking, increased cough, ecchymosis, emotional lability, epistaxis, hyperkinesia, infection, manic reaction, rash, sinusitis, and weight loss were reported in 2 or more of the 57 pediatric patients receiving fluvoxamine and more frequently than among the patients receiving placebo.[1]

The risks, if any, that may be associated with extended use of fluvoxamine in children and adolescents with obsessive-compulsive disorder have not been systematically evaluated.[1] The evidence relied upon to conclude that fluvoxamine is safe for use in children and adolescents was derived from relatively short-term clinical studies and from extrapolation of experience gained with adult patients.[1] In addition, the effects of long-term fluvoxamine use on the growth, development, and maturation of children and adolescents have not been established.[1] Regular monitoring of weight and growth is recommended if treatment of a child with an SSRI is to be continued long term.[1]

FDA has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders.[23 24] However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide.[23 25 45] (See Cautions: Pediatric Precautions, in Fluoxetine Hydrochloride 28:16.04.20.) Anyone considering the use of fluvoxamine in a child or adolescent for any clinical use must therefore balance the potential risks with the clinical need.[23 25] (See Suicidality Precautions under Dosage and Administration: Dosage.)

For further information on use of SSRIs in the treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant agent for a particular patient, see Uses: Major Depressive Disorder, in Fluoxetine Hydrochloride 28:16.04.20.

Other Considerations

Pending revision, the material in this section should be considered in light of more recently available information in the MEDWATCH notification at the beginning of this monograph.

Concomitant use of fluvoxamine is contraindicated in patients receiving astemizole (no longer commercially available in the US), cisapride, pimozide, or terfenadine (no longer commercially available in the US), since fluvoxamine may inhibit metabolism of these drugs and increase the potential for serious adverse cardiac effects.[1]

Since mean AUCs of alosetron were increased approximately sixfold and the elimination half-life was increased approximately

threefold during concurrent fluvoxamine administration in one pharmacokinetic study, concurrent use of these drugs is contraindicated.[1 34]

In a limited number of male patients with schizophrenia, concomitant use of thioridazine and low-dosage fluvoxamine (25 mg twice daily for 1 week) resulted in a threefold increase in plasma concentrations of thioridazine and its two active metabolites (mesoridazine and sulforidazine).[1 26] Thioridazine produces a dose-related prolongation of the QT_C interval, which is associated with serious ventricular arrhythmias (e.g., torsades de pointes) and sudden death. [1] The possible effects of combining higher dosages of thioridazine and/or fluvoxamine are not yet known, but may be even more pronounced. [1] Therefore, concurrent administration of fluvoxamine and thioridazine is contraindicated.[1]

In a limited number of healthy individuals, concurrent administration of fluvoxamine (100 mg daily for 4 days) and tizanidine (single 4-mg dose) resulted in a 12-fold increase in peak plasma tizanidine concentrations, a threefold increase in elimination half-life of tizanidine, and a 33-fold increase in the AUC of tizanidine.[1 35 42] The mean cardiovascular effects observed in this study were a decrease in systolic blood pressure of 35 mm Hg, a decrease in diastolic blood pressure of 20 mm Hg, and a decrease in heart rate of 4 beats/minute.[1 35] In addition, drowsiness was substantially increased and psychomotor performance was substantially impaired during concurrent therapy.[1 35] Since fluvoxamine has been shown to markedly affect the pharmacokinetics of tizanidine and to increase the risk of adverse cardiovascular (including substantial hypotension) and CNS (e.g., drowsiness, psychomotor impairment) effects associated with tizanidine use,[1 35 42] concomitant use of tizanidine and fluvoxamine is contraindicated.[1 35 36 42]

Caution should be exercised if fluvoxamine is used concomitantly with benzodiazepines that are metabolized by hepatic oxidation (e.g., alprazolam, midazolam, triazolam).[1] Concomitant use of diazepam and fluvoxamine generally should be avoided.[1] The clearance of diazepam was reduced by 65% and that of its active metabolite *N*-desmethyldiazepam could not be determined during concomitant administration with fluvoxamine in one study.[1] Concomitant use of fluvoxamine (100 mg daily) and alprazolam (1 mg 4 times daily) resulted in plasma alprazolam concentrations that were approximately twice those observed when alprazolam was administered alone.[1] The initial dosage of alprazolam should be reduced by at least 50% if the drugs are administered concomitantly, with subsequent alprazolam dosages titrated to the lowest effective dosage; modification of fluvoxamine maleate is not necessary.[1] The clearance of benzodiazepines that are metabolized by glucuronidation (e.g., lorazepam, oxazepam, temazepam) is unlikely to be affected by fluvoxamine.[1]

Fluvoxamine (50 mg twice daily for 7 days) reduced the clearance of mexiletine (administered as a single dose of 200 mg) by 38% in a limited number of healthy Japanese males in one pharmacokinetic study.[1 38] Pending further accumulation of data, close patient monitoring and monitoring of serum mexiletine concentrations are recommended when fluvoxamine and mexiletine are given concurrently.[1 38]

Since fluvoxamine coadministration decreased theophylline clearance by approximately threefold, the theophylline dosage should be reduced to approximately one-third of the usual daily maintenance dosage and plasma theophylline concentrations should be monitored if the drugs are administered concomitantly.[1]

Epidemiologic case-control and cohort design studies that have demonstrated an association between selective serotonin-reuptake inhibitor therapy and an increased risk of upper GI bleeding also have shown that concurrent use of aspirin or other nonsteroidal anti-inflammatory agents substantially increases the risk of GI bleeding.[1 39 41] Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated.[1] The precise mechanism for this increased risk remains to be clearly established; however, serotonin release by platelets is known to play an important role in hemostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets, thereby decreasing the amount of serotonin in platelets.[1 40 41] Patients receiving fluvoxamine should be cautioned about the concomitant use of drugs that interfere with hemostasis, including aspirin and other nonsteroidal anti-inflammatory agents.[1]

Patients receiving fluvoxamine concomitantly with oral anticoagulants (e.g., warfarin) should have close monitoring of prothrombin times and adjustment of their anticoagulant dosage if indicated.[1] Prothrombin times were prolonged and plasma warfarin concentrations were increased when the drug was administered concomitantly with fluvoxamine.[1]

■ **Dosage in Renal and Hepatic Impairment**

Because patients with hepatic impairment have reduced fluvoxamine clearance, reduction of the initial dosage and modification of subsequent dosage titration may be appropriate; subsequent dosage adjustments generally should be made in smaller increments and at longer intervals in such patients.[1 19] Limited evidence indicates that dosage modification is not necessary in patients with renal impairment.[1 18 19]

■ **Treatment of Pregnant Women during the Third Trimester**

Some neonates exposed to fluvoxamine and other selective serotonin-reuptake inhibitors or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed complications, which have sometimes been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special-care nurseries.[1 27 28 29 30 31 32 33] Therefore, the clinician should carefully consider the potential risks and benefits of treating a pregnant woman with fluvoxamine during the third trimester of pregnancy.[1 28 29 30 33] In addition, consideration may be given to cautiously tapering fluvoxamine therapy in the third trimester prior to delivery if the drug is administered during pregnancy.[1 30] For additional information on use of selective serotonin-reuptake inhibitors during pregnancy, see Pregnancy, under Cautions: Pregnancy, Fertility, and Lactation, in Fluoxetine Hydrochloride 28:16.04.20.

Description

Fluvoxamine maleate, a selective serotonin-reuptake inhibitor (SSRI), is an aralkylketone-derivative antidepressant agent.[1 7] The drug differs structurally from other SSRIs (e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline) and also differs structurally from other currently available antidepressant agents (e.g., monoamine oxidase inhibitors, and tricyclic and tetracyclic antidepressants).[1 3 4 6 46] The exact mechanism of action of fluvoxamine has not been fully elucidated but appears to involve inhibition of reuptake of serotonin (5-hydroxytryptamine [5-HT]) at the presynaptic membrane.[1 3 4 8 9] Data from in vitro studies suggest that fluvoxamine is more potent than clomipramine, fluoxetine, and desipramine as a serotonin-reuptake inhibitor.[3 4 6 7] Although not clearly established, it has been suggested that the mechanism of action of fluvoxamine and other drugs (e.g., clomipramine, fluoxetine, sertraline) used in the management of obsessive compulsive disorder may be related to their

serotonergic activity.[1 2 7 9 47] Fluvoxamine appears to have little or no effect on reuptake of other neurotransmitters such as norepinephrine and dopamine.[3 4 6] In addition, the selectivity of fluvoxamine in inhibiting serotonin versus norepinephrine reuptake appears to be substantially greater than that of other SSRIs (e.g., fluoxetine, paroxetine, sertraline) and tricyclic antidepressants, including clomipramine.[3 4 6 9] In vitro studies have demonstrated that fluvoxamine possesses virtually no affinity for α_1- or α_2-adrenergic, β-adrenergic, muscarinic, dopamine D_2, histamine H_1, GABA-benzodiazepine, opiate, 5-HT_1, or 5-HT_2 receptors.[1 3 4 6]

AHFS® DRUG INFORMATION

21 March 2010

Thioridazine

Thioridazine Hydrochloride

AHFS Class: Phenothiazines (28:16.08.24)

VA Class: CN701

Make a selection below to quickly jump to a specific section.

Choose...

Introduction

Thioridazine is a phenothiazine antipsychotic agent. The drug is considered a conventional or first-generation antipsychotic agent.[100]

See Uses in the associated General Statement for more information.

Uses

■ Psychotic Disorders

Thioridazine is used for the symptomatic management of psychotic disorders. However, because thioridazine has the potential for substantial, and possibly life-threatening, proarrhythmic effects and can precipitate sudden death, use of the drug is reserved for patients with schizophrenia whose disease fails to respond adequately to appropriate courses with at least 2 different antipsychotic agents, either because of insufficient efficacy or the inability to achieve an effective dosage due to intolerable adverse effects. In addition, use of thioridazine in patients with refractory schizophrenia has not been evaluated in controlled clinical trials and efficacy of the drug in such patients is not known.

Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to improve symptoms between episodes and to minimize the risk of recurrent acute episodes. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia and generally are effective in all subtypes of the disorder and subgroups of patients. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile. For additional information on the symptomatic management of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ Other Uses

Thioridazine is used for the short-term treatment of adults with major depression who have varying degrees of associated anxiety, and for the symptomatic management of agitation, anxiety, depressed mood, tension, sleep disturbances, and fears in geriatric patients (see Cautions).

Thioridazine also has been used for the treatment of severe behavioral problems in children marked by combativeness and/or explosive hyperexcitable behavior (out of proportion to immediate provocations), and for the short-term treatment of hyperactive children who exhibit excessive motor activity with accompanying conduct disorders. However, the possible risks of developing tardive dyskinesia, withdrawal dyskinesia, and other extrapyramidal reactions associated with the drug should be considered. Some clinicians recommend routine administration of the Abnormal Involuntary Movement Scale (AIMS) to all children receiving antipsychotic agents for this indication.

See Dosage and Administration in the associated General Statement for more information.

Dosage and Administration

■ Administration

Thioridazine and thioridazine hydrochloride are administered orally. When thioridazine hydrochloride oral concentrate solution is used, the dose should be diluted (e.g., with water or fruit juice) just before administration.

■ Dosage

Dosage of thioridazine and thioridazine hydrochloride is expressed in terms of the hydrochloride salt. Dosage must be carefully adjusted according to individual requirements and response using the lowest possible effective dosage. Dosage should be increased more gradually in debilitated or geriatric patients.

Psychotic Disorders

For the symptomatic management of psychotic disorders, the usual initial adult dosage of thioridazine is 50–100 mg 3 times daily. Dosage may gradually be increased, depending on the patient's therapeutic response and tolerance. The manufacturer recommends that dosages greater than 300 mg daily be reserved for adults with severe neuropsychiatric conditions. Dosages up to 800 mg daily given in 2–4 divided doses may be required in hospitalized, institutionalized, or severely psychotic adults. Dosage during prolonged maintenance therapy with thioridazine should be kept at the lowest effective level; once an adequate response has been obtained, dosage should be gradually reduced and subsequently adjusted according to the patient's therapeutic response and tolerance. Because of the risk of adverse reactions associated with cumulative effects of phenothiazines, patients with a history of long-term therapy with thioridazine and/or other antipsychotic agents should be evaluated periodically to determine whether drug therapy could be discontinued.

For the management of hospitalized, severely disturbed, or psychotic children 2–12 years of age, the usual initial dosage of thioridazine is 0.5 mg/kg daily, administered in divided doses. Dosage may be gradually increased until optimum therapeutic effect is obtained. Dosage for children should not exceed 3 mg/kg daily.

Other Conditions

For the short-term treatment of adults with major depression who also have varying degrees of associated anxiety, or for the symptomatic management of agitation, anxiety, depressed mood, tension, sleep disturbances, and fears in geriatric patients (see Cautions), the usual initial dosage of thioridazine is 25 mg 3 times daily. Dosage ranges from 20–200 mg daily in these patients, depending on the severity of the condition.

See Cautions in the associated General Statement for more information.

Cautions

Thioridazine shares the toxic potentials of other phenothiazines, and the usual precautions of phenothiazine therapy should be observed. (See Cautions in the Phenothiazines General Statement 28:16.08.24.) At recommended dosages, adverse effects of thioridazine are generally mild and transient.

Geriatric patients with dementia-related psychosis treated with either conventional (first-generation) or atypical (second-generation) antipsychotic agents are at an increased risk of mortality.[101 102 103 104] For additional information on the use of antipsychotic agents for dementia-associated psychosis and other behavioral disturbances, see Geriatric Considerations under Psychotic Disorders: Schizophrenia and Other Psychotic Disorders, in Uses and see Cautions: Geriatric Precautions, in the Phenothiazines General Statement 28:16.08.24.

Care should be taken to avoid skin contact with thioridazine oral suspension or thioridazine hydrochloride oral concentrate solution, since contact dermatitis has occurred rarely.

Because a rubbery, orange substance was noticed in the stool of a patient who ingested chlorpromazine oral solution immediately after ingesting carbamazepine oral suspension, and subsequent testing has shown that mixing thioridazine oral liquid with carbamazepine oral suspension also results in a rubbery, orange precipitate, it has been recommended that thioridazine oral liquid not be administered simultaneously with carbamazepine oral suspension. It is not known whether the development of this precipitate results in decreased bioavailability of either thioridazine or carbamazepine.

■ Arrhythmias and Associated Precautions and Contraindications

Dose-related serious cardiac effects, including prolongation of the QT interval corrected for rate (QT_C), arrhythmias (e.g., atypical ventricular tachycardia [torsades de pointes]), and/or sudden death, have been reported in patients receiving thioridazine. A causal relationship to the drug has not been established; however, since thioridazine and its major metabolite mesoridazine have been shown to prolong the QT_C interval, such a relationship is possible. Although, thioridazine has been shown to prolong the QT_C interval in a dose-dependent manner, prolongation of the QT_C interval and sudden death have been reported occasionally at usual dosages. In a crossover study, healthy men receiving a single 50-mg dose of thioridazine hydrochloride had a greater increase in QT_C interval (mean maximum of about 23 msec) than those receiving either a 10-mg dose or placebo; however, the manufacturer states that even further prolongation of the QT_C interval may be observed in clinical practice.

The risk of atypical ventricular tachycardia (e.g., torsades de pointes) and/or sudden death may be increased in patients with bradycardia, hypokalemia, or congenital long QT syndrome and in those receiving thioridazine concomitantly with drugs that can prolong the QT_C interval. Use of antiarrhythmic agents (e.g., disopyramide, procainamide, quinidine) that can prolong the QT_C interval and potentially exacerbate the cardiotoxic effects of thioridazine should be avoided in treating arrhythmias associated with the antipsychotic agent. (See Acute Toxicity: Treatment.) In patients who experience symptoms of possible atypical ventricular tachycardia (torsades de pointes), such as dizziness, palpitations, or syncope, further cardiac evaluation (e.g., Holter monitoring) should be considered.

Cardiotoxic effects may be associated with increased plasma concentrations of thioridazine and its metabolites. Increased plasma concentrations of the drug are most likely to develop in patients with poor metabolizer phenotypes of the cytochrome P-450 (CYP) 2D6 isoenzyme; and in patients receiving drugs known to inhibit the CYP2D6 isoenzyme (e.g., fluoxetine, paroxetine) or reduce the clearance of thioridazine by other mechanisms (e.g., fluvoxamine, pindolol, propranolol).

Because thioridazine may be associated with serious adverse cardiac effects, ECG and serum potassium concentrations should be determined at baseline and periodically thereafter; such monitoring may be particularly useful during a period of dosage adjustment. Serum potassium concentrations should be within the normal range before thioridazine therapy is initiated; patients with a QT_C interval exceeding 450 msec should not receive thioridazine. Thioridazine should be discontinued if the QT_C interval exceeds 500 msec. Patients receiving thioridazine should be informed about the risk of developing adverse cardiac effects and the possibility of switching from thioridazine to another antipsychotic agent should be considered based on the possible risks and likely benefits associated with thioridazine.

Because thioridazine has been shown to be more cardiotoxic in overdosage than other antipsychotic agents, some clinicians caution against its use in actively suicidal patients.

Patients receiving of thioridazine concomitantly with drugs that prolong the QT_C interval, inhibit the CYP2D6 isoenzyme (e.g., fluoxetine, paroxetine), or reduce clearance of the phenothiazine by other mechanisms (e.g., fluvoxamine, pindolol, propranolol); those with poor metabolizer phenotypes of the CYP2D6 isoenzyme; and those with underlying conditions that might prolong the QT_C interval (e.g., congenital long QT syndrome, history of arrhythmias) may be at increased risk of developing cardiac arrhythmias (e.g., atypical ventricular tachycardia [torsades de pointes]) that may be fatal. Therefore, use of thioridazine in such patients is contraindicated.

Drug Interactions

■ Drugs Affecting Hepatic Microsomal Enzymes

Drugs that inhibit the cytochrome P-450 (CYP) 2D6 isoenzyme (e.g., fluoxetine, paroxetine) appear to inhibit the metabolism of the phenothiazine which has resulted in elevated plasma concentrations of the phenothiazine. Since thioridazine has been shown to prolong the QT interval corrected for rate (QT_C) in a dose-dependent manner, increased plasma concentrations of the drug may be expected to augment such prolongation and thus may increase the risk of serious, potentially fatal, cardiac arrhythmias (e.g., atypical ventricular tachycardia [torsades de pointes]). Therefore, concomitant use of thioridazine with drugs that inhibit the CYP2D6 isoenzyme is contraindicated.

■ Other Drugs that Reduce Clearance of Thioridazine

Fluvoxamine

In a limited number of male patients with schizophrenia, concomitant use of thioridazine and fluvoxamine (25 mg twice daily for 1 week) resulted in a threefold increase in steady-state plasma concentrations of thioridazine and its 2 active metabolites (mesoridazine and sulforidazine). Therefore, fluvoxamine and thioridazine should not be used concomitantly.

Propranolol

Concomitant use of propranolol (100–800 mg daily) and thioridazine reportedly resulted in increased plasma concentrations of thioridazine (approximately 50–400%) and its metabolites (approximately 80–300%). Therefore, propranolol and thioridazine should not be used concomitantly.

Pindolol

Concomitant use of pindolol and thioridazine has resulted in moderate, dose-related increases in serum concentrations of thioridazine and 2 of its metabolites in addition to higher than expected serum concentrations of pindolol. Therefore, pindolol and thioridazine should not be used concomitantly.

■ Drugs that Prolong QT_C Interval

Although specific drug interaction studies have not been performed to evaluate the concomitant use of thioridazine with drugs that prolong the QT_C interval, the manufacturers state that additive effects of such concomitant therapy on the QT_C interval can be expected. Therefore, concomitant use of thioridazine with these drugs is contraindicated.

See Lab Test Interferences in the associated General Statement for more information.

Acute Toxicity

■ Pathogenesis

Although the minimum toxic or lethal doses and blood concentrations of thioridazine remain to be definitely established, it has been suggested that blood thioridazine concentrations of 1 mg/dL or greater are toxic, and those of 2–8 mg/dL are potentially lethal.

■ Manifestations

Overdosage of phenothiazines (e.g., thioridazine) may be expected to produce effects that are extensions of common adverse effects. (See Acute Toxicity: Manifestations, in the Phenothiazines General Statement 28:16.08.24.) However, results of case reports and several studies suggest that overdosage of thioridazine may be associated with cardiotoxicity (e.g., prolongation of QT intervals and QRS complex) more frequently than other antipsychotic agents.

■ Treatment

Management of thioridazine overdosage generally involves symptomatic and supportive care with cardiovascular (e.g., ECG) monitoring. A patent airway must be established and maintained, and adequate oxygenation and ventilation must be ensured.

Following acute ingestion of thioridazine, gastric lavage and repeated doses of activated charcoal should be considered. Induction of emesis is less preferable to gastric lavage because of the risk of dystonia and the potential for aspiration of vomitus. In addition, emesis should not be induced in patients expected to deteriorate rapidly or in those with impaired consciousness.

To detect arrhythmias, continuous ECG monitoring may be necessary for at least 24 hours or for as long as the QT_C is prolonged. Management of thioridazine-induced arrhythmias may include ventricular pacing, defibrillation, administration of IV magnesium sulfate, lidocaine, phenytoin, or isoproterenol and correction of electrolyte abnormalities and/or acid-base balance. Lidocaine must be administered with caution in patients with overdosage of thioridazine since use of this antiarrhythmic in such patients may increase the risk of developing seizures. Antiarrhthmic agents that can prolong the QT interval (e.g., class IA [disopyramide, procainamide, quinidine] or III agents) should be *avoided* in treating overdosage-associated arrhthmias in which prolongation of the QT_C is a manifestation. For additional information on treatment of acute toxicity, see Acute Toxicity: Treatment, in the Phenothiazines General Statement 28:16.08.24.

See Pharmacology in the associated General Statement for more information.

Pharmacology

The principal pharmacologic effects of thioridazine are similar to those of chlorpromazine. On a weight basis, thioridazine is about as potent as chlorpromazine. Thioridazine has strong anticholinergic and sedative effects and weak extrapyramidal effects. Thioridazine has little antiemetic activity.

See Pharmacokinetics in the associated General Statement for more information.

See Chemistry and Stability in the associated General Statement for more information.

Chemistry and Stability

■ Chemistry

Thioridazine is a phenothiazine antipsychotic agent. The drug is an alkylpiperidine derivative of phenothiazine which differs structurally from other phenothiazine derivatives in the presence of a thiomethyl group at the 2 position of the phenothiazine nucleus. Thioridazine is commercially available as the base and as the hydrochloride salt. Each 110 mg of thioridazine hydrochloride is approximately equivalent to 100 mg of thioridazine.

Thioridazine occurs as a white or slightly yellow, crystalline or micronized powder, which is odorless or has a faint odor and is practically insoluble in water and freely soluble in dehydrated alcohol. Thioridazine hydrochloride occurs as a white to slightly yellow, granular powder with a faint odor and a very bitter taste, and is freely soluble in water.

■ Stability

Commercially available thioridazine hydrochloride oral concentrate solution should be stored in tight, light-resistant containers at a temperature less than 30°C, preferably between 15–30°C; freezing should be avoided. Thioridazine hydrochloride tablets should be protected from light and stored in well-closed containers at a temperature less than 40°C, preferably at 15–30°C.

Testing has shown that mixing thioridazine oral liquid with carbamazepine oral suspension results in a rubbery, orange precipitate. (See Cautions.) It is not known whether the development of this precipitate results in decreased bioavailability of either thioridazine or carbamazepine. Therefore, it is recommended that thioridazine oral liquid not be administered simultaneously with carbamazepine oral suspension.

For further information on chemistry and stability, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of thioridazine, see the Phenothiazines General Statement 28:16.08.24.

clinician of any unusual behavioral changes. Patients, family members, and caregivers also should be advised not to make any changes to the anticonvulsant regimen without first consulting with the responsible clinician. They should pay close attention to any day-to-day changes in mood, behavior, and actions; since changes can happen very quickly, it is important to be alert to any sudden differences. In addition, patients, family members, and caregivers should be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). If these or any new and worrisome behaviors occur, the responsible clinician should be contacted immediately. FDA also recommends that clinicians who prescribe felbamate or any other anticonvulsant balance the risk for suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician must consider whether the emergence of these symptoms in any given patient may be related to the illness being treated.

Because steady-state plasma concentrations of concomitantly administered anticonvulsants may be altered in patients receiving combination therapy including felbamate, monitoring of plasma concentrations of other anticonvulsant agents and appropriate adjustment of felbamate and/or other anticonvulsant dosage may be necessary during concomitant therapy; the value of monitoring plasma concentrations of felbamate has not been established. Specialized references and the manufacturer's labeling should be consulted for specific recommendations. Although clinical trials indicate that routine monitoring of laboratory parameters is not necessary for safe use of felbamate, clinicians should exercise clinical judgment regarding monitoring of laboratory parameters during therapy with the drug.

Patients receiving felbamate should be instructed to take the drug only as prescribed and to store the drug in its tightly closed container at room temperature away from excessive heat, direct sunlight, moisture, and children.

Because of the possibility of increasing seizure frequency, anticonvulsant drugs, including felbamate, should not be discontinued suddenly.

Felbamate is contraindicated in patients with known hypersensitivity to the drug or any ingredient in the formulation. The drug also is contraindicated in patients who have demonstrated hypersensitivity reactions to other carbamates. Felbamate should not be used in patients with a history of any blood dyscrasia or hepatic dysfunction.

■ **Pediatric Precautions** Felbamate is indicated as adjunctive therapy for the treatment of partial and generalized seizures associated with Lennox-Gastaut syndrome in children 2–14 years of age; safety and efficacy of the drug for this indication in children younger than 2 years of age have not been established. Safety and efficacy of felbamate for other indications in children have not been established.

■ **Geriatric Precautions** Safety and efficacy of felbamate in geriatric patients have not been evaluated systematically, and clinical trials did not include sufficient numbers of patients older than 65 years of age to determine whether they respond differently than younger patients. Other clinical experience has not identified any differences in responses between geriatric and younger patients. If felbamate is used in geriatric patients, the initial dosage usually should be at the low end of the dosage range and caution should be exercised since renal, hepatic, and cardiovascular dysfunction and concomitant disease or other drug therapy are more common in this age group than in younger patients.

■ **Mutagenicity and Carcinogenicity** No evidence of mutagenicity was demonstrated by felbamate in the Ames *Salmonella* microbial mutagen test, the CHO/HGPRT mammalian cell forward gene mutation assay, the sister chromatid exchange assay in CHO cells, or bone marrow cytogenetics assay.

Studies to determine the carcinogenic potential of felbamate were performed in mice and rats. Mice received felbamate orally in dosages of 300, 600, and 1200 mg/kg daily for 92 weeks, while male rats received the drug orally in dosages of 30, 100, and 300 mg/kg and female rats received 10, 30, and 100 mg/kg daily for 104 weeks. The maximum dosages used in these studies produced steady-state plasma felbamate concentrations that were equal to or less than the steady-state plasma concentrations in patients with epilepsy receiving 3600 mg of the drug daily. There was an increase in hepatic cell adenomas in male and female mice receiving the high dosages as well as in female rats receiving the high dosages. Hepatic hypertrophy also was increased in a dose-related manner in mice, principally in males, but also in females. Hepatic hypertrophy was not found in female rats. The relationship between the occurrence of benign hepatocellular adenomas and the finding of liver hypertrophy resulting from hepatic enzyme induction has not been evaluated. There also was an increase in benign interstitial cell tumors of the testes in male rats receiving high dosages of felbamate. The relevance of these findings to humans is not known.

As a result of the synthetic process involved in producing felbamate, the drug could contain small amounts of two known animal carcinogens, the genotoxic compound ethyl carbamate (urethane) and the nongenotoxic compound methyl carbamate. Theoretically, it is possible that a 50-kg patient receiving 3600 mg of felbamate could be exposed to up to 0.72 mcg of urethane and 1800 mcg of methyl carbamate. These daily doses of urethane and methyl carbamate are approximately 1/35,000 and 1/5500, respectively, on a mg/kg basis (1/10,000 and 1/1600, respectively, on a mg/m² basis) of the dose levels shown to be carcinogenic in rodents. Any presence of these two compounds in felbamate used in the lifetime carcinogenicity studies was inadequate to cause tumors.

■ **Pregnancy, Fertility, and Lactation** Reproduction studies in rats and rabbits receiving felbamate doses of up to 13.9 and 4.2 times, respectively, the human daily dose of the drug on mg/kg basis (3 and less than 2 times, respectively, the human daily dose on a mg/m² basis) did not reveal evidence of teratogenicity; however, in rats, there was a decrease in pup weight and an increase in pup deaths during lactation. The cause of these deaths is not known. The dose at which there was no effect on rat pup mortality was 6.9 times the human dose on a mg/kg basis (1.5 times the human dose on a mg/m² basis). Felbamate crosses the placenta in rats. There are, however, no adequate and controlled studies to date using the drug in pregnant women, and the effect of felbamate on labor and delivery in humans also is not known. Placental disorder, fetal death, microcephaly, genital malformation, and sudden infant death syndrome (SIDS) have been reported with felbamate, usually when used as adjunctive therapy; however, a causal relationship to the drug has not been established. Felbamate should be used during pregnancy only when clearly needed.

Reproduction studies in rats revealed no evidence of impaired fertility in males or females receiving oral felbamate dosages of up to 13.9 times the human total daily dosage of 3600 mg on a mg/kg basis (up to 3 times the human total daily dosage on a mg/m² basis).

Felbamate is distributed into milk. Since the potential effect in nursing infants is not known, felbamate should be used with caution in nursing women.

Description

Felbamate, a dicarbamate, is an anticonvulsant agent. Felbamate is structurally related to but pharmacologically distinct from meprobamate. Felbamate has a unique spectrum of activity compared with other currently available anticonvulsants.

The exact mechanism of action of felbamate is not known, but available data suggest that the drug increases seizure threshold and reduces seizure spread. A predominant effect on any particular cell process has not been demonstrated to date, but felbamate appears to exhibit a spectrum of anticonvulsant activity that is pharmacologically distinct from other currently available agents. In animals, felbamate protects against seizures induced by electrical stimulation, suggesting that it would be effective in the management of tonic-clonic (grand mal) seizures and partial seizures. In animals, felbamate also protects against seizures induced by pentylenetetrazol, indicating that it may be effective in the management of absence (petit mal) seizures. Felbamate also protects against seizures in animals induced by picrotoxin, glutamate, or *N*-methyl-D-aspartic acid; it does not protect against seizures induced by bicuculline or strychnine.

In vitro studies indicate that felbamate has weak inhibitory effects on binding at γ-aminobutyric acid (GABA) receptors and benzodiazepine receptors. The monocarbamate, *p*-hydroxy, and 2-hydroxy metabolites of felbamate appear to contribute little, if any, to the anticonvulsant action of the drug.

SumMon® (see Users Guide). **For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.**

Gabapentin

■ Gabapentin is an anticonvulsant structurally related to the inhibitory CNS neurotransmitter γ-aminobutyric acid (GABA).

Uses

■ **Seizure Disorders** Gabapentin is used in combination with other anticonvulsant agents in the management of partial seizures with or without secondary generalization in adults and children 12 years of age and older and in the management of partial seizures in children 3–12 years of age. Although the comparative efficacy of therapeutically effective dosages of gabapentin versus other anticonvulsants remains to be established, the anticonvulsant potential of

gabapentin has been established in studies in which gabapentin or placebo was administered as adjunctive therapy in adults and children older than 3 years of age with refractory partial seizures.

In several placebo-controlled clinical studies, gabapentin was effective in reducing seizure frequency, including that of secondarily generalized tonic-clonic seizures, in 17–26% of patients with partial seizures refractory to therapy with conventional anticonvulsant drugs (e.g., phenytoin, carbamazepine, phenobarbital, valproic acid). Patients in these studies had a history of at least 4 partial seizures (with or without secondary tonic-clonic generalization) per month despite optimum therapy with one or more anticonvulsants and were eligible for study entry if they continued to have at least 2–4 seizures per month during a 12-week baseline period while receiving their established anticonvulsant regimen. Efficacy of gabapentin in these studies was evaluated principally in terms of the percentage of patients with a reduction in seizure frequency of 50% or greater compared with baseline values (i.e., responder rate) and the change in seizure frequency associated with the addition of gabapentin or placebo to existing anticonvulsant treatment (i.e., response ratio, calculated as treatment seizure frequency minus baseline seizure frequency divided by the sum of the treatment and baseline seizure frequencies). Combined analysis of these response parameters in patients receiving various dosages of gabapentin (600, 900, 1200, or 1800 mg in 3 divided doses daily) or placebo indicated a dose-related reduction in the frequency of partial seizures with gabapentin, although a dose-response relationship was not consistently found in the individual studies. The efficacy of adjunctive therapy with gabapentin for the management of partial seizures does not appear to be affected by patient gender or age, although the influence of these characteristics on efficacy has not been studied systematically.

Gabapentin also is used in combination with other anticonvulsant agents in the management of partial seizures in children 3–12 years of age. Efficacy of gabapentin as adjunctive therapy in children 3–12 years of age with partial seizures was established in a multicenter randomized controlled trial. Response ratios were substantially better in patients receiving gabapentin 25–35 mg/kg daily compared with patients receiving placebo; for the same population, the responder rate for the drug (21%) was not substantially different from placebo (18%). Another study in children 1 month to 3 years of age reported no substantial difference in either the response ratio or responder rate for those receiving gabapentin compared with those receiving placebo.

Because addition of gabapentin to an existing anticonvulsant regimen does not appreciably alter steady-state plasma concentrations of concomitantly administered anticonvulsants, additional monitoring of plasma concentrations of anticonvulsant agents for adjustment of gabapentin and/or other anticonvulsant dosage generally is not necessary during such concomitant therapy; the value of monitoring plasma concentrations of gabapentin has not been established. Although clinical trials indicate that routine monitoring of laboratory parameters is not necessary for the safe use of gabapentin, clinicians should exercise clinical judgment regarding such monitoring during therapy with the drug.

■ **Neuropathic Pain** ***Postherpetic Neuralgia*** Gabapentin is used in the management of postherpetic neuralgia (PHN) in adults. In 2 placebo-controlled clinical studies in patients with postherpetic neuralgia, gabapentin was effective in relieving pain (based on an 11-point numeric rating scale) in patients who continued to experience pain for longer than 3 months after healing of the herpes zoster rash. In these studies, gabapentin dosage was titrated over the first 3 days of therapy to a maximum dosage of 900 mg daily and then was increased further over a period of 3–4 weeks in increments of 600 mg to 1.2 g daily at intervals of 3–7 days to the designated target dosage. In 1 study, 29% of patients receiving a target dosage of 3.6 g daily reported a reduction in pain of at least 50% compared with baseline; in the other study, the same level of pain relief (50% reduction) was achieved in 32 or 34% of patients receiving a target gabapentin dosage of 1.8 or 2.4 g daily, respectively.

Other Neuropathic Uses Gabapentin is used for the treatment of pain associated with diabetic neuropathy†. In an 8-week controlled clinical study in patients with diabetic neuropathy, gabapentin was more effective than placebo in improving pain (based on an 11-point numeric rating scale), sleep, and mood during weeks 2–8 of the study. Most patients in this study (67%) received gabapentin in dosages of 3.6 g daily. In addition, 2 comparative studies reported that gabapentin was at least as effective as amitriptyline in relieving pain associated with diabetic neuropathy. Analysis of data from randomized studies in patients with pain associated with diabetic neuropathy indicates that 40% of patients who received gabapentin for neuropathic pain obtained good pain relief.

Gabapentin also has been used with some evidence of benefit for the relief of chronic neurogenic pain† in a variety of conditions including trigeminal neuralgia†, pain and control of paroxysmal symptoms of multiple sclerosis†, complex regional pain syndromes† (CRPS), HIV-related peripheral neuropathy†, and neuropathic pain associated with cancer†. Limited evidence indicates that gabapentin is not effective for the management of acute pain. Gabapentin also has been used in the treatment of restless legs syndrome† (RLS). Additional study and experience are needed to further elucidate the precise role of gabapentin in the management of these conditions.

■ **Vasomotor Symptoms** Gabapentin has been used for the management of vasomotor symptoms† in women with breast cancer and in postmenopausal women. Therapy with the drug has improved both the frequency and severity of vasomotor symptoms (hot flushes [flashes]) in these women.

Most women receiving systemic antineoplastic therapy for breast cancer experience vasomotor symptoms, particularly those receiving tamoxifen therapy. In a randomized, double-blind, placebo-controlled study in 420 women with breast cancer (68–75% were receiving tamoxifen) who were experiencing 2 or more episodes of hot flushes daily, the percentage reductions in hot flush severity score at 4 and 8 weeks of treatment were 21 and 15%, respectively, for placebo; 33 and 31%, respectively, for gabapentin 300 mg daily (100 mg 3 times daily), and 49 and 46%, respectively, for gabapentin 900 mg daily (300 mg 3 times daily). Comparisons among treatment groups showed that only the 900-mg daily dosage was associated with a statistically significant reduction in hot flush frequency and severity. Whether higher dosages will provide further reductions in vasomotor symptoms remains to be determined. The role of gabapentin in managing vasomotor symptoms in women with breast cancer relative to other nonhormonal therapies (e.g., selective serotonin-reuptake inhibitors [SSRIs], selective serotonin- and norepinephrine-reuptake inhibitors [SNRIs]) remains to be determined. Well-designed, comparative studies are needed to establish optimum nonhormonal therapy, both in terms of efficacy and patient tolerance of adverse effects, in these women.

Because of the risks associated with hormone replacement therapy (HRT) for vasomotor symptoms in perimenopausal and postmenopausal women, alternative nonhormonal therapies are being investigated. In a randomized, double-blind, placebo-controlled study in 59 postmenopausal women who were experiencing 7 or more hot flushes daily, intent-to-treat analysis revealed that 12 weeks of gabapentin 900 mg daily (300 mg 3 times daily) was associated with a 45% reduction in hot flush frequency and a 54% reduction in composite hot flush score (frequency and severity). In a continuation open-label phase in which patients were permitted upward titration of dosage as needed to a maximum of 2.7 g daily (25% received 900 mg or less daily, 61% received 900 mg–1.8 g daily, 14% received 1.8–2.7 g daily), the associated reductions in hot flush frequency and composite score were 54 and 67%, respectively. The role of gabapentin therapy relative to other nonhormonal therapies (e.g., SSRIs, SNRIs) for postmenopausal vasomotor symptoms, both in terms of efficacy and safety, as well as the optimum dosage remain to be established.

Current evidence indicates that gabapentin is effective and well tolerated in the short-term treatment of vasomotor symptoms associated with breast cancer treatment and with menopause. The principal adverse effects associated with gabapentin therapy in women with vasomotor symptoms have been somnolence, fatigue, dizziness, and rash (with or without peripheral edema). Additional study and experience are needed to further elucidate the role of gabapentin relative to other nonhormonal therapies, and to establish longer-term (i.e., beyond 17 weeks) efficacy and safety.

The possible role of gabapentin in the management of vasomotor symptoms† associated with antiandrogenic therapy in men with prostate cancer remains to be established. Current evidence of efficacy is limited; well-designed, controlled studies are under way in this population.

Dosage and Administration

■ **Administration** Gabapentin is administered orally. The drug may be administered without regard to meals.

If Neurontin® film-coated scored tablets containing 600 or 800 mg of gabapentin are to be used in patients requiring a 300- or 400-mg dose, the tablets can be halved to allow administration of the appropriate dose. Patients should be instructed to take one-half tablet; the remaining half-tablet should be used for the next dose. Half-tablets that are not used within several days should be discarded.

Patients who are currently receiving or beginning therapy with gabapentin and/or any other anticonvulsant for any indication should be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. (See Suicidality under Cautions: Nervous System Effects and see Cautions: Precautions and Contraindications.)

■ **Dosage** ***Seizure Disorders*** Because of the possibility of increasing seizure frequency, anticonvulsant drugs, including gabapentin, should *not* be discontinued abruptly. (See Cautions: Precautions and Contraindications.) Discontinuance of gabapentin therapy and/or addition of an alternative anticonvulsant drug to therapy should be done gradually over a minimum of 1 week.

For adjunctive therapy in the management of partial seizures with or without secondary generalization in adults and children older than 12 years of age, the effective dosage of gabapentin is 900 mg to 1.8 g daily administered in 3 divided doses. Gabapentin therapy is initiated at a dosage of 300 mg 3 times daily.

If necessary, the dosage of gabapentin may be increased up to 1.8 g daily in 3 divided doses. Dosages up to 2.4 g daily have been tolerated well as adjunctive therapy by patients in long-term clinical studies, and a small number of patients have tolerated dosages of 3.6 g daily for short periods. With thrice-daily dosing, the interval between doses should not exceed 12 hours. It is not necessary to monitor plasma gabapentin concentrations to optimize therapy.

For adjunctive therapy in the management of partial seizures, the effective dosage of gabapentin in patients 5 years of age and older is 25–35 mg/kg daily administered in 3 divided doses; for patients 3 and 4 years of age, the effective dosage is 40 mg/kg daily administered in 3 divided doses. Gabapentin therapy in patients 3–12 years of age should be initiated at a dosage of 10–15 mg/kg per day in 3 divided doses. Dosages up to 50 mg/kg daily have been well tolerated by patients 3–12 years of age in a long-term clinical study. When

administered 3 times daily, the interval between doses should not exceed 12 hours.

If gabapentin is discontinued and/or an alternative anticonvulsant is added to the regimen, such changes in therapy should be done gradually over a period of at least 1 week.

Postherpetic Neuralgia For the management of postherpetic neuralgia in adults, the initial dosage regimen of gabapentin is 300 mg once daily on the first day, 300 mg twice daily on the second day, and 300 mg 3 times daily on the third day. Subsequently, the dosage may be increased as needed for relief of pain up to a total daily dosage of 1.8 g administered in 3 divided doses. In clinical studies evaluating gabapentin for the treatment of postherpetic neuralgia, dosages of the drug ranging from 1.8–3.6 g daily were effective, but there was no evidence that dosages exceeding 1.8 g daily provided any additional benefit.

Diabetic Neuropathy For the symptomatic treatment of diabetic neuropathy† in adults, gabapentin dosages of 900 mg to 3.6 g daily have been used; however, pain relief generally has been observed in patients receiving dosages exceeding 1.8 g daily.

Vasomotor Symptoms Although the optimum dosage remains to be established, a gabapentin dosage of 300 mg 3 times daily has been effective in reducing both the severity and frequency of vasomotor symptoms† in women with breast cancer and in postmenopausal women. Some clinicians recommend that therapy be initiated with a dosage of 300 mg once daily at bedtime. If needed, the dosage can be increased to 300 mg twice daily, and then to 300 mg 3 times daily, at 3- to 4-day intervals. A dosage of 100 mg 3 times daily appears to be no more effective than placebo, whereas dosages exceeding 900 mg daily (e.g., up to 2.7 g daily administered as 900 mg 3 times daily) may provide additional benefit in some women.

■ **Dosage in Renal Impairment** In adults and children 12 years of age and older with impaired renal function and/or undergoing hemodialysis, dosage and/or frequency of administration of gabapentin should be modified in response to the degree of renal impairment. Such patients with a creatinine clearance of 60 mL/minute or greater may receive 300 mg to 1.2 g of gabapentin 3 times daily (i.e., up to a total dosage of 3.6 g daily), and those with a creatinine clearance of 30–59 mL/minute may receive 200–700 mg of gabapentin twice daily (i.e., up to a total dosage of 1.4 g daily). Patients with a creatinine clearance of 15–29 mL/minute may receive 200–700 mg of gabapentin once daily, and those with a creatinine clearance of 15 mL/minute may receive 100–300 mg of gabapentin daily. In patients with a creatinine clearance of less than 15 mL/minute, dosage of gabapentin should be reduced proportionally (e.g., patients with a creatinine clearance of 7.5 mL/minute should receive one-half the dosage that patients with a creatinine clearance of 15 mL/minute should receive). Anephric patients may receive maintenance doses of gabapentin based on estimates of creatinine clearance, with supplemental doses of 125–350 mg of gabapentin given after each 4-hour hemodialysis session.

The use of gabapentin in children less than 12 years of age with impaired renal function has not been evaluated.

Cautions

Gabapentin generally is well tolerated, and adverse effects of the drug usually are mild to moderate in severity and may be self-limiting. Nervous system effects are the most frequently reported adverse affects of gabapentin and those most frequently requiring discontinuance of the drug. The most frequent adverse effects of gabapentin as adjunctive therapy in the treatment of partial seizures in adults and children 12 years of age and older are somnolence, dizziness, ataxia, fatigue, and nystagmus. Discontinuance of gabapentin because of adverse effects was required in 7% of adults and children 12 years of age and older receiving the drug as adjunctive therapy in the treatment of partial seizures in premarketing uncontrolled and controlled clinical trials; the adverse effects most frequently associated with discontinuance of gabapentin were somnolence (1.2% of patients), ataxia (0.8% of patients), fatigue (0.6% of patients), nausea and/or vomiting (0.6% of patients), and dizziness (0.6% of patients). The most frequent adverse effects of gabapentin as adjunctive therapy in the treatment of partial seizures in patients 3–12 years of age were viral infection, fever, nausea and/or vomiting, somnolence, and hostility. Discontinuance of gabapentin because of adverse effects was required in approximately 7% of patients 3–12 years of age in clinical trials; the adverse effects most frequently associated with discontinuance of gabapentin were emotional lability (1.6%), hostility (1.3%), and hyperkinesia (1.1%).

Because clinical trials of gabapentin therapy in the treatment of partial seizures involved specific patient populations and use of the drug as adjunctive therapy, it is difficult to determine whether a causal relationship exists for many reported adverse effects, to compare adverse effect frequencies with other clinical reports, and/or to extrapolate the adverse effect experience from controlled clinical trials to usual clinical practice.

In placebo-controlled studies, the adverse effects most frequently reported in adults receiving gabapentin for the management of postherpetic neuralgia were dizziness, somnolence, and peripheral edema. Discontinuance of gabapentin because of adverse effects was required in 16% of patients receiving the drug in 2 clinical trials; the adverse effects most frequently associated with discontinuance of gabapentin for the management of postherpetic neuralgia were dizziness, somnolence, and nausea.

■ **Nervous System Effects** Nervous system effects were among the most frequent adverse effects reported in patients with epilepsy receiving gabapentin as adjunctive therapy in controlled clinical trials in adults and children 12 years of age and older. Somnolence was the most frequent adverse nervous system effect, occurring in about 19% of those receiving gabapentin; the incidence and severity of somnolence appear to be dose related. Dizziness or ataxia was reported in about 17 or 12.5%, respectively, of patients receiving gabapentin as adjunctive therapy in controlled trials; the incidence and severity of ataxia also appear to be dose related. Fatigue reportedly occurred in about 11% of adults receiving gabapentin as adjunctive therapy in controlled trials. Nystagmus was reported in about 8%, tremor in about 7%, nervousness in 2.4%, dysarthria in 2.4%, amnesia in 2.2%, depression in 1.8%, abnormal thinking in 1.7%, twitching in 1.3%, and abnormal coordination in 1.1% of patients receiving gabapentin as adjunctive therapy in controlled trials. Other nervous system effects occurring in more than 1% of patients receiving gabapentin as adjunctive therapy, but with equal or greater frequency in patients receiving placebo, were headache, seizures, confusion, insomnia, and emotional lability.

Vertigo, hyperkinesia, paresthesia, decreased or absent reflexes, increased reflexes, anxiety, hostility, asthenia, or malaise was reported in at least 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. CNS tumors, syncope, abnormal dreaming, aphasia, hypoesthesia, intracranial hemorrhage, hypotonia, dysesthesia, paresis, dystonia, hemiplegia, facial paralysis, stupor, cerebellar dysfunction, positive Babinski sign, positive Romberg test, decreased position sense, subdural hematoma, apathy, hallucination, decrease or loss of libido, agitation, paranoia, depersonalization, euphoria, feeling high, doped-up sensation, psychosis, or migraine occurred in at least 0.1% but less than 1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Choreoathetosis, orofacial dyskinesia, encephalopathy, nerve palsy, personality disorder, increased libido, subdued temperament, apraxia, fine motor control disorder, meningismus, local myoclonus, hyperesthesia, hypokinesia, mania, neurosis, hysteria, antisocial reaction, strange feelings, or lassitude occurred in less than 0.1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Somnolence, hostility (including aggressive behavior), emotional lability, fatigue, hyperkinesia, and dizziness were reported in 8.4, 7.6, 4.2, 3.4, 2.5, and 2.5% of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Headache and convulsions were reported in more than 2% and equally or more frequently than among those receiving placebo in children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Somnambulism, aura disappeared, and occipital neuralgia were reported during controlled clinical trials in children 3–12 years of age, but were not reported in trials of adults receiving gabapentin. Thought disorders (e.g., concentration difficulty, change in school performance) have been reported in 1.7% of children 3–12 years of age receiving the drug.

Dizziness was reported in 28%, somnolence in 21.4%, asthenia in 5.7%, headache in 3.3%, ataxia in 3.3%, and abnormal thinking in 2.7% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials. Abnormal gait, incoordination, amnesia, and hypesthesia occurred in 1.2–1.5% of patients receiving the drug. Pain, tremor, and neuralgia were reported in greater than 1% of patients receiving gabapentin in clinical studies for the management of PHN but occurred with equal or greater frequency in patients receiving placebo.

Suicidality The US Food and Drug Administration (FDA) has analyzed suicidality reports from placebo-controlled studies involving 11 anticonvulsants, including gabapentin, and found that patients receiving anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%).

FDA's analysis included 199 randomized, placebo-controlled studies of 11 anticonvulsants (carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, and zonisamide) involving over 43,000 patients 5 years of age or older; the studies evaluated the effectiveness of the anticonvulsants in epilepsy, psychiatric disorders (e.g., bipolar disorder, depression, anxiety), and other conditions (e.g., migraine, neuropathic pain). The increased suicidality risk was observed as early as one week after beginning therapy and continued through 24 weeks. The results were generally consistent among the 11 drugs studied. In addition, patients who were treated for epilepsy, psychiatric disorders, and other conditions were all found to be at increased risk for suicidality when compared with placebo; there did not appear to be a specific demographic subgroup of patients to which the increased risk could be attributed. However, the relative risk for suicidality was found to be higher in patients with epilepsy compared with patients who were given one of the drugs for psychiatric or other conditions. (See Cautions: Precautions and Contraindications.)

In uncontrolled and controlled clinical trials, suicidal attempt occurred in at least 0.1% but less than 1% of patients receiving gabapentin as adjunctive therapy, and suicide occurred in less than 0.1% of patients receiving the drug as adjunctive therapy.

■ **GI Effects** Dyspepsia was the most frequent adverse GI effect in adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials, occurring in 2.2% of such patients. Dry mouth or throat occurred in 1.7%, constipation in 1.5%, dental abnormalities in 1.5%, and increased appetite in 1.1% of patients receiving the drug. Nausea and/or vomiting, abdominal pain, or diarrhea was reported in more than 1% of patients receiving gabapentin as adjunctive therapy in controlled clinical trials but occurred with equal or greater frequency in patients receiving placebo.

Anorexia, flatulence, or gingivitis was reported in at least 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Glossitis, gingival hemorrhage, thirst, stomatitis, increased salivation, taste loss, unusual taste, gastroenteritis, hemorrhoids, bloody stools, or fecal incontinence occurred in at least 0.1% but less than 1% of such patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Dysphagia, eructation, pancreatitis, peptic ulcer, colitis, blisters in mouth, tooth discolor, perléche, enlarged salivary gland, lip hemorrhage, esophagitis, hiatal hernia, hematemesis, proctitis, irritable bowel syndrome, rectal hemorrhage, or esophageal spasm was reported in less than 0.1% of adults and children 12 years of age or older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Nausea and/or vomiting was reported in 8.4% of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Diarrhea and anorexia were reported in more than 2% of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials.

Diarrhea was reported in 5.7%, dry mouth in 4.8%, constipation in 3.9%, nausea in 3.9%, and vomiting in 3.3% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials. Abdominal pain and flatulence occurred in 2.7 and 2.1%, respectively, of patients receiving the drug. Dyspepsia and dyspnea were reported in greater than 1% of patients receiving gabapentin in clinical studies of the management of PHN, but occurred with equal or greater frequency in patients receiving placebo.

■ **Cardiovascular Effects** Peripheral edema was reported in 1.7%, and vasodilation in 1.1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Hypertension occurred in more than 1% of patients receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials, and hypotension, angina pectoris, peripheral vascular disorder, palpitation, tachycardia, heart murmur, or generalized edema was reported in at least 0.1% but less than 1% of such patients. Atrial fibrillation, heart failure, thrombophlebitis, deep-vein thrombophlebitis, myocardial infarction, cerebrovascular accident, pulmonary thrombosis, ventricular extrasystole, bradycardia, atrial premature contraction, pericardial rub, heart block, pulmonary embolus, hyperlipidemia, hypercholesterolemia, pericardial effusion, or pericarditis occurred in less than 0.1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Peripheral edema was reported in 8.3% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials.

■ **Respiratory Effects** Rhinitis occurred in 4.1%, pharyngitis in 2.8%, and coughing in 1.8% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Pneumonia occurred in more than 1%; epistaxis, dyspnea, or apnea in at least 0.1% but less than 1%; and mucositis, aspiration pneumonia, hyperventilation, hiccup, laryngitis, nasal obstruction, snoring, bronchospasm, hypoventilation, or lung edema in less than 0.1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Bronchitis and respiratory infection were reported in 3.4 and 2.5%, respectively, of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Pharyngitis, upper respiratory infection, rhinitis, and coughing were reported in more than 2% of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Pseudocroup and hoarseness were reported during controlled clinical trials in children 3–12 years of age, but were not reported in trials in adults receiving gabapentin as adjunctive therapy.

Pharyngitis was reported in 1.2% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials.

■ **Ocular and Otic Effects** Diplopia was reported in 5.9%, and amblyopia in 4.2%, of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Abnormal vision was reported in more than 1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Cataract, conjunctivitis, dry eyes, ocular pain, visual field defect, photophobia, bilateral or unilateral ptosis, ocular hemorrhage, ocular twitching, or hordeolum (stye) occurred in at least 0.1% but less than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Ocular itching, abnormal accommodation, ocular focusing difficulty, watery eyes, retinopathy, glaucoma, iritis, corneal disorders, lacrimal dysfunction, degenerative ocular changes, blindness, retinal degeneration, miosis, chorioretinitis, or strabismus was reported in less than 0.1% of patients receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials.

Hearing loss, earache, tinnitus, inner ear infection, otitis, or otic fullness occurred in at least 0.1% but less than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Eustachian tube dysfunction, labyrinthitis, otitis externa, perforated eardrum, or sensitivity to noise was reported in less than 0.1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Otitis media was reported in more than 2% of children 3–12 years of age receiving gabapentin as adjunctive therapy in clinical studies.

Amblyopia occurred in 2.7%, and conjunctivitis, diplopia, and otitis media each occurred in 1.2% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials.

■ **Musculoskeletal Effects** Myalgia was reported in 2%, back pain in 1.8%, and fracture in 1.1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Arthralgia was reported in more than 1% of adults and children 12 years of age and older receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials, and tendinitis, arthritis, joint stiffness, or joint swelling occurred in at least 0.1% but less than 1% of such patients. Costochondritis, osteoporosis, bursitis, and contracture were reported in less than 0.1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Back pain was reported in greater than 1% of adults receiving gabapentin in clinical studies for the management of postherpetic neuralgia (PHN) but occurred with equal or greater frequency in patients receiving placebo.

■ **Endocrine Effects** Hyperthyroidism, hypothyroidism, goiter, hypoestrogenism, and cushingoid manifestations were reported in less than 0.1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled trials.

■ **Genitourinary Effects** Impotence was reported in 1.5% of patients receiving gabapentin as adjunctive therapy in controlled clinical trials. Hematuria, dysuria, cystitis, urinary frequency, urinary retention, urinary incontinence, vaginal hemorrhage, amenorrhea, dysmenorrhea, menorrhagia, breast cancer, inability to climax, and abnormal ejaculation occurred in at least 0.1% but less than 1% of patients receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials, and renal pain, renal lithiasis, acute renal failure, anuria, nephrosis, nocturia, pyuria, urinary urgency, leukorrhea, genital pruritus, vaginal pain, ovarian failure, testicular pain, epididymitis, and swollen testicle were reported in less than 0.1% of such patients.

■ **Dermatologic and Sensitivity Reactions** Pruritus or abrasion occurred in 1.3% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Rash or acne were reported in more than 1% of patients receiving the drug in controlled studies but occurred with equal or greater frequency with placebo.

Facial edema was reported in at least 1% of patients receiving gabapentin as adjunctive therapy in uncontrolled or controlled clinical trials. Allergy, alopecia, eczema, dry skin, increased sweating, urticaria, hirsutism, seborrhea, cysts, and herpes simplex occurred in at least 0.1% but less than 1% of patients receiving the drug as adjunctive therapy in uncontrolled and controlled trials. Herpes zoster, skin discoloration, skin papules, photosensitivity reaction, leg ulcer, scalp seborrhea, psoriasis, desquamation, maceration, skin nodule, subcutaneous nodule, melanosis, skin necrosis, or local swelling was reported in less than 0.1% of such patients.

Angioedema, erythema multiforme, and Stevens-Johnson syndrome have been reported during postmarketing experience with gabapentin; however, the manufacturers state that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to gabapentin.

Rash also was reported in 1.2% of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials.

■ **Hepatic Effects** Hepatomegaly occurred in at least 0.1% but less than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Elevated liver function test results and jaundice have been reported during postmarketing experience with gabapentin; however, the manufacturers state that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to gabapentin.

Hepatitis was reported during controlled clinical trials in children 3–12 years of age, but was not reported in trials in adults receiving gabapentin.

■ **Electrolyte and Metabolic Effects** A decrease in body weight occurred in at least 0.1% but less than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials; weight gain also has been reported. Glycosuria was reported in less than 0.1% of patients receiving the drug as adjunctive therapy in uncontrolled and controlled clinical trials.

Weight gain and hyperglycemia were reported in 1.8 and 1.2%, respectively, of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials.

Fluctuation in blood glucose concentrations and hyponatremia have been reported during postmarketing experience with gabapentin; however, the manufacturers state that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to gabapentin.

Weight increase was reported in 3.4% of children 3–12 years of age receiving gabapentin in controlled clinical trials.

■ **Hematologic Effects** Leukopenia was reported in 1.1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled clinical trials. Purpura (generally described as bruises resulting from physical trauma) was reported in at least 1% of patients receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Anemia, thrombocytopenia, or lymphadenopathy occurred in at least 0.1% but less than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials. Increased leukocyte count, lymphocytosis, non-Hodgkin's lymphoma, or increased bleeding time was reported in less than 0.1% of such patients.

Coagulation defect was reported during controlled clinical trials in children 3–12 years of age, but was not reported in trials in adults receiving gabapentin.

■ **Other Adverse Effects** Viral infection or fever occurred in more than 1% of adults and children 12 years of age and older receiving gabapentin as adjunctive therapy in controlled trials but was equally or more frequent with placebo. Odd smell occurred in less than 0.1% of patients receiving the drug in uncontrolled and controlled trials. Alcohol intolerance, hangover effect, or breast pain occurred in less than 0.1% of adults receiving gabapentin as adjunctive therapy in uncontrolled and controlled clinical trials.

Fever has been reported during postmarketing experience with gabapentin; however, the manufacturers state that data are insufficient to provide an estimate of the incidence of such effects or to establish a causal relationship to gabapentin.

Viral infection and fever were reported in 10.9 and 10.1%, respectively, of children 3–12 years of age receiving gabapentin as adjunctive therapy in controlled clinical trials. Dehydration and infectious mononucleosis were reported during controlled clinical trials in children 3–12 years of age, but were not reported in trials in adults receiving gabapentin as adjunctive therapy.

Infection and accidental injury were reported in 5.1 and 3.3%, respectively, of adults receiving gabapentin for the management of postherpetic neuralgia (PHN) in controlled clinical trials. Flu syndrome was reported in greater than 1% of patients receiving gabapentin for the management of PHN but occurred with equal or greater frequency in patients receiving placebo in clinical studies.

■ **Precautions and Contraindications** The US Food and Drug Administration (FDA) has informed healthcare professionals about an increased risk of suicidality (suicidal behavior or ideation) observed in an analysis of studies using various anticonvulsants, including gabapentin, compared with placebo. (See Suicidality under Cautions: Nervous System Effects.) Based on the current analysis of the available data, FDA recommends that all patients who are currently receiving or beginning therapy with any anticonvulsant for any indication be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. Symptoms such as anxiety, agitation, hostility, mania, and hypomania may be precursors to emerging suicidality. Clinicians should inform patients, their families, and caregivers of the potential for an increased risk of suicidality so that they are aware and able to notify their clinician of any unusual behavioral changes. Patients, family members, and caregivers also should be advised not to make any changes to the drug regimen without first consulting with the responsible clinician. They should pay close attention to any day-to-day changes in mood, behavior, and actions; since changes can happen very quickly, it is important to be alert to any sudden differences. In addition, patients, family members, and caregivers should be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). If these or any new and worrisome behaviors occur, the responsible clinician should be contacted immediately.

FDA recommends that clinicians who prescribe gabapentin or any other anticonvulsant balance the risk for suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician must consider whether the emergence of these symptoms in any given patient may be related to the illness being treated.

Because of the possibility of increased seizure frequency, anticonvulsant drugs, including gabapentin, should not be discontinued suddenly. In controlled studies, the incidence of status epilepticus was 0.6% in adults and children 12 years of age and older receiving gabapentin and 0.5% in those receiving placebo. In all (uncontrolled and controlled) clinical studies of gabapentin as adjunctive therapy in adults and children 12 years of age and older, the incidence of status epilepticus was 1.5%. Because adequate historical data are unavailable for comparison, it has not been established whether the incidence of status epilepticus in patients with epilepsy treated with gabapentin is higher or lower than would be expected in a similar population of patients not treated with the drug. Discontinuance of gabapentin and/or addition of an alternative anticonvulsant drug to existing therapy should be done gradually over a minimum of 1 week.

Adverse CNS events (emotional lability, hostility [including aggressive behaviors], thought disorders [including concentration problems and change in school performance], and hyperkinesia) have been reported in epileptic children 3–12 years of age. (See Cautions: Nervous System Effects.)

During the premarketing development of gabapentin, 8 sudden and unexplained deaths were reported among a cohort of 2203 patients with epilepsy (2103 patient-years of exposure). Although the rate of these deaths exceeds that expected to occur in a healthy (nonepileptic) population matched for age and gender, this rate was similar to that occurring in a similar population of epileptic patients not receiving gabapentin. This evidence suggests, but does not prove that the incidence of sudden, unexplained death observed with adjunctive gabapentin therapy may be reflective of the population itself rather than the effects of gabapentin.

Gabapentin can produce drowsiness and dizziness, and patients should be cautioned that the drug may impair their ability to perform hazardous activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle).

Concomitant use of morphine in patients receiving gabapentin may result in increased plasma concentrations of gabapentin. Patients experiencing symptoms of CNS depression such as somnolence may require a decrease in dosage of morphine or gabapentin.

Gabapentin is contraindicated in patients with known hypersensitivity to the drug or any ingredient in the formulation.

■ **Pediatric Precautions** Safety and efficacy of gabapentin as adjunctive therapy in the management of partial seizures in children younger than 3 years of age have not been established. Safety and efficacy of gabapentin in the management of postherpetic neuralgia also have not been established in children.

■ **Geriatric Precautions** Safety and efficacy of gabapentin in the management of partial seizures in geriatric patients have not been evaluated systematically, and clinical trials did not include sufficient numbers of patients 65 years of age and older to determine whether they respond differently than do younger patients. However, in clinical studies of the drug in patients ranging from 20–80 years of age, gabapentin plasma clearance, renal clearance, and renal clearance adjusted for body surface area declined with age. Although safety and efficacy of gabapentin in geriatric patients with postherpetic neuralgia have not been established specifically, 30% of the patients receiving the drug in clinical studies were 65–74 years of age and 50% were 75 years of age and older. In these studies, gabapentin appeared to be more effective for the management of postherpetic neuralgia in patients older than 75 years of age than in younger patients. The manufacturers state that the apparent greater efficacy in geriatric patients may be related to decreased renal function in this age group. Although adverse effects reported in older patients generally were similar to those reported in younger adults, the incidence of peripheral edema and ataxia appears to increase with age. If gabapentin is used in geriatric patients, the initial dosage may need to be reduced and caution should be exercised since renal, hepatic, and cardiovascular dysfunction and concomitant disease or other drug therapy are more common in this age group than in younger patients.

■ **Pregnancy, Fertility, and Lactation** ***Pregnancy*** Although there are no adequate and controlled studies to date in humans, gabapentin has been shown to be teratogenic in mice and rats. Delayed ossification of several bones in the skull, vertebrae, forelimbs, and hindlimbs occurred in mice, and hydroureter and hydronephrosis occurred in rat pups when gabapentin was administered prior to and during mating or during organogenesis in dosages 1–4 times or up to 1–5 times (on a mg/m^2 basis), respectively, the maximum human daily dosage of 3.6 g. The dosage at which these effects did not occur in mice was approximately half the human daily dosage on a mg/m^2 basis. The dosages (on a mg/m^2 basis) at which these effects did not occur in rat pups were those equal to the maximum human daily dosage (in a teratogenicity study) or approximately 3 times the maximum human daily dosage (in a fertility and general reproductive performance study). There also was an increased incidence of postimplantation fetal loss in rabbits receiving gabapentin dosages one-fourth to 8 times the maximum human daily dosage (on a mg/m^2 basis). Other than hydroureter and hydronephrosis, the etiologies of which are unclear, the incidence of malformations was not increased compared with controls in offspring of mice, rats, or rabbits given dosages up to 50 times (mice), 30 times (rats), or 25 times (rabbits) the human daily dosage on a mg/kg basis, or 4 times (mice), 5 times (rats), or 8 times (rabbits) the human daily dosage on a mg/m^2 basis. Gabapentin should be used during pregnancy only when the potential benefits justify the possible risks to the fetus.

Reproduction studies revealed no adverse effects on fertility or reproduction in rats receiving gabapentin dosages up to 5 times the maximum recommended human daily dosage on a mg/m^2 basis.

Lactation Gabapentin is distributed into milk following oral administration. Because of the potential for serious adverse reactions to gabapentin in nursing infants, the drug should be administered to nursing women only if the potential benefits justify the risk to the infant.

Description

Gabapentin is an anticonvulsant agent structurally related to the inhibitory CNS neurotransmitter γ-aminobutyric acid (GABA). Although gabapentin was developed as a structural analog of GABA that would penetrate the blood-brain barrier (unlike GABA) and mimic the action of GABA at inhibitory neuronal synapses, the drug has no direct GABA-mimetic action and its precise mechanism of action has not been elucidated.

Results of some studies in animals indicate that gabapentin protects against seizure and/or tonic extensions induced by the GABA antagonists picrotoxin and bicuculline or by GABA synthesis inhibitors (e.g., 3-mercaptopropionic acid, isonicotinic acid, semicarbazide). However, gabapentin does not appear to bind to GABA receptors nor affect GABA reuptake or metabolism and does not act as a precursor of GABA or of other substances active at GABA receptors. Gabapentin also has no affinity for binding sites on common neuroreceptors (e.g., benzodiazepine; glutamate; quisqualate; kainate; strychnine-insensitive or -sensitive glycine; α_1-, α_2-, or β-adrenergic; adenosine A_1 or A_2; cholinergic [muscarinic or nicotinic]; dopamine D_1 or D_2; histamine H_1; type 1 or 2 serotonergic [5-HT_1 or 5-HT_2]; opiate μ, δ, or κ) or ion channels (e.g., voltage-sensitive calcium channel sites labeled with nitrendipine or diltiazem, voltage-sensitive sodium channel sites labeled with batrachotoxinin A 20α-benzoate). Conflicting results have been reported in studies of gabapentin affinity for and activity at *N*-methyl-d-aspartic acid (NMDA) receptors. Although

in vitro studies have identified a novel gabapentin binding site in the neocortex and hippocampus of rat brain, additional studies are required to fully elucidate the identity and function of this binding site.

In animal test systems, gabapentin exhibits anticonvulsant activity similar to that of other commonly used anticonvulsant drugs. The drug protects against seizures induced in animals by electrical stimulation or pentylenetetrazole, suggesting that it may be effective in the management of tonic-clonic (grand mal) and partial seizures or absence (petit mal) seizures, respectively. However, available data in animals and humans are conflicting regarding the effect of gabapentin on EEG spike and wave activity associated with absence (petit mal) seizures. Gabapentin also prevents seizures in some animals with congenital epilepsy and protects against audiogenic tonic extensions and clonic seizures in mice.

Although the mechanism of action is unknown as yet, gabapentin also has demonstrated analgesic activity. In animals, gabapentin has been shown to prevent allodynia (pain-related behavior in response to normally innocuous stimuli) and hyperalgesia (exaggerated response to painful stimuli) in several models of neuropathic pain. Gabapentin also has been shown to decrease pain-related responses after peripheral inflammation in animals; however, the drug has not altered immediate pain-related behaviors. The clinical relevance of these findings is not known.

Gabapentin does not bind to plasma proteins, is not appreciably metabolized, does not induce hepatic enzyme activity, and does not appear to alter the pharmacokinetics of commonly used anticonvulsant drugs (e.g., carbamazepine, phenytoin, valproate, phenobarbital, diazepam) or oral contraceptives. In addition, the pharmacokinetics of gabapentin are not altered substantially by concomitant administration of other anticonvulsant drugs.

Children younger than 5 years of age have a higher clearance of gabapentin normalized for weight compared with those 5 years of age and older; clearance of the drug in children 5 years of age and older is consistent with that in adults after a single dose. Therefore, a higher daily dosage is required in children 3–5 years of age to achieve average plasma concentrations similar to those in patients 5 years of age and older. (See Dosage and Administration: Dosage.) Infants younger than 1 year of age have a highly variable clearance.

SumMon‡ (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Lamotrigine

■ Lamotrigine is a phenyltriazine anticonvulsant.

Uses

■ **Seizure Disorders** ***Partial Seizures*** Lamotrigine is used in combination with other anticonvulsant agents in the management of partial seizures in adults and children. Lamotrigine also is used as monotherapy in patients converting from monotherapy with a hepatic enzyme-inducing anticonvulsant agent (e.g., phenytoin, carbamazepine, phenobarbital, primidone) in the management of partial seizures in adults.

In controlled clinical studies, adjunctive therapy with lamotrigine was effective in reducing seizure frequency in patients with simple and/or complex partial seizures refractory to therapy with one or more conventional anticonvulsant drugs (e.g., phenytoin, carbamazepine, phenobarbital); the median reduction in seizure frequency was 24–36%. In a controlled clinical study in children 2–16 years of age with partial seizures, the median reduction in frequency of all partial seizures was 36 or 7% in patients receiving lamotrigine or placebo, respectively, in addition to their current therapy (up to 2 conventional anticonvulsant drugs).

The effectiveness of lamotrigine monotherapy in adults with partial seizures who are converting from monotherapy with a hepatic enzyme-inducing anticonvulsant drug (e.g., phenytoin, carbamazepine, phenobarbital, primidone) was established in a controlled clinical study of patients who experienced at least 4 simple or complex partial seizures, with or without secondary generalization, during each of 2 consecutive 4-week baseline periods; during the baseline periods, patients were receiving either phenytoin or carbamazepine monotherapy. Patients were randomized either to lamotrigine (target dose: 500 mg daily) or valproic acid (1000 mg daily) therapy, which was added to their baseline regimen over a 4-week period. Patients were then converted to either lamotrigine or valproic acid monotherapy over another 4-week period and monotherapy continued for another 12-week period. Study end points were either successful completion of the 12-week monotherapy period or meeting a study "escape" criterion, relative to baseline. Escape criteria were defined as doubling of the mean monthly seizure count; doubling of the highest consecutive 2-day seizure frequency; emergence of a new seizure type (defined as a seizure that did not occur during the 8-week baseline period) that was more severe than the other seizure types occurring during the study period; or clinically important prolongation of generalized tonic-clonic seizures. The proportion of lamotrigine- or valproic acid-treated patients meeting escape criteria was 42 or 69%, respectively; no differences in efficacy were detected based on age, race, or gender. It was noted that the patients in the valproic acid control arm were treated intentionally with a relatively low valproic acid dosage because the intent of the study was to establish the effectiveness of lamotrigine monotherapy, and that the study results cannot be interpreted to imply the superiority of lamotrigine therapy to adequate valproic acid therapy. In addition, the manufacturer states that the use of lamotrigine therapy for the management of partial seizures has not been established as initial monotherapy; for conversion from monotherapy with anticonvulsant drugs that do *not* induce hepatic enzymes (e.g., valproate); or for simultaneous conversion to monotherapy from 2 or more concomitant anticonvulsant drugs.

Primary Generalized Tonic-Clonic Seizures Lamotrigine is used in combination with other anticonvulsant agents in the management of primary generalized tonic-clonic seizures in adults and children 2 years of age and older. Efficacy of the drug as adjunctive therapy was established in a placebo-controlled trial in adult and pediatric patients at least 2 years of age who had experienced at least 3 primary generalized tonic-clonic seizures during an 8-week baseline phase. Patients were randomized to receive either placebo or lamotrigine in a fixed-dose regimen (target dosages of 200–400 mg daily in adults and 3–12 mg/kg daily in children) for 19–24 weeks, which was added to their current anticonvulsant regimen of up to 2 anticonvulsant drugs. Patients receiving lamotrigine experienced a substantially greater median reduction in seizure frequency compared with baseline than did patients receiving placebo (66 and 34%, respectively).

Seizures Associated with Lennox-Gastaut Syndrome Lamotrigine also is used in combination with other anticonvulsant agents in the management of generalized seizures associated with Lennox-Gastaut syndrome in pediatric patients and adults. In a controlled clinical trial in patients with Lennox-Gastaut syndrome, adjunctive therapy with lamotrigine resulted in a 32, 34, and 36% decrease in major motor seizures, drop attacks, and tonic-clonic seizures, respectively.

■ **Bipolar Disorder** Lamotrigine is used in the maintenance therapy of bipolar I disorder to prevent or attenuate recurrences of bipolar episodes in patients who remain at high risk of relapse following treatment of an acute depressive or manic episode. The American Psychiatric Association (APA) currently recommends use of lamotrigine as an alternative to first-line maintenance therapies (e.g., lithium, valproic acid, or divalproex). The APA also states that both lamotrigine and lithium are effective in the maintenance treatment of bipolar I disorder; however, the results of two randomized, double-blind, placebo-controlled studies of 18 months' duration indicate that lamotrigine may be more effective in preventing depressive episodes while lithium may be more effective in preventing manic episodes.

Although efficacy of the drug in the acute treatment of mood episodes has yet to be fully established, lamotrigine is considered a first-line agent by the APA for the management of acute depressive episodes in patients with bipolar disorder†. The APA also recommends the use of lamotrigine as an alternative to lithium, valproic acid, or divalproex in the management of patients with rapid cycling bipolar disorder†, particularly in those with the bipolar 2 form of rapid cycling.

For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Molindone Hydrochloride

Oral		
Tablets	5 mg	Moban*, Endo
	10 mg	Moban*, Endo
	25 mg	Moban*, Endo
	50 mg	Moban*, Endo

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Pimozide

■ Pimozide is a diphenylbutylpiperidine-derivative antipsychotic agent. The drug is considered a conventional or first-generation antipsychotic agent.

Uses

■ **Tourette's Syndrome** Pimozide is used for suppression of motor and vocal tics of Tourette's syndrome (Gilles de la Tourette's syndrome).

Pimozide has been used concomitantly with a stimulant in children with tic disorders (e.g., Tourette's syndrome) and comorbid attention deficit hyperactivity disorder (ADHD)† in whom stimulants alone cannot control tics.

Overview Tourette's syndrome is a neurologic genetic disorder with a spectrum of neurobehavioral manifestations that may vary with time and fluctuate in severity and frequency of symptoms during the natural course of the disease. The diagnosis of Tourette's syndrome usually is based on a history and observation of tics often accompanied by behavioral disorders (e.g., ADHD, obsessive-compulsive disorder). Tics may be sudden, brief, intermittent, involuntary, or semivoluntary movements (motor tics) or sounds (phonic or vocal tics). For a diagnosis of Tourette's syndrome, the criteria established by the Tourette Syndrome Classification Study Group may be used. According to this classification, both multiple motor tics and one or more phonic tics must be present at some time during the disease (although not necessarily concurrently), and such tics must occur many times a day and nearly every day, or intermittently, throughout a period of more than 1 year. Motor and phonic tics must be witnessed directly by a reliable examiner some time during the disease or be recorded by video or cinematography. In addition, anatomical location, number, frequency, type, complexity, or severity of tics must undergo a change over time. Involuntary movements and sounds must not be explained by a medical condition other than Tourette's syndrome. Although the onset of the syndrome must occur in patients younger than 21 years of age, in most patients the disease is manifested by 11 years of age, usually beginning in children 2–15 years old. Generally, tics become more severe when patients reach the age of 10 years, and 50% of patients are free from tics by the time they reach the age of 18 years. Severity of tics usually decreases when reaching adulthood. These and other diagnostic criteria are designed to assist clinicians in reaching an accurate diagnosis (e.g., differentiating Tourette's syndrome from other tic disorders) and those investigating the genetic factors associated with the syndrome.

Therapeutic Considerations Initially, management of Tourette's syndrome should include proper education of patients, family members, and teachers in order to provide a proper environment (at home and in school) for children with the disease. Drug therapy usually is considered when symptoms of the disorder begin to interfere with the patient's activities of daily living (e.g., work, school, social activities). Because Tourette's syndrome is associated with a wide variety of neurologic and behavioral manifestations, drug therapy should be individualized and the most severe symptoms should be treated first. The goal in the management of ties is to relieve tic-related discomfort and embarrassment and to achieve a degree of control of tics that allows the patient to function as normally as possible. Dopamine receptor blocking agents are considered the most effective drugs for the management of tics, although only haloperidol and pimozide are approved by the US Food and Drug Administration (FDA) for the treatment of Tourette's syndrome. Haloperidol generally has been considered the drug of choice for the management of Tourette's syndrome and pimozide has been an effective alternative in some patients who have had an inadequate response to or did not tolerate haloperidol. Limited data suggest that pimozide may be more effective than haloperidol in reducing tics. Some clinicians, however, prefer other antipsychotic drugs including molindone, phenothiazines (e.g., fluphenazine, thioridazine, trifluoperazine), risperidone, thiothixene, or tiapride (not commercially available in the US). It is not known whether some other atypical antipsychotics (e.g., clozapine, olanzapine, quetiapine) are effective in the management of tics or other symptoms of Tourette's syndrome; however, limited data indicate that ziprasidone may decrease the severity of tics. Tetrabenazine (not commercially available in the US), a drug that interferes with monoamine neurotransmitters and blocks dopamine receptors, has been effective for the management of tics and, unlike conventional antipsychotic agents, tetrabenazine does not appear to cause tardive dyskinesia. Although several other drugs (e.g., cannabinoids, clonazepam, pergolide, nicotine gum, nicotine transdermal system) have been shown to be effective in the management of tics, these agents have not been evaluated in well-designed, controlled studies. Focal motor and vocal ties have responded to injections of botulinum toxin in the affected muscles.

Pimozide is considered an orphan drug and is used for suppression of motor and vocal tics of Tourette's syndrome (Gilles de la Tourette's syndrome) in children and adults. The drug usually should be reserved for the treatment of those patients with Tourette's syndrome who have an inadequate response to, or who do not tolerate, conventional therapy (e.g., haloperidol) and whose development and/or daily life function is severely compromised by the presence of motor and vocal tics. Pimozide usually is *not* intended as a treatment of first choice for this syndrome, *nor* is it intended for suppression of tics that are only annoying or cosmetically troublesome.

Controlled studies in patients with Tourette's syndrome have shown that pimozide is effective in reducing the number of stimulated and unstimulated motor and vocal tics and the severity of associated symptomatology. Results of several studies suggest that pimozide is at least as effective as haloperidol in the management of Tourette's syndrome and may be associated with fewer and possibly less severe adverse effects, particularly sedation, in some patients. The long-term safety of pimozide in the management of this syndrome, however, remains to be determined, and additional well-controlled studies comparing pimozide and haloperidol are needed to assess their relative efficacy and safety. Haloperidol generally has been considered the drug of choice for the management of Tourette's syndrome, and pimozide has been an effective alternative in some patients who have an inadequate response to or do not tolerate haloperidol. Because limited data suggest that pimozide may be more effective than haloperidol in reducing tics and pimozide appears to be better tolerated than haloperidol, some clinicians and experts prefer the use of pimozide in patients with Tourette's syndrome. Limited data suggest that pimozide may be more effective than clonidine and that pimozide and penfluridol (not commercially available in the US) may have comparable efficacy in the management of Tourette's syndrome. Well-controlled clinical studies comparing the efficacy and safety of pimozide and other agents used in the management of Tourette's syndrome are needed.

Comorbid Conditions Patients with Tourette's syndrome often exhibit comorbid conditions (e.g., ADHD, obsessive-compulsive disorder). Although CNS stimulants, including amphetamines, have been reported to exacerbate motor and vocal tics in patients with Tourette's syndrome, results of several studies indicate that stimulants are effective in the management of ADHD in patients with Tourette's syndrome and the rate of tics is not increased in the majority of patients. In patients in whom the rate of tics increases, some experts recommend addition of an α-adrenergic agonist (e.g., clonidine, guanfacine), risperidone, pimozide, or haloperidol. Clonidine or guanfacine have been used in the management of ADHD. Although less effective than stimulants, clonidine and guanfacine do not increase the frequency or severity of tics. Tricyclic antidepressants (e.g., imipramine, nortriptyline) also may be used for the treatment of mild cases of ADHD and concomitant tics or Tourette's syndrome in patients who do not respond to or otherwise do not tolerate stimulants, in whom tics are exacerbated by stimulants, or those who develop clinically important depression.

In addition, there is a high incidence of obsessive-compulsive disorder in patients with Tourette's syndrome. Many clinicians recommend that patients with Tourette's syndrome and coexisting obsessive-compulsive disorder receive therapy with a selective serotonin-reuptake inhibitor or a selective serotonin- and norepinephrine-reuptake inhibitor (e.g., citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, venlafaxine) alone or, if needed, in combination with buspirone, clonazepam, lithium, or a dopamine receptor antagonist. In a limited number of patients, other drugs (e.g., clomipramine, risperidone) also have been effective in the management of this comorbid condition.

■ **Schizophrenia** Pimozide has been used for the symptomatic management of a variety of psychiatric illnesses†, principally schizophrenia†, but other agents generally are preferred.

Pimozide appears to be as effective as phenothiazines or haloperidol for the symptomatic management of schizophrenia†. The drug is effective in reducing hallucinations, thought disorders, change in affect, and autism. Pimozide also appears to be effective for the management of social adjustment problems, emotional withdrawal, motor retardation, apathy, and conceptual disorganization. Delusions, bizarre mannerisms, chronic paranoia, anxiety, guilt feelings, disorientation, and hostility also may be reduced during therapy with the drug. Pimozide should *not* be used for the management of schizophrenia in patients whose main manifestations include excitement, agitation, or hyperactivity, because the efficacy of the drug in these patients has not been established.

Pimozide also has been used for the symptomatic management of acute schizophrenic episodes†. Results of initial clinical studies were not encouraging, but subsequent uncontrolled clinical studies suggest that pimozide may be effective in the management of acute schizophrenic episodes when used at dosages substantially higher than those used for the management of schizophrenia. Limited data suggest that high-dose pimozide therapy may be as effective as haloperidol or phenothiazines; however, the frequency and severity of pimozide-induced extrapyramidal reactions are increased at high dosages. Pimozide currently is *not* recommended for the management of acute schizo-

phrenic episodes. For further information on the symptomatic management of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Mania** Pimozide has been used for the management of manic episodes† (mania) in patients with major affective disorders. Although limited data suggest that pimozide may be as effective as phenothiazines, the efficacy of the drug has not been clearly established, and pimozide currently is *not* recommended for the management of manic episodes.

■ **Behavioral Disorders** The efficacy of pimozide for the management of behavioral disorders in patients with mental retardation has not been established, but limited data suggest that the drug may reduce irritability, anxiety, and hyperactivity and improve social behavior in mentally retarded adolescents, without substantially affecting cognition or learning performance. Further controlled studies are needed.

■ **Dyskinesias** Pimozide has been used for the management of various dyskinesias†, including chronic progressive hereditary chorea (Huntington's chorea), acute chorea (Sydenham's chorea), tardive dyskinesia, and tardive dystonia; however, the usefulness of the drug for the management of dyskinesias is questionable because it has both dyskinesia-ulleviating and dyskinesia-producing properties. Because pimozide tends to worsen parkinsonian symptoms, the drug should not be used for the management of levodopa-induced dyskinesias in patients with parkinsonian syndrome.

■ **Other Uses** Results of uncontrolled clinical studies suggest that pimozide may be useful for the management of phencyclidine-induced psychosis† or various personality disorders† (e.g., paranoid, schizoid, compulsive). Pimozide also has reportedly been beneficial in some patients for the management of pathologic jealousy†, erotomania†, and monosymptomatic hypochondriacal psychosis†, including delusions of parasitosis.

Although pimozide has been used in the treatment of anorexia nervosa†, use of the drug for this purpose does not appear to provide substantial benefit.

Dosage and Administration

■ **Administration** Pimozide is administered orally. The drug may usually be administered once daily but also may be given in divided doses, particularly if once-daily dosing is not well tolerated. Some clinicians recommend administration of the drug as a single dose at bedtime to minimize adverse effects.

■ **Dosage** When pimozide is used for suppression of motor and vocal tics in patients with Tourette's syndrome, the initial dosage of the drug should be low and dosage adjustments should be made gradually. Dosage of pimozide must be carefully adjusted to balance symptomatic relief and the suppression of tics against the adverse effects of the drug. Patients receiving pimozide should have an ECG performed before therapy with the drug is initiated and periodically thereafter, particularly during the period of dosage adjustment. (See Cautions: Precautions and Contraindications.)

Adult Dosage For the suppression of motor and vocal tics in adults with Tourette's syndrome, the usual initial dosage of pimozide is 1–2 mg daily. The manufacturer and some clinicians state that dosage may be increased every other day according to the patient's tolerance and therapeutic response. Because of pimozide's prolonged elimination half-life, other clinicians suggest that dosage be increased at longer intervals (e.g., every 5–7 days) until signs and symptoms of the disorder decrease by at least 70%, adverse effects occur without symptomatic benefit, or symptomatic benefit and adverse effects occur at the same time. If adverse effects are minimal and do not interfere with functioning (e.g., dry mouth, slight sedation) but adequate response has not been achieved, dosage should not be increased further until these adverse effects resolve. If adverse effects interfere with functioning but are not severe, dosage can be reduced by 1-mg increments at weekly intervals until such effects resolve. Dosage should be reduced by 50% immediately or the drug withheld if severe adverse effects occur. (See Cautions: Precautions and Contraindications.) Once serious adverse effects resolve, therapy can be reinstituted with more gradual titration, increasing dosage at intervals ranging from 7–30 days. Most patients are adequately treated with dosages less than 0.2 mg/kg daily or 10 mg daily, whichever is less, and the manufacturer recommends that these dosages not be exceeded.

Pediatric Dosage For the suppression of motor and vocal tics in children with Tourette's syndrome, the usual initial dosage of pimozide is 0.05 mg/kg daily, preferably at bedtime. The dose may be increased every third day to a maximum of 0.2 mg/kg or 10 mg per day. Reliable dose-response data for the effects of the drug on tic manifestations in children younger than 12 years of age are not available.

Dosage of pimozide during prolonged maintenance therapy should be kept at the lowest possible effective level. Once an adequate response has been achieved, periodic attempts (e.g., every 6–12 months) should be made to reduce dosage of the drug to determine whether the initial intensity and frequency of tics persist. When attempting to reduce the dosage of pimozide, consideration should be given to the possibility that observed increases of tic intensity and frequency may represent a transient, withdrawal-related phenomenon rather than a return of the syndrome's symptoms. Before concluding that an increase in tic manifestations is a function of the underlying disorder rather than a response to drug withdrawal, at least 1–2 weeks should be allowed to elapse. If pimozide therapy is to be discontinued, dosage of the drug should be gradually reduced.

Cautions

■ **Nervous System Effects** The most frequent and potentially severe adverse effects of pimozide involve the CNS.

Extrapyramidal Reactions Extrapyramidal reactions occur frequently with pimozide, especially during the first few days of therapy. In most patients, these reactions consist of parkinsonian symptoms (e.g., tremor, rigidity, akinesia) that are mild to moderate in severity and usually reversible following discontinuance of the drug. Dystonic reactions and feelings of motor restlessness (i.e., akathisia) occur less frequently. Generally, the occurrence and severity of most extrapyramidal reactions are dose related because they occur at relatively high dosages and disappear or become less severe following a reduction in dosage; however, severe extrapyramidal reactions have reportedly occurred at relatively low dosages. Extrapyramidal reactions appear to occur in about 10–15% of patients receiving usual dosages of pimozide. Administration of anticholinergic antiparkinsonian agents (e.g., benztropine, trihexyphenidyl) or diphenhydramine may be necessary to control parkinsonian extrapyramidal reactions. If persistent extrapyramidal reactions occur, pimozide therapy may have to be discontinued.

The most common dystonic reaction is torticollis, which generally is accompanied by orofacial symptoms and, in some instances, oculogyric crisis, as well as spasms of the face, tongue, and jaw. Dyskinesias of the mouth and throat areas, trismus, dysarthria, muscle cramps, and athetoid movements have occurred occasionally.

Akathisia occurs relatively frequently in patients receiving pimozide, but usually can be managed by reducing the dosage of pimozide or by concomitant administration of an anticholinergic antiparkinsonian agent, diphenhydramine, a benzodiazepine, or propranolol.

Like other antipsychotic agents, pimozide has been associated with neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment. For additional information on NMS, see Extrapyramidal Reactions in Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia Like other antipsychotic agents, pimozide has been associated with persistent dyskinesias. Tardive dyskinesia may occur in some patients during long-term administration of pimozide or possibly following discontinuance of the drug. The risk of developing tardive dyskinesia appears to be greater in geriatric patients receiving high dosages of the drug, especially females. The symptoms are persistent and in some patients appear to be irreversible. Tardive dyskinesia is characterized by rhythmic involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of the tongue, puffing of cheeks, chewing movements, puckering of the mouth), which sometimes may be accompanied by involuntary movements of the extremities and trunk. Although not clearly established, the risk of developing the syndrome and the likelihood that it will become irreversible may increase with the duration of therapy and total cumulative dose of antipsychotic agent(s) administered; however, the syndrome may occur, although much less frequently, after relatively short periods of treatment with low dosages. There is no proven or uniformly effective treatment for tardive dyskinesia; anticholinergic antiparkinsonian agents do not alleviate and often exacerbate the symptoms of this syndrome. If possible, antipsychotic agents should be discontinued if signs or symptoms of tardive dyskinesia occur. The syndrome may partially or completely remit if antipsychotic agents are discontinued, although some patients may require many months for improvement. Tardive dyskinesia may be masked if therapy is reinstituted, dosage is increased, or therapy with another antipsychotic agent is initiated. The effect that masking of the symptoms may have on the long-term course of the syndrome is not known. Fine vermicular movement of the tongue may be an early sign of tardive dyskinesia; prompt discontinuance of pimozide after this sign occurs may prevent development of the syndrome.

In general, abrupt withdrawal of antipsychotic agents following short-term administration is not associated with adverse effects; however, transient dyskinetic signs have occurred following abrupt withdrawal in some patients receiving maintenance therapy. In some of these patients, the dyskinetic movements are indistinguishable, except on the basis of duration, from persistent tardive dyskinesia. It is not known whether gradual withdrawal of antipsychotic agents reduces the incidence of withdrawal-emergent neurologic signs; however, if pimozide therapy must be discontinued, gradual withdrawal of the drug is recommended, if possible, pending further accumulation of data.

Other Nervous System Effects Pimozide is generally considered to be relatively nonsedating compared with other antipsychotic agents, but sedation, lethargy, and/or drowsiness appear to be the most common adverse effects of the drug in patients with Tourette's syndrome. Other adverse nervous system effects of pimozide include insomnia, dizziness, excitement, agitation, nervousness, fainting, aggressiveness, irritability, anxiety, tension, headache, depression, decreased attentiveness, confusion, nightmares, hallucinations, phobia, impaired motivation, speech disorder, handwriting change, fatigue, weakness, transient affective disturbance, and aggravation of psychotic symptomatology. Rarely, pimozide has been associated with seizures, including tonic-clonic (grand mal) seizures, in patients without a previous history of seizure disorder.

Adverse anticholinergic effects of pimozide include dry mouth, blurred vision, difficulty with accommodation, urinary retention, constipation, and urinary and fecal incontinence.

■ **Cardiovascular Effects** Various ECG changes, such as prolongation of the QT (including QT_c) interval; flattening, notching, and inversion of the T wave; and appearance of U waves, have occurred in some patients receiving pimozide. The clinical importance of pimozide-induced ECG changes has not been clearly established, but some clinicians believe that the changes are comparable to those induced by phenothiazines. Sudden, unexpected deaths have occurred in some patients receiving high doses of the drug (i.e., exceeding 10 mg; in the range of 1 mg/kg) for conditions other than Tourette's syndrome or in patients receiving concomitant pimozide and clarithromycin. (See Drug Interactions: Drugs and Foods Affecting Hepatic Microsomal Enzymes.) A possible mechanism for these deaths is prolongation of the QT interval, predisposing the patients to ventricular arrhythmia. Patients receiving pimozide should have ECG evaluations before and periodically during therapy with the drug. (See Cautions: Precautions and Contraindications.)

Pimozide rarely may produce hypotension, orthostatic hypotension, hypertension, tachycardia, or palpitations. In some patients, particularly geriatric or debilitated patients, transient hypotension for several hours after administration of the drug has occurred.

■ **Endocrine and Metabolic Effects** Amenorrhea, dysmenorrhea, and mild galactorrhea have occurred in some patients receiving pimozide. Like other antipsychotic agents, pimozide increases serum prolactin concentrations. (See Cautions: Mutagenicity and Carcinogenicity.) Loss of libido, impotence, and weight gain or, more frequently, weight loss, has occurred in patients receiving pimozide.

■ **GI Effects** Adverse GI effects of pimozide include increased salivation, nausea, vomiting, anorexia, GI distress, diarrhea, constipation, and abdominal cramps or pain. Thirst, altered taste, gingival hyperplasia, and increased appetite also have been reported.

■ **Other Adverse Effects** Rash, urticaria, skin irritation, facial edema (may be severe), periorbital edema, sweating, cataracts, visual disturbances or sensitivity to light, chest pain, nocturia, and urinary frequency have been reported in patients receiving pimozide. Hemolytic anemia also has occurred in pimozide-treated patients, although a causal relationship to the drug has not been established. Hyponatremia has occurred in patients receiving the drug following marketing approval.

The possibility that pimozide may cause other adverse effects reported with other antipsychotic agents should be considered. In addition, because clinical experience with pimozide for the management of Tourette's syndrome is limited, uncommon adverse effects may not have been detected to date.

■ **Precautions and Contraindications** Pimozide shares the toxic potentials of other antipsychotic agents (e.g., phenothiazines, butyrophenones), and the usual precautions associated with therapy with these agents should be observed. (See Cautions in the Phenothiazines General Statement 28:16.08.24.) Because treatment with pimozide exposes the patient to potentially serious risks, the decision to use the drug for the long-term management of Tourette's syndrome should be carefully considered by the patient (and/or the patient's family or guardians) and the physician. The use of pimozide for the management of Tourette's syndrome involves different considerations of risks and benefits than the use of other antipsychotic agents for other conditions. Because the goal of treatment is symptomatic improvement, the patient's view of the need for treatment and assessment of response are critical in evaluating the relative benefits and risks of pimozide therapy. Patients should be informed that pimozide has an adverse effect profile similar to that of other antipsychotic agents and that adverse effects associated with these agents may occur with pimozide.

Geriatric patients with dementia-related psychosis treated with either conventional (first-generation) or atypical (second-generation) antipsychotic agents are at an increased risk of mortality. For additional information on the use of antipsychotic agents for dementia-associated psychosis and other behavioral disturbances, see Geriatric Considerations under Psychotic Disorders: Schizophrenia and Other Psychotic Disorders, in Uses and see also Cautions: Geriatric Precautions, in the Phenothiazines General Statement 28:16.08.24.

Because of the likelihood that a proportion of patients receiving long-term therapy with an antipsychotic agent will develop tardive dyskinesia, patients in whom long-term pimozide therapy is considered should be fully informed, if possible, about the risk of developing this syndrome. The decision to inform the patient (and/or the patient's family or guardians) should take into account the clinical circumstances and the competency of the patient to understand the information. Because of the risk of tardive dyskinesia, long-term pimozide therapy should generally be reserved for patients whose syndrome is responsive to the drug and for whom alternative, equally effective, but potentially less toxic therapy is not available or appropriate. In patients requiring long-term treatment, the smallest effective dosage and shortest duration of therapy producing an adequate clinical response should be employed. Patients receiving pimozide should be evaluated periodically to determine whether maintenance dosage could be decreased or the drug discontinued.

Because sudden, unexpected deaths, which may be related to an effect of pimozide on the heart, have occurred in some patients receiving high doses of the drug (i.e., exceeding 10 mg; in the range of 1 mg/kg) for conditions other than Tourette's syndrome, an ECG should be performed before pimozide therapy is initiated and periodically thereafter, particularly during the period of dosage adjustment. Some clinicians recommend that a cardiologist be consulted before initiating therapy with the drug in patients with a baseline QT_c interval exceeding 440 ms. Patients should be instructed *not* to exceed the prescribed dosage and should be aware of the need for the initial ECG and follow-up ECGs during pimozide therapy. Prolongation of the QT_c interval (QT interval corrected for rate) to greater than 470 ms in children or 520 ms in adults, or more than 25% beyond the patient's pretreatment value, or the development of other T-wave abnormalities should be considered a basis for stopping further dosage increases and considering a dosage reduction. Dosage reduction also should be considered if bradycardia (less than 50 bpm) occurs. Some clinicians recommend that pimozide be withheld if T-wave inversion, U waves, or cardiac arrhythmia occurs and reinstituted only after ECG findings are normal. Because pimozide may cause ECG changes, the drug should be used with caution in patients with cardiovascular disorders. Because hypokalemia has been associated with ventricular arrhythmias, potassium insufficiency secondary to diuretics, diarrhea, or other causes should be corrected before pimozide therapy is initiated, and normal serum potassium concentrations should be maintained during pimozide therapy.

The clinical importance is not known, but pimozide has produced a dose-related increase in benign pituitary tumors in female mice. (See Cautions: Mutagenicity and Carcinogenicity.) The tumorigenic potential of pimozide should be given careful consideration by the patient and physician in the decision to use the drug, especially if the patient is young and long-term therapy is anticipated.

Patients should be warned that pimozide may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle), especially during the first few days of therapy.

Because pimozide produces adverse anticholinergic effects, the drug should be used with caution in individuals whose conditions may be aggravated by anticholinergic activity.

Like other antipsychotic agents, pimozide should be used with caution in patients receiving anticonvulsant agents and in those with EEG abnormalities or a history of seizures because the drug may lower the seizure threshold. If necessary, adequate anticonvulsant therapy should be maintained during pimozide therapy.

Pimozide should be used with caution in patients with hepatic or renal impairment.

Because pimozide has an antiemetic effect, the drug should be used with caution when suppression of nausea and vomiting might obscure diagnosis of an underlying physical disorder.

Because increased plasma concentrations of pimozide have occurred following concomitant use of pimozide and sertraline, the manufacturers of pimozide and sertraline state that concomitant use of the drugs is contraindicated. In addition, increased plasma pimozide concentrations were observed during concurrent use with paroxetine. The manufacturers of paroxetine state that concomitant use of these drugs is contraindicated because of the narrow therapeutic index of pimozide and its known ability to prolong the QT interval. Because of the risk of QT-interval prolongation, the manufacturer of citalopram hydrobromide and escitalopram oxalate states that concurrent use of either of these drugs with pimozide is contraindicated. Concurrent use of pimozide and fluoxetine also is contraindicated because of the potential for adverse drug interactions or QT_c prolongation. In addition, fluvoxamine should not be used concurrently with pimozide. (See Drug Interactions: Selective Serotonin-reuptake Inhibitors.)

Because pimozide prolongs the QT interval, the drug also is contraindicated in patients with congenital long QT syndrome or a history of cardiac arrhythmias, and in patients receiving other drugs that prolong the QT interval or that inhibit the metabolism of pimozide by inhibiting the cytochrome P-450 (CYP) 3A4 isoenzyme such as macrolide antibiotics (e.g., clarithromycin, erythromycin, azithromycin, dirithromycin, troleandomycin), azole antifungal agents (e.g., itraconazole, ketoconazole), protease inhibitors (e.g., ritonavir, saquinavir, indinavir, nelfinavir), nefazodone, or zileuton. (See Drug Interactions: Drugs That Prolong the QT Interval, and Drugs and Foods Affecting Hepatic Microsomal Enzymes.)

Pimozide is contraindicated in the treatment of simple tics or tics other than those associated with Tourette's syndrome. Pimozide should not be used in patients receiving drugs that may cause motor and vocal tics (e.g., pemoline [no longer commercially available in the US], methylphenidate, amphetamines) until such drugs have been withdrawn to determine whether the drugs or Tourette's syndrome is responsible for the tics.

Pimozide is contraindicated in patients with known hypokalemia or hypomagnesemia.

Pimozide is contraindicated in patients with severe toxic CNS depression or in those who are comatose from any cause; patients with blood dyscrasias, depressive disorders, or parkinsonian syndrome; and in patients who are hypersensitive to the drug. It is not known whether cross-sensitivity exists among antipsychotic agents; however, pimozide should be used with particular caution in patients with known hypersensitivity to other antipsychotic agents.

■ **Pediatric Precautions** The onset of Tourette's syndrome usually occurs between the ages of 2 and 15 years, but data on the use and efficacy of pimozide in children younger than 12 years of age are limited. Further study is needed to fully evaluate the use and efficacy of the drug for Tourette's syndrome in this age group. Limited clinical evidence suggests that the safety profile of pimozide in children aged 2–12 years generally is comparable to that observed in older patients. Safety and efficacy of pimozide for the management

of other conditions in children have not been evaluated, and use of the drug in children for any condition other than Tourette's syndrome is *not* recommended.

■ **Mutagenicity and Carcinogenicity** No evidence of pimozide-induced mutagenesis was seen in the Ames microbial mutagen test, the micronucleus test in rats, or the dominant lethal assay in mice.

No evidence of carcinogenesis was seen in rats receiving oral pimozide dosages up to 50 times the maximum recommended human dosage for 2 years; however, because of the limited number of rats surviving the study, the meaning of the results is unclear. Reversible gingival hyperplasia has occurred in dogs receiving oral pimozide dosages greater than 1.5 mg/kg daily (about 5 times the maximum recommended human dosage) for 12 months, and has occurred in at least one patient receiving the drug following marketing approval. Following oral administration of pimozide 0.62, 5, or 40 mg/kg daily for 18 months in mice, dose-related increases in the incidence of pituitary adenomas and mammary gland adenocarcinomas were observed in females. Pituitary changes at a dosage of 0.62 mg/kg daily were characterized as hyperplasia, while benign adenomas occurred at the higher dosages. The mechanism of pimozide-induced pituitary tumors in mice and the clinical importance of this finding are not known; however, the tumorigenic potential of pimozide should be given careful consideration by the patient and physician in the decision to use the drug, especially if the patient is young and long-term therapy is anticipated.

Although an increase in mammary neoplasms has been found in rodents following long-term administration of prolactin-stimulating antipsychotic agents, no clinical or epidemiologic studies conducted to date have shown an association between long-term administration of these drugs and mammary tumorigenesis in humans. Current evidence is considered too limited to be conclusive, and further study is needed to determine the clinical importance in most patients of elevated serum prolactin concentrations associated with antipsychotic agents. Because in vitro tests indicate that approximately one-third of human breast cancers are prolactin dependent, pimozide should be used with caution in patients with previously detected breast cancer.

■ **Pregnancy, Fertility, and Lactation** Reproduction studies in rats and rabbits using oral pimozide dosages up to 2.5 mg/kg daily (up to about 8 times the maximum recommended human dosage) have not revealed evidence of fetal malformation; however, in rats receiving oral pimozide dosages of 2.5 mg/kg daily or higher, a decreased pregnancy rate, increased fetal resorption, and retarded development of fetuses occurred. The observed effects may have resulted from delay or inhibition of implantation. In rabbits, dose-related maternotoxicity, mortality, decreased weight gain, and embryotoxicity, including increased fetal resorption, occurred. There are no adequate and controlled studies to date using pimozide in pregnant women, and the drug should be used during pregnancy only when the potential benefits justify the possible risks to the fetus.

Reproduction studies in animals using oral pimozide were not adequate to fully assess potential effects of the drug on fertility. Female rats receiving oral pimozide dosages up to 2.5 mg/kg daily had prolonged estrus cycles.

It is not known whether pimozide is distributed into milk. Because of the potential for serious adverse reactions (e.g., tumorigenicity, unknown cardiovascular effects) to pimozide in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Drug Interactions

■ **Selective Serotonin-reuptake Inhibitors** ***Citalopram*** In a controlled study, administration of a single 2-mg dose of pimozide in individuals receiving citalopram (40 mg once daily for 11 days) was associated with mean increases in the QT_c interval of approximately 10 msec compared with pimozide given alone. Citalopram did not substantially affect the mean AUC or peak plasma concentrations of pimozide. The mechanism for this potential pharmacodynamic interaction is not known. The manufacturer of citalopram hydrobromide states that concurrent use of citalopram and pimozide is contraindicated.

Escitalopram In a controlled study, administration of a single 2-mg dose of pimozide in individuals receiving racemic citalopram (40 mg once daily for 11 days) was associated with mean increases in the QT_c interval of approximately 10 msec compared with pimozide given alone. Racemic citalopram did not substantially affect the mean AUC or peak plasma concentrations of pimozide. Concurrent pimozide and escitalopram administration has not been specifically evaluated to date. Pending further accumulation of data, the manufacturer of escitalopram states that concurrent use of escitalopram and pimozide is contraindicated.

Fluoxetine Clinical studies evaluating pimozide and other antidepressants have demonstrated an increase in adverse drug interactions or QT_c prolongation during combined therapy. In addition, rare case reports have suggested possible additive cardiovascular effects of pimozide and fluoxetine, resulting in bradycardia. Marked changes in mental status (e.g., stupor, inability to think clearly) and hypersalivation also were reported in one woman who received both drugs concurrently. Although a specific study evaluating concurrent pimozide and fluoxetine has not been performed to date, concurrent use of these drugs is contraindicated because of the potential for adverse drug interactions or QT_c prolongation.

Fluvoxamine Concomitant use of fluvoxamine is contraindicated in patients receiving pimozide, since fluvoxamine may inhibit the metabolism of pimozide and increase the potential for serious adverse cardiac effects.

Paroxetine In a controlled study, concurrent administration of single 2-mg doses of pimozide in healthy individuals receiving paroxetine (dosage titrated up to 60 mg daily) was associated with mean increases of 151 and 62% in the area under the plasma concentration-time curve (AUC) and peak plasma concentrations of pimozide, respectively, compared with pimozide given alone. The manufacturers of paroxetine state that concomitant use of paroxetine and pimozide is contraindicated because of the narrow therapeutic index of pimozide and its known ability to prolong the QT interval.

Sertraline Administration of a single 2-mg dose of pimozide in individuals receiving sertraline 200 mg daily has resulted in a mean increase of about 40% in pimozide AUC and peak plasma concentrations, but was not associated with changes in ECG parameters. The effect on QT interval and pharmacokinetic parameters of pimozide administered in higher doses (i.e., doses exceeding 2 mg) in combination with sertraline is as yet unknown. Concomitant use of sertraline and pimozide is contraindicated because of the low therapeutic index of pimozide and because the reported interaction between the 2 drugs occurred at a low dose of pimozide. The mechanism of this interaction is as yet unknown.

■ **Other CNS Agents** Pimozide may be additive with, or may potentiate the action of, other CNS depressants such as opiates or other analgesics, barbiturates or other sedatives, anxiolytics, or alcohol. When pimozide is used concomitantly with other CNS depressants, caution should be used to avoid excessive CNS depression.

■ **Drugs That Prolong the QT Interval** Because pimozide prolongs the QT interval, an additive effect on the QT interval might occur if the drug is administered with other agents that may prolong the QT interval such as phenothiazines, tricyclic antidepressants, or antiarrhythmic agents. Therefore, the manufacturer states that pimozide is contraindicated in patients receiving dofetilide, quinidine, sotalol, and other class IA and III antiarrhythmics; chlorpromazine, droperidol, mesoridazine (no longer commercially available in the US), and thioridazine; gatifloxacin, moxifloxacin, and sparfloxacin; halofantrine (licensed in the US but not commercially available); mefloquine; pentamidine; arsenic trioxide; levomethadyl acetate (no longer commercially available in the US); dolasetron mesylate; probucol (no longer commercially available in the US); tacrolimus; ziprasidone; and any other drugs that have demonstrated QT prolongation as one of their pharmacodynamic effects. (See Cautions: Cardiovascular Effects and see also Cautions: Precautions and Contraindications.)

■ **Drugs and Foods Affecting Hepatic Microsomal Enzymes** Prolongation of QT interval and, rarely, serious cardiovascular effects, including ventricular arrhythmias and death, have been reported in patients receiving drugs that inhibit the cytochrome P-450 (CYP) 3A4 isoenzyme such as macrolide antibiotics (e.g., clarithromycin, erythromycin, azithromycin, dirithromycin, troleandomycin), azole antifungal agents (e.g., itraconazole, ketoconazole), protease inhibitors (e.g., ritonavir, saquinavir, indinavir, nelfinavir), nefazodone, or zileuton concomitantly with pimozide. Macrolide antibiotics inhibit metabolism of pimozide, which may result in increased plasma concentrations of unchanged drug. Such alterations in pharmacokinetics of pimozide may be associated with prolongation of the QT and QT_c intervals, and, rarely, associated with ventricular arrhythmias. The manufacturer of pimozide states that concomitant administration of pimozide and macrolide antibiotics, azole antifungal agents, protease inhibitors, nefazodone, or zileuton is contraindicated.

Patients receiving pimozide should avoid grapefruit juice because it may inhibit drug metabolism by the CYP3A4 isoenzyme.

Because pimozide also may be metabolized by the CYP1A2 isoenzyme, the manufacturer states the theoretical potential for drug interactions with drugs that inhibit this enzyme system should be considered.

Acute Toxicity

■ **Pathogenesis** The acute lethal dose of pimozide in humans is not known. The oral LD_{50} of pimozide is 228, 5120, 188, and 40 mg/kg in mice, rats, guinea pigs, and dogs, respectively. The IV and subcutaneous LD_{50}s of pimozide are 11.1 and 40 mg/kg, respectively, for mice, and 5 and 40 mg/kg, respectively, for rats.

■ **Manifestations** In general, overdosage of pimozide may be expected to produce effects that are extensions of pharmacologic effects and adverse reactions, predominantly ECG abnormalities (including prolongation of the QT interval and torsades de pointes), severe extrapyramidal reactions, hypotension, seizures, and comatose state with respiratory depression.

A 17-year-old female who reportedly intentionally ingested 100 mg of pimozide and underwent gastric lavage (apparently no drug was recovered) had a complete and uneventful recovery except for slight tremor of the extremities that subsided within a few hours after ingestion. A 2½-year-old male who accidentally reportedly ingested 60 mg of pimozide exhibited mild extrapyramidal symptoms that subsequently subsided, and the patient recovered completely. Delayed-onset dystonia, hypotension, tachycardia, and drowsiness were reported in an 18-month-old female who ingested up to 6 mg (0.5 mg/kg) of pimozide; manifestations developed more than 12 hours after the accidental ingestion. The dystonia subsided over the following 12 hours while the drowsiness and tachycardia persisted for 40 hours. The child recovered fully without sequelae.

■ **Treatment** Treatment of pimozide overdosage generally involves symptomatic and supportive care, with ECG, blood pressure, and respiratory monitoring. There is no specific antidote for pimozide intoxication.

Following acute ingestion of the drug, the stomach should be emptied immediately, preferably by gastric lavage. If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of gastric contents. As in the case of phenothiazine overdosage, induction of emesis should generally *not* be attempted because a pimozide-induced dystonic reaction of the head or neck may result in aspiration of gastric contents during emesis; however, if the ingestion has only recently occurred (i.e., within an hour or so), induction of emesis may be considered. Following gastric lavage and/or emesis, activated charcoal should be administered. A patent airway should be established, using controlled or mechanically assisted respiration as necessary. ECG monitoring should be initiated immediately and continued until ECG parameters are within normal ranges. For hypotension or circulatory collapse, IV fluids, plasma, albumin, and/or vasopressor agents (e.g., norepinephrine) may be used. Epinephrine should *not* be used. For severe extrapyramidal reactions, anticholinergic antiparkinsonian agents or diphenhydramine should be administered. Because of the long elimination half-life of pimozide, patients should be observed for at least 4 days following acute ingestion of the drug. Clinicians should consider contacting a poison control center for additional information on the management of pimozide overdosage.

Pharmacology

The principal pharmacologic effects of pimozide are similar to those of haloperidol and, to a lesser extent, those of phenothiazines. In animal studies that are correlated with antipsychotic activity, pimozide is, on a weight basis, almost as potent as haloperidol and more potent than chlorpromazine following oral or subcutaneous administration.

■ **Nervous System Effects** In the CNS, pimozide has pharmacologic actions similar to those of haloperidol. The precise mechanism(s) of pimozide in suppressing motor and vocal tics in patients with Tourette's syndrome and its antipsychotic action have not been determined, but it may be related principally to the antidopaminergic effects of the drug. Although it has not been clearly established, most evidence suggests that pimozide is a selective dopamine-2 (D_2) receptor antagonist. Like butyrophenones (e.g., haloperidol), pimozide appears to predominantly block postsynaptic dopamine receptor sites, although the drug also may block presynaptic dopamine receptor sites. Blockade of dopamine receptors by pimozide may be accompanied by a series of secondary alterations in central dopamine metabolism and function that may contribute to the drug's therapeutic and adverse effects. Pimozide inhibits electrically induced dopamine release in brain tissue in vitro and increases synthesis and turnover of brain dopamine. Unlike most other currently available antipsychotic agents, pimozide appears to have little effect on catecholamines other than dopamine, although turnover of brain norepinephrine may be increased at high doses. Like other antipsychotic agents, however, pimozide has various effects on CNS receptor systems (e.g., γ-aminobutyric acid [GABA]) that are not fully characterized. Pimozide may decrease brain acetylcholine indirectly via its antidopaminergic effects, but such activity is considered relatively weak. Unlike haloperidol and chlorpromazine, the drug does not provide protection against a lethal dose of norepinephrine in rats.

Pimozide does not affect total sleep time or rapid eye movement (REM) sleep. The drug may cause EEG changes, including an increase in α-wave activity. Although not clearly established, pimozide may also lower the seizure threshold. The drug does not exhibit anticonvulsant activity in rats.

Although the exact mechanism(s) of action has not been elucidated, pimozide has an antiemetic effect. The antiemetic activity may be mediated via a direct effect of the drug on the medullary chemoreceptor trigger zone (CTZ), apparently by blocking dopamine receptors in the CTZ. Pimozide inhibits the central and peripheral effects of apomorphine.

Like haloperidol and phenothiazines, pimozide inhibits conditioned avoidance behaviors and produces catalepsy and ptosis in animals. The drug also antagonizes behavioral effects mediated by amphetamines in animals. In humans, pimozide antagonizes the euphoric response to amphetamines in amphetamine-dependent individuals, but apparently does not antagonize amphetamine-mediated behavioral effects in patients with schizophrenic disorder. Unlike many other centrally acting agents, pimozide does not appear to exhibit analgesic activity. The drug appears to exhibit anxiolytic activity in patients with chronic schizophrenic disorder who exhibit anxiety and in patients with various anxiety states.

In animals, pimozide does not substantially affect body temperature; however, the drug does inhibit apomorphine- and amphetamine-induced fever.

Pimozide exhibits some anticholinergic activity, although it is generally considered to be relatively weak compared with most other antipsychotic agents; however, anticholinergic effects (e.g., dry mouth, urinary retention, constipation) may occur during therapy with the drug.

■ **Cardiovascular Effects** Pimozide exhibits weak α-adrenergic blocking activity. The drug rarely may produce hypotension, orthostatic hypotension, hypertension, or tachycardia. Pimozide may also produce ECG changes, including prolongation of the QT interval; flattening, notching, and inversion of the T wave; and appearance of U waves. (See Cautions: Cardiovascular Effects.)

■ **Endocrine Effects** Pimozide induces secretion of prolactin from the anterior pituitary. The exact mechanism of increased prolactin secretion has not been determined, but it may be related principally to inhibition of dopamine receptors in the pituitary and hypothalamus.

■ **Other Effects** In vitro, pimozide exhibits weak antispasmodic effects, resulting from antagonism of various mediator substances (e.g., histamine, bradykinin, angiotensin). Pimozide also may inhibit transmembrane influx of extracellular calcium ions via slow calcium channels.

Pharmacokinetics

Limited information is available on the pharmacokinetics of pimozide.

■ **Absorption** Pimozide is slowly and variably absorbed from the GI tract following oral administration. Based on limited data, the drug appears to be at least 40–50% absorbed. Pimozide also appears to undergo extensive first-pass metabolism. It is not known whether food, disease, or concomitant administration of other drugs affects the absorption of pimozide.

Following oral administration of an individual dose of pimozide, peak plasma concentrations of the drug and its metabolites generally occur within 6–8 hours (range: 4–12 hours). Following oral administration of a single 6- or 24-mg dose in patients with chronic schizophrenic disorder, peak plasma pimozide concentrations of approximately 4 or 18–19 ng/mL, respectively, were attained. There are considerable interindividual variations in peak plasma concentrations and areas under the plasma concentration-time curves (AUCs) following single or multiple oral doses of pimozide. In a group of patients with chronic schizophrenic disorder receiving 2–10 mg of pimozide daily, steady-state serum concentrations of the drug varied considerably with specific dosages and ranged from undetectable (less than 1 ng/mL) to about 50 ng/mL. Because there is little correlation between plasma pimozide concentrations and clinical response, the clinical importance of interindividual variations is unclear. In a group of adults with acute schizophrenic disorder, a correlation between plasma pimozide concentration and dopamine receptor blocking activity, but not between clinical response and dopamine receptor blocking activity, was reported.

■ **Distribution** Distribution of pimozide into human body tissues and fluids has not been well characterized. Following subcutaneous administration in animals, pimozide is widely distributed, with highest concentrations attained in the liver, lungs, kidneys, and heart; the drug also is distributed into the brain, thymus, adrenals, thyroid, uterus, and ovaries, and apparently into bile. In animals, there is a direct relationship between the administered dose of pimozide and concentrations of the drug attained in the liver and brain. Following subcutaneous administration in animals, pimozide is widely distributed throughout the brain, principally as unchanged drug, with highest concentrations attained in the pituitary and caudate nucleus. The drug appeared to be selectively retained in the pituitary, caudate nucleus, chemoreceptor trigger zone (CTZ), floor of the third ventricle, lateral hypothalamus, and medulla. There was no correlation between concentrations of pimozide in the caudate nucleus and antagonism of effects mediated by amphetamine or apomorphine, but distribution of pimozide into nerve endings in the caudate nucleus was correlated with antagonism of these effects.

The extent of pimozide binding to plasma proteins is not known.

It is not known whether pimozide crosses the placenta or is distributed into milk.

■ **Elimination** Following multiple oral doses in patients with chronic schizophrenic disorder, the elimination half-life of pimozide averaged 55 hours. In one patient who developed a severe dystonic reaction, the elimination half-life of the drug was reportedly 154 hours.

The exact metabolic fate of pimozide is not clearly established, but the drug appears to undergo extensive first-pass metabolism. Pimozide is metabolized principally by oxidative *N*-dealkylation in the liver; this metabolism is catalyzed mainly by the cytochrome P-450 (CYP) 3A4 isoenzyme and, to a lesser extent, by cytochrome P-450 (CYP) isoenzyme 1A2. The major metabolites are 4,4-*bis*(4-fluorophenyl) butyric acid and 1-(4-piperidyl)-2-benzimidazolinone. The pharmacologic activity of these metabolites has not been determined; however, results of animal studies suggest that the metabolites of pimozide are inactive.

Pimozide and its metabolites are excreted principally in urine and, to a lesser extent, in feces. About 40% (range: 25–60%) of a single oral dose of the drug is excreted in urine and about 15% (range: 5–20%) in feces within 7 days; most urinary excretion occurs within 3–4 days, and most fecal excretion occurs within 3–6 days. Pimozide appears to be excreted in urine almost completely, as metabolites, with probably less than 1% excreted as unchanged drug. Fecal excretion has not been well characterized, but pimozide appears to be excreted in feces mainly as unchanged drug and to a small extent as metabolites. It is not known whether fecal excretion of the drug and metabolites represents unabsorbed drug or drug excreted via biliary elimination. In animals, pimozide and its metabolites are excreted in feces following parenteral administration, apparently via biliary elimination.

It is not known if pimozide and/or its metabolites are removed by hemodialysis or peritoneal dialysis.

Chemistry and Stability

■ **Chemistry** Pimozide is a diphenylbutylpiperidine-derivative antipsychotic agent. The drug is structurally similar to butyrophenones (e.g., haloper-

idol). Pimozide occurs as a white microcrystalline powder and has solubilities of less than 0.01 mg/mL in water and approximately 7 mg/mL in alcohol at room temperature. The drug has a pK_a of 7.32.

■ **Stability** Pimozide tablets should be stored in tight, light-resistant containers at 25°C but may be exposed to temperatures ranging from 15–30°C.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

ANOREXIGENIC AGENTS AND RESPIRATORY AND CEREBRAL STIMULANTS 28:20

AMPHETAMINES 28:20.04

Amphetamines General Statement

■ Amphetamines exhibit pharmacologic actions that include CNS and respiratory stimulation and sympathomimetic effects.

Uses

Amphetamines are used as stimulants to decrease daytime sleepiness in the management of narcolepsy. Amphetamines also are used as adjuncts to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD). Certain amphetamines also have been used as adjuncts to caloric restriction and behavioral modification in the short-term treatment of exogenous obesity. However, short-term or intermittent therapy with anorexigenic drugs is unlikely to maintain a long-term benefit, and prolonged administration of amphetamines for the treatment of obesity is not recommended. Amphetamines, particularly methamphetamine, have been misused and abused for their CNS stimulatory effects.

■ **Narcolepsy** Amphetamines are used as stimulants to decrease daytime sleepiness in the management of narcolepsy. Amphetamines should not be used to combat fatigue or exhaustion or to replace sleep in normal individuals.

Amphetamines remain the mainstay of treatment for narcolepsy based on a long record of clinical experience. However, because most clinical trials have involved small numbers of patients, the risk-to-benefit remains to be further established.

In determining the most appropriate stimulant therapy for a given patient, clinicians should consider benefit-to-risk (including adverse effect profile); drug cost, convenience of administration, and cost of ongoing care (including the possible need for laboratory monitoring).

Patients who fail to respond to an adequate trial of stimulant drug therapy should be assessed carefully for other possible causes of excessive sleepiness such as insufficient sleep, inadequate sleep hygiene, circadian rhythm disorders, obstructive sleep apnea syndrome, or periodic limb movement disorder.

Tolerance to the clinical effects may develop with long-term therapy, particularly at high dosages.

Narcolepsy rarely occurs in children, and the relative safety and efficacy of various stimulant drugs in this age group remains to be elucidated. Although amphetamines can be used, methylphenidate appears to be used most commonly based principally on extensive experience with the drug in pediatric patients with ADHD.

■ **Attention Deficit Hyperactivity Disorder** Amphetamines also are used as adjuncts to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in children, adolescents, and adults. Almost all studies comparing behavioral therapy versus stimulants alone have shown a much stronger therapeutic effect from stimulants than from behavioral therapy, and stimulants (e.g., methylphenidate, amphetamines) remain the drugs of choice for the management of ADHD. For a more detailed discussion on the management of ADHD, including the use of stimulants such as amphetamines, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.92.

Few, if any, differences have been found between amphetamines (e.g., dextroamphetamine), methylphenidate, or pemoline (no longer commercially available in the US) or various dosage forms (short-, intermediate-, or long-acting formulations) of the drugs in short-term clinical studies in children with ADHD, and the choice of stimulant therapy should be individualized. Because hepatic toxicities have been associated with pemoline, some experts recommended its use *only* in patients who failed to respond to adequate trials of methylphenidate *and* an amphetamine, as well as adequate trials of second-line therapies (e.g., tricyclic antidepressants, bupropion). However, in 2005, the US Food and Drug Administration (FDA) determined that the risk of hepatic toxicity associated with the drug outweighs its benefits and the drug no longer is commercially available in the US.

Short-term and longer-term (up to 14 months' duration) studies have shown unequivocal beneficial effects of the stimulants on the defining core symptoms of ADHD (attention and concentration, activity, distractibility, impulsivity) and associated aggressiveness during continued therapy with the drugs. Children who fail to show positive therapeutic effects or who experience intolerable adverse effects with one stimulant should be tried on an alternative stimulant since most such children will exhibit a positive response to alternative stimulants and current evidence from crossover studies supports the efficacy of different stimulants in the same child; likewise, children who fail an adequate trial of 2 stimulants should be tried on a third type or formulation of stimulant. However, stimulants usually do not normalize the entire spectrum of behavioral problems, and many children effectively treated with these drugs still manifest a higher level of some behavioral problems than children without ADHD or other behavioral disturbances. Although stimulants have been shown to remain effective over many years, long-term benefits remain to be established.

■ **Exogenous Obesity** Amphetamines also have been used as adjuncts to caloric restriction and behavioral modification in the short-term treatment of exogenous obesity. The anorexigenic effect of sympathomimetic compounds used in the treatment of obesity appears to be temporary, seldom lasting more than a few weeks, and tolerance may occur. To help bring about and maintain loss of weight, the patient must be taught to curtail overeating and to consume a suitable diet. Prolonged administration of amphetamines is not recommended; however, obesity usually is a chronic disease, and short-term or intermittent therapy with anorexigenic drugs is unlikely to maintain a long-term benefit and is not recommended. Other anorexigenic agents (e.g., amphetamine congeners such as phentermine) with better safety profiles, including reduced potentials for misuse and abuse, generally are preferred to prototype amphetamines for the management of obesity. In the past, it was suggested that combined† therapy with fenfluramine (an amphetamine congener that stimulates release of serotonin [5-HT] at synapses and selectively inhibits the reuptake of serotonin at the presynaptic serotonergic nerve endings resulting in increased postsynaptic concentrations of serotonin in the CNS) and phentermine (an amphetamine congener that inhibits uptake of norepinephrine and dopamine) may provide complementary anorexigenic effects; therefore, such combined† therapy had been used widely in the 1990s in the management of obesity. However, because accumulated data on adverse effects associated with the drugs, fenfluramine hydrochloride (Pondimin®) and its dextrorotatory isomer dexfenfluramine hydrochloride (Redux®) were withdrawn from the US market in 1997. (See Cautions.)

Currently, the only legend (prescription) anorexigenic agent labeled by the US Food and Drug Administration (FDA) for use as an adjunct to behavioral modification, caloric restriction, and exercise in the long-term management of exogenous obesity is sibutramine, a β-phenethylamine that is structurally similar to amphetamine. Sibutramine therapy is indicated for patients with no underlying risk factor, but a pretreatment body mass index (BMI) of 30 kg/m² or greater, and for those with an underlying risk factor (e.g., hypertension, diabetes mellitus, hyperlipidemia) and a pretreatment BMI of 27 kg/m² or greater. Safety and efficacy of sibutramine for use exceeding 1 year have not been adequately studied to date. It appears that the anorexigenic effect of sibutramine, similar to dexfenfluramine, is secondary to inhibition of reuptake of norepinephrine and serotonin; however, unlike dexfenfluramine, sibutramine does not cause an increase in release of serotonin from nerve cells. Orlistat (a chemically synthesized derivative of lipostatin) is used as an adjunct to behavioral modification, caloric restriction, and exercise in the management of exogenous obesity. Some clinicians state that orlistat may be used in the long-term management of obesity; however, safety and efficacy of the drug beyond 2 years of therapy have not been established. Orlistat is not an anorexigenic agent, but is a reversible inhibitor of gastric, pancreatic, and pancreatic carboxylester lipases and thus appears to block fat absorption. (See Orlistat 56:92.)

■ **Misuse and Abuse** Misuse and abuse of amphetamines, especially methamphetamine, for CNS stimulatory effects have experienced a resurgence. In large part, this resurgence has resulted from the relative ease with which methamphetamine can be synthesized clandestinely from readily available chemicals such as ephedrine or pseudoephedrine. (See Chronic Toxicity.) Recent restrictions (including enactment of the Comprehensive Methamphetamine Control Act of 1996, the Methamphetamine Anti-Proliferation Act [MAPA] of 2000, and the Combat Methamphetamine Epidemic Act of 2005) on the availability of these compounds are hoped to reverse this resurgence in misuse and abuse. For a more detailed discussion on methamphetamine abuse, see Uses: Misuse and Abuse, in Pseudoephedrine 12:12.12.

Dosage and Administration

■ **Administration** Amphetamines are administered orally. When used in the treatment of narcolepsy or attention deficit hyperactivity disorder, the initial dose is given on awakening. Because of the potential for insomnia, when amphetamines are administered in divided doses, late evening doses should be avoided. When used as an anorexigenic, the dose is usually given 30–60 minutes before meals.

rate of *N*-demethylation of the drug in the liver. The absence of either a bimodal or trimodal distribution of clearance values suggests that the rate of such metabolism may be under polygenic control. The half-life of fluoxetine reportedly is prolonged (to approximately 4–5 days) after administration of multiple versus single doses, suggesting a nonlinear pattern of drug accumulation during long-term administration. Norfluoxetine appears to exhibit dose-proportional pharmacokinetics following multiple dosing, although limited data indicate that the rate of formation of the metabolite is decreased slightly once steady-state plasma concentrations have been achieved.

Following oral administration of single doses of fluoxetine in healthy individuals, total apparent plasma clearances of fluoxetine and norfluoxetine average approximately 346 mL/minute (range: 94–703 mL/minute) and 145 mL/minute (range: 61–284 mL/minute), respectively. Limited data suggest that plasma clearance of fluoxetine decreases by approximately 75% following multiple oral doses of the drug once steady-state plasma fluoxetine concentrations have been achieved. Plasma clearances of fluoxetine and norfluoxetine also reportedly are decreased in patients with chronic liver disease (e.g., cirrhosis). Evidence from single-dose studies indicates that clearances of the drug and its principal metabolite are not altered substantially in patients with renal impairment.

The exact metabolic fate of fluoxetine has not been fully elucidated. The drug appears to be metabolized extensively, probably in the liver, to norfluoxetine and several other metabolites. Norfluoxetine (desmethylfluoxetine), the principal metabolite, is formed by *N*-demethylation of fluoxetine, which may be under polygenic control. The potency and selectivity of norfluoxetine's serotonin-reuptake inhibiting activity appear to be similar to those of the parent drug. Both fluoxetine and norfluoxetine undergo conjugation with glucuronic acid in the liver, and limited evidence from animals suggests that both the parent drug and its principal metabolite also undergo *O*-dealkylation to form *p*-trifluoromethylphenol, which subsequently appears to be metabolized to hippuric acid.

Following oral administration, fluoxetine and its metabolites are excreted principally in urine. In healthy individuals, approximately 60% of an orally administered, radiolabeled dose of fluoxetine is excreted in urine within 35 days, with approximately 72.8% of excreted drug as unidentified metabolites, 10% as norfluoxetine, 9.5% as norfluoxetine glucuronide, 5.2% as fluoxetine glucuronide, and 2.5% as unchanged drug. Approximately 12% of the dose was eliminated in feces within 28 days following oral administration, but the relative proportion of unabsorbed versus absorbed drug that is excreted in feces (e.g., via biliary elimination) is not known.

The effect of age on the elimination of fluoxetine has not been fully elucidated. Single-dose studies suggest that the pharmacokinetics of fluoxetine in healthy geriatric individuals do not differ substantially from those in younger adults. However, because the drug has a relatively long half-life and nonlinear disposition following multiple-dose administration, single-dose studies are not sufficient to exclude the possibility of altered pharmacokinetics in geriatric individuals, particularly those with systemic disease and/or in those receiving multiple medications concomitantly. The elimination half-lives of fluoxetine and norfluoxetine may be prolonged in patients with hepatic impairment. Following a single oral dose of the drug in patients with hepatic cirrhosis, the elimination half-lives of fluoxetine and norfluoxetine reportedly average approximately 7 and 12 days, respectively.

The elimination half-lives of fluoxetine and norfluoxetine do not appear to be altered substantially in patients with renal impairment following oral administration of single doses of the drug, although multiple-dose studies are needed to determine whether accumulation of the parent drug and/or its metabolites occurs during long-term therapy in such patients.

Fluoxetine and norfluoxetine are not removed substantially by hemodialysis. Because of the large volume of distribution and extensive protein binding of the drug and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion also are likely to be ineffective in removing substantial amounts of fluoxetine and norfluoxetine from the body.

Chemistry and Stability

■ **Chemistry** Fluoxetine, a selective serotonin-reuptake inhibitor (SSRI) antidepressant, is a phenylpropylamine-derivative. The drug differs structurally from other selective serotonin-reuptake inhibitor antidepressants (e.g., citalopram, paroxetine, sertraline) and also differs structurally and pharmacologically from other currently available antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors).

Fluoxetine contains a *p*-trifluoromethyl substituent that appears to contribute to the drug's high selectivity and potency for inhibiting serotonin reuptake, possibly as a result of its electron-withdrawing effect and lipophilicity. The commercially available drug is a racemic mixture of 2 optical isomers. Limited in vivo and in vitro data suggest that the pharmacologic activities of the optical isomers do not differ substantially, although the dextrorotatory isomer appears to have slightly greater serotonin-reuptake inhibiting activity and a longer duration of action than the levorotatory isomer.

Fluoxetine is commercially available as the hydrochloride salt, which occurs as a white to off-white crystalline solid and has a solubility of 14 mg/mL in water.

■ **Stability** Fluoxetine hydrochloride capsules and the oral solution should be stored in tight, light-resistant containers, both at 15–30°C. Fluoxetine tablets and delayed-release capsules should be stored at 15–30°C.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Fluoxetine Hydrochloride

Oral		
Capsules	10 mg (of fluoxetine)*	**Fluoxetine Hydrochloride Capsules**
		Prozac® Pulvules®, Dista
		Sarafem® Pulvules®, Lilly
	20 mg (of fluoxetine)*	**Fluoxetine Hydrochloride Capsules**
		Prozac® Pulvules®, Dista
		Sarafem® Pulvules®, Lilly
	40 mg (of fluoxetine)*	**Fluoxetine Hydrochloride Capsules**
		Prozac® Pulvules®, Dista
Capsules, delayed-release (containing enteric-coated pellets)	90 mg (of fluoxetine)	**Prozac® Weekly**, Dista
Solution	20 mg (of fluoxetine) per 5 mL*	**Fluoxetine Hydrochloride Oral Solution**
		Prozac®, Dista
Tablets	10 mg (of fluoxetine)*	**Fluoxetine Hydrochloride Tablets** (scored)
		Sarafem®, Warner Chilcott
	15 mg (of fluoxetine)*	**Serafem®**, Warner Chilcott
	20 mg (of fluoxetine)*	**Fluoxetine Hydrochloride Tablets**
		Sarafem®, Warner Chilcott

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Fluoxetine Hydrochloride Combinations

Oral		
Capsules	25 mg (of fluoxetine) with Olanzapine 6 mg	**Symbyax® (combination)**, Lilly
	25 mg (of fluoxetine) with Olanzapine 12 mg	**Symbyax® (combination)**, Lilly
	50 mg (of fluoxetine) with Olanzapine 6 mg	**Symbyax® (combination)**, Lilly
	50 mg (of fluoxetine) with Olanzapine 12 mg	**Symbyax® (combination)**, Lilly

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Paroxetine

■ Paroxetine hydrochloride and paroxetine mesylate, selective serotonin-reuptake inhibitors (SSRIs), are antidepressant agents.

Uses

Paroxetine is commercially available in the US as paroxetine hydrochloride (e.g., Paxil®, Paxil CR®) and as paroxetine mesylate (i.e., Pexeva®). The US Food and Drug Administration (FDA) considers paroxetine mesylate (Pexeva®) conventional tablets to be a pharmaceutical *alternative* (as described in section 505[b][2] of the Federal Food, Drug, and Cosmetic Act) and not a pharmaceutical (generic) equivalent to paroxetine hydrochloride conventional tablets (e.g., Paxil®), since both contain the same active moiety (paroxetine) but have different salts. The clinical studies that established efficacy of paroxetine in various conditions have been conducted with paroxetine hydrochloride. Because paroxetine hydrochloride and paroxetine mesylate contain the same active moiety (paroxetine), clinical efficacy is expected to be similar between the 2 different salts.

Paroxetine hydrochloride conventional tablets and oral suspension are used in the treatment of major depressive disorder, obsessive-compulsive disorder, panic disorder with or without agoraphobia, social phobia (social anxiety disorder), generalized anxiety disorder, and posttraumatic stress disorder. Paroxetine hydrochloride extended-release tablets are used in the treatment of major depressive disorder, panic disorder with or without agoraphobia, social phobia, and premenstrual dysphoric disorder (PMDD). Paroxetine mesylate conventional tablets are used in the treatment of major depressive disorder, obsessive-compulsive disorder, and panic disorder with or without agoraphobia. In addition, paroxetine has been used in the treatment of premature ejaculation†,

diabetic neuropathy†, chronic headache†, and depression associated with bipolar disorder†.

■ **Major Depressive Disorder** Paroxetine is used in the treatment of major depressive disorder. A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features, alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, see Drug Interactions: Tricyclic and Other Antidepressants, and see Drug Interactions: Lithium.)

The efficacy of paroxetine for the management of major depression has been established by placebo-controlled studies of 6 weeks' duration in adult outpatients from 18–73 years of age who met DSM-III criteria for major depressive disorder. In these studies, paroxetine hydrochloride was found to be more effective than placebo in improving scores by at least 2 on the Hamilton Depression Rating Scale (HDRS) and the Clinical Global Impression and Severity of Illness Scale. Paroxetine hydrochloride also was more effective than placebo in improving HDRS subfactor scores, including the depressed mood item, sleep disturbance factor, and the anxiety factor.

The efficacy of paroxetine hydrochloride extended-release tablets for the management of depression has been established in 2 flexible-dosage, controlled studies of 12-weeks' duration in adults 18–88 years of age who met DSM-IV criteria for major depressive disorder. In these studies, paroxetine was more effective than placebo in improving scores on the HDRS, the Hamilton depressed mood item, and the Clinical Global Impression-Severity of Illness Scale.

In a study of depressed outpatients who had responded by the end of an initial 8-week open treatment phase to paroxetine (mean dosage: approximately 30 mg daily; HDRS total score of less than 8) and were randomized to continue paroxetine or receive placebo for 1 year, the relapse rate in the paroxetine-treated patients (15%) was substantially lower than that in those who received placebo (39%). An analysis of these data for possible gender-related effects on treatment outcome did not suggest any difference in efficacy based on the gender of the patient. In controlled studies of depressed patients who had responded to a 6-week course of paroxetine or imipramine and were randomized to receive either the same antidepressant or placebo for up to 1 year, both paroxetine and imipramine were more effective than placebo in maintaining euthymia; however, paroxetine was better tolerated than imipramine during long-term therapy. While the optimum duration of paroxetine therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). In placebo-controlled studies, paroxetine has been shown to be effective for the long-term (e.g., up to 1 year) management of depression. In addition, the drug has been used in some patients for longer periods (e.g., up to 4 years) without apparent loss of clinical effect or increased toxicity. However, when paroxetine is used for extended periods, the need for continued therapy should be reassessed periodically. (See Dosage and Administration: Dosage.)

The efficacy of paroxetine as an antidepressant in hospital settings has not been studied adequately to date; however, the drug has been shown to be effective in hospitalized patients with severe depression in at least one controlled study.

As with other antidepressants, the possibility that paroxetine may precipitate hypomanic or manic attacks in patients with bipolar or other major affective disorder should be considered. Paroxetine is *not* approved for use in treating bipolar depression.

Considerations in Choosing Antidepressants A variety of antidepressant drugs are available for the treatment of major depressive disorder, including selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., desvenlafaxine, duloxetine, venlafaxine), tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine, tranylcypromine), and other antidepressants (e.g., bupropion, maprotiline, nefazodone, trazodone). Most clinical studies have shown that the antidepressant effect of usual dosages of paroxetine in patients with depression is greater than that of placebo and comparable to that of usual dosages of tricyclic antidepressants (e.g., amitriptyline, imipramine, doxepin), other SSRIs (e.g., fluoxetine, fluvoxamine, sertraline), and other antidepressants (e.g., nefazodone). The onset of antidepressant action of paroxetine appears to be comparable to that of tricyclic antidepressants and other SSRIs, although there is some evidence that the onset of action may occur slightly earlier with paroxetine than with imipramine and fluoxetine.

In general, response rates in patients with major depression are similar for currently available antidepressants, and the choice of antidepressant agent for a given patient depends principally on other factors such as potential adverse effects, safety or tolerability of these adverse effects in the individual patient, psychiatric and medical history, patient or family history of response to specific therapies, patient preference, quantity and quality of available clinical data, cost, and relative acute overdose safety. No single antidepressant can be recommended as optimal for all patients because of substantial heterogeneity in individual responses and in the nature, likelihood, and severity of adverse effects. In addition, patients vary in the degree to which certain adverse effects and other inconveniences of drug therapy (e.g., cost, dietary restrictions) affect their preferences.

In the large-scale Sequenced Treatment Alternatives to Relieve Depression (STAR*D) effectiveness trial, patients with major depressive disorder who did not respond to or could not tolerate therapy with one SSRI (citalopram) were randomized to switch to extended-release ("sustained-release") bupropion, sertraline, or extended-release venlafaxine as a second step of treatment (level 2). Remission rates as assessed by the 17-item Hamilton Rating Scale for Depression (HRSD-17) and the Quick Inventory of Depressive Symptomatology—Self Report (QIDS-SR-16) were approximately 21 and 26% for extended-release bupropion, 18 and 27% for sertraline, and 25 and 25% for extended-release venlafaxine therapy, respectively; response rates as assessed by the QIDS-SR-16 were 26, 27, and 28% for extended-release bupropion, sertraline, and extended-release venlafaxine therapy, respectively. These results suggest that after unsuccessful initial treatment of depressed patients with an SSRI, approximately 25% of patients will achieve remission after therapy is switched to another antidepressant and that either another SSRI (e.g., sertraline) or an agent from another class (e.g., bupropion, venlafaxine) may be reasonable alternative antidepressants in patients not responding to initial SSRI therapy.

Patient Tolerance Considerations. Because of differences in the adverse effect profile between SSRIs and tricyclic antidepressants, particularly less frequent anticholinergic effects, cardiovascular effects, and/or weight gain with SSRIs, these drugs may be preferred in patients in whom such effects are not tolerated or are of potential concern. The decreased incidence of anticholinergic effects associated with paroxetine and other SSRIs compared with tricyclic antidepressants is a potential advantage, since such effects may result in discontinuance of the drug early during therapy in unusually sensitive patients. In addition, some anticholinergic effects may become troublesome during long-

term tricyclic antidepressant therapy (e.g., persistent dry mouth may result in tooth decay). Although SSRIs share the same overall tolerability profile, certain patients may tolerate one drug in this class better than another. Antidepressants other than SSRIs may be preferred in patients in whom certain adverse GI effects (e.g., nausea, anorexia), nervous system effects (e.g., anxiety, nervousness, insomnia), and/or weight loss are not tolerated or are of concern, since such effects appear to occur more frequently with paroxetine and other drugs in this class.

Pediatric Considerations. The clinical presentation of depression in children and adolescents can differ from that in adults and generally varies with the age and developmental stages of the child. Younger children may exhibit behavioral problems such as social withdrawal, aggressive behavior, apathy, sleep disruption, and weight loss; adolescents may present with somatic complaints, self esteem problems, rebelliousness, poor performance in school, or a pattern of engaging in risky or aggressive behavior.

Data from controlled clinical studies evaluating various antidepressant agents in children and adolescents are less extensive than with adults, and many of these studies have methodologic limitations (e.g., nonrandomized or uncontrolled, small sample size, short duration, nonspecific inclusion criteria). However, there is some evidence that the response to antidepressants in pediatric patients may differ from that seen in adults, and caution should be used in extrapolating data from adult studies when making treatment decisions for pediatric patients. Results of several studies evaluating tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline) in preadolescent and adolescent patients with major depression indicate a lack of overall efficacy in this age group. Based on the lack of efficacy data regarding use of tricyclic antidepressants and MAO inhibitors in pediatric patients and because of the potential for life-threatening adverse effects associated with the use of these drugs, many experts consider selective serotonin-reuptake inhibitors the drugs of choice when antidepressant therapy is indicated for the treatment of major depressive disorder in children and adolescents. However, the US Food and Drug Administration (FDA) states that, while efficacy of fluoxetine has been established in pediatric patients, efficacy of other newer antidepressants (i.e., paroxetine, citalopram, desvenlafaxine, duloxetine, escitalopram, fluvoxamine, mirtazapine, nefazodone, sertraline, venlafaxine) was not conclusively established in clinical trials in pediatric patients with major depressive disorder. In addition, FDA warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) FDA currently states that anyone considering using an antidepressant in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications.)

Geriatric Considerations. The response to antidepressants in depressed geriatric patients without dementia is similar to that reported in younger adults, but depression in geriatric patients often is not recognized and is not treated. In geriatric patients with major depressive disorder, SSRIs appear to be as effective as tricyclic antidepressants but may cause fewer overall adverse effects than these other agents. Geriatric patients appear to be especially sensitive to anticholinergic (e.g., dry mouth, constipation, vision disturbance), cardiovascular, orthostatic hypotensive, and sedative effects of tricyclic antidepressants. The low incidence of anticholinergic effects associated with paroxetine and other SSRIs compared with tricyclic antidepressants is a potential advantage in geriatric patients, since such effects (e.g., constipation, dry mouth, confusion, memory impairment) may be particularly troublesome in these patients.However, SSRI therapy may be associated with other troublesome adverse effects (e.g., nausea and vomiting, agitation and akathisia, parkinsonian adverse effects, sexual dysfunction, weight loss, and hyponatremia). Some clinicians state that SSRIs including paroxetine may be preferred for treating depression in geriatric patients in whom the orthostatic hypotension associated with many antidepressants (e.g., tricyclics) potentially may result in injuries (such as severe falls). However, despite the fewer cardiovascular and anticholinergic effects associated with SSRIs, these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered at increased risk of falls and appropriate measures should be taken. In addition, clinicians prescribing SSRIs in geriatric patients should be aware of the many possible drug interactions associated with these drugs, including those involving metabolism of the drugs through the cytochrome P-450 system. (See Drug Interactions.)

Patients with dementia of the Alzheimer's type (Alzheimer's disease, presenile or senile dementia) often present with depressive symptoms, such as depressed mood, appetite loss, insomnia, fatigue, irritability, and agitation. Most experts recommend that patients with dementia of the Alzheimer's type who present with clinically important and persistent depressive symptoms be considered as candidates for pharmacotherapy even if they fail to meet the criteria for a major depressive syndrome. The goals of such therapy are to improve mood, functional status (e.g., cognition), and quality of life. Treatment of depression also may reduce other neuropsychiatric symptoms associated with depression in patients with dementia, including aggression, anxiety, apathy, and psychosis. Although patients may present with depressed mood alone, the possibility of more extensive depressive symptomatology should be considered. Therefore, patients should be evaluated and monitored carefully for indices of major depression, suicidal ideation, and neurovegetative signs since safety measures (e.g., hospitalization for suicidal ideation) and more vigorous and aggressive therapy (e.g., relatively high dosages, multiple drug trials) may be needed in some patients.

Although placebo-controlled trials of antidepressants in depressed patients with concurrent dementia have shown mixed results, the available evidence and experience with the use of antidepressants in patients with dementia of the Alzheimer's type and associated depressive manifestations indicate that depressive symptoms (including depressed mood alone and with neurovegetative changes) in such patients are responsive to antidepressant therapy. In some patients, cognitive deficits may partially or fully resolve during antidepressant therapy, but the extent of response will be limited to the degree of cognitive impairment that is directly related to depression. SSRIs such as citalopram, escitalopram, fluoxetine, paroxetine, or sertraline are generally considered as first-line agents in the treatment of depressed patients with dementia since they usually are better tolerated than some other antidepressants (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). Some possible alternative agents to SSRIs include bupropion, mirtazapine, and venlafaxine. Some geriatric patients with dementia and depression may be unable to tolerate the antidepressant dosages needed to achieve full remission. When a rapid antidepressant response is not critical, some experts therefore recommend a very gradual dosage increase to increase the likelihood that a therapeutic dosage of the SSRI or other antidepressant will be reached and tolerated. In a controlled study comparing paroxetine and imipramine in patients with coexisting depression and dementia, both drugs were found to be effective; however, paroxetine was better tolerated (fewer anticholinergic and serious adverse effects).

Cardiovascular Considerations. The relatively low incidence of adverse cardiovascular effects, including orthostatic hypotension and conduction disturbances, associated with paroxetine and other SSRIs may be advantageous in patients in whom the cardiovascular effects associated with tricyclic antidepressants may be hazardous. In a controlled trial comparing paroxetine and nortriptyline in patients with stable ischemic disease, both antidepressants were found to be effective in treating depression and neither drug substantially affected blood pressure or conduction intervals; however, paroxetine did not produce sustained effects on heart rate or rhythm or heart rate variability whereas nortriptyline increased heart rate and reduced heart rate variability. Most clinical studies of paroxetine for the management of depression did not include individuals with cardiovascular disease (e.g., those with a recent history of myocardial infarction or unstable cardiovascular disease), and further experience in such patients is necessary to confirm the relative lack of cardiotoxicity reported with the drug to date. (See Cautions: Cardiovascular Effects and see Cautions: Precautions and Contraindications.)

Sedative Considerations. Because paroxetine and other SSRIs generally are less sedating than some other antidepressants (e.g., tricyclics), some clinicians state that these drugs may be preferable in patients who do not require the sedative effects associated with many antidepressant agents or in patients who are prone to accidents; however, an antidepressant with more prominent sedative effects (e.g., trazodone) may be preferable in certain patients (e.g., those with insomnia).

Suicidal Risk Considerations. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidal thinking and behavior (suicidality) in certain patients during the early phases of treatment. FDA states that antidepressants increased the risk of suicidality in short-term studies in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older. It is currently unknown whether the suicidality risk extends to longer-term antidepressant use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression. Because the risk of suicidality in depressed patients may persist until substantial remission of depression occurs, appropriate monitoring and close observation of patients of all ages who are receiving antidepressant therapy are recommended. (See Suicidality under Cautions: Nervous System Effects, and see Cautions: Precautions and Contraindications.)

Other Considerations. Paroxetine has been effective in patients with moderate to severe depression, endogenous depression, reactive depression (including traumatic grief), depression associated with human immunodeficiency virus (HIV) infection, and depression associated with anxiety and/or agitation.

■ **Obsessive-Compulsive Disorder** Paroxetine is used in the treatment of obsessive-compulsive disorder when obsessions or compulsions cause marked distress, are time-consuming (take longer than 1 hour daily), or interfere substantially with the patient's normal routine, occupational or academic functioning, or usual social activities or relationships. Obsessions are recurrent and persistent thoughts, impulses, or images that, at some time during the disturbance, are experienced as intrusive and inappropriate (i.e., "ego dystonic") and that cause marked anxiety or distress but that are not simply excessive worries about real-life problems. Compulsions are repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) performed in response to an obsession or according to rules that must be applied rigidly (e.g., in a stereotyped fashion). Although

the behaviors or acts are aimed at preventing or reducing distress or preventing some dreaded event or situation, they either are not connected in a realistic manner with what they are designed to neutralize or prevent or are clearly excessive. At some time during the course of the disturbance, the patient, if an adult, recognizes that the obsessions or compulsions are excessive or unreasonable; children may not make such recognition.

The efficacy of paroxetine hydrochloride for the management of obsessive-compulsive disorder in adults has been established by 2 multicenter, placebo-controlled studies of 12 weeks' duration. In these clinical studies, paroxetine was more effective than placebo in reducing the severity of obsessive-compulsive manifestations in adult outpatients with moderate to severe obsessive-compulsive disorder (Yale-Brown Obsessive-Compulsive Scale [YBOCS] baseline values of 23–26). In a fixed-dose study of 12 weeks' duration involving paroxetine dosages of 20, 40, or 60 mg daily, patients receiving 40 or 60 mg of the drug daily experienced substantially greater reductions in the YBOCS total score (approximately 6 and 7 points, respectively) than those receiving paroxetine 20 mg daily (approximately 4 points) or placebo (approximately 3 points). The effective dosage of paroxetine was 40 or 60 mg daily. In a 12-week study with flexible dosing of paroxetine (20–60 mg daily) or clomipramine (25–250 mg daily) compared with placebo, paroxetine-treated patients exhibited a mean reduction of approximately 7 points on the YBOCS total score, which was substantially greater than the mean reduction of approximately 4 points in patients receiving placebo. No age- or gender-related differences in outcome were noted in either of these studies.

The efficacy of paroxetine for long-term use (i.e., longer than 12 weeks) has been demonstrated in a 6-month relapse prevention trial, which was an extension of the fixed-dose study of 12 weeks' duration in patients who had responded to paroxetine. Patients who received paroxetine relapsed substantially less frequently than those receiving placebo in a double-blind placebo-controlled study. The manufacturers and many experts state that obsessive-compulsive disorder is chronic and requires several months or longer of sustained therapy. Therefore, it is reasonable to continue therapy in responding patients. If paroxetine is used for extended periods, dosage should be adjusted so that patients are maintained on the lowest effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Results from comparative studies to date suggest that paroxetine and other SSRIs (e.g., fluoxetine, fluvoxamine, sertraline) are as effective as or somewhat less effective than clomipramine in the management of obsessive-compulsive disorder. In a pooled analysis of separate short-term (10–13 weeks) studies comparing clomipramine, fluoxetine, fluvoxamine, or sertraline with placebo, clomipramine was calculated as being more effective (as determined by measures on the YBOC scale) than SSRIs, although all drugs were superior to placebo. Like clomipramine, SSRIs reduce but do not completely eliminate obsessions and compulsions.

Many clinicians consider an SSRI (e.g., paroxetine, fluoxetine, fluvoxamine, sertraline) or clomipramine to be the drugs of choice for the pharmacologic treatment of obsessive-compulsive disorder. The decision whether to initiate therapy with an SSRI or clomipramine often is made based on the adverse effect profile of these drugs. For example, some clinicians prefer clomipramine in patients who may not tolerate the adverse effect profile of SSRIs (nausea, headache, overstimulation, sleep disturbances) while SSRIs may be useful alternatives in patients unable to tolerate the adverse effects (anticholinergic effects, cardiovascular effects, sedation) associated with clomipramine therapy. Consideration of individual patient characteristics (age, concurrent medical conditions), pharmacokinetics of the drug, potential drug interactions, and cost of therapy may also influence clinicians when selecting between SSRIs and clomipramine as first-line therapy in patients with obsessive-compulsive disorder.

Pediatric Considerations In children† with obsessive-compulsive disorder, cognitive behavioral therapy and/or serotonin-reuptake inhibitors (such as clomipramine and SSRIs) may be beneficial. Controlled studies evaluating paroxetine in this setting currently are lacking and it remains to be established whether one serotonin-reuptake inhibitor is more effective than another. Pending further data, some experts state that the choice of an agent may depend on their adverse effect profile, potential for adverse drug interactions, and the presence of comorbid conditions. Although clomipramine has been more extensively studied to date than SSRI, it has the most prominent anticholinergic effects, requires electrocardiographic (ECG) monitoring, and is the most toxic following acute overdosage. SSRIs do not require ECG monitoring; however, they are associated with headache, nausea, insomnia, and agitation. If a decision is made to initiate SSRI therapy in a child with obsessive-compulsive disorder, some experts recommend starting with a low initial dosage and then gradually increasing the dosage as tolerated. If there is no clinical response after 10–12 weeks, consideration should be given to switching to another SSRI or clomipramine. (See Cautions: Pediatric Precautions.)

Although combined clomipramine and SSRI therapy has been effective in a limited number of children and adolescents with obsessive-compulsive disorder, very close monitoring of the ECG, blood clomipramine concentrations, and vital signs is necessary because of the risks of potentially dangerous drug interactions (including serotonin syndrome) and adverse effects with such combinations. (See Drug Interactions: Serotonergic Drugs.) As in adults, the optimal duration of pharmacologic therapy in children with obsessive-compulsive disorder remains unclear. Although periodic trials of gradual withdrawal from drug therapy are advisable, some children appear to require long-term maintenance therapy to prevent relapse.

■ **Panic Disorder** Paroxetine is used in the treatment of panic disorder with or without agoraphobia. Panic disorder is characterized by the occurrence of unexpected panic attacks and associated concern about having additional attacks, worry about the implications or consequences of the attacks, and/or a clinically important change in behavior related to the attacks.

According to DSM-IV, panic disorder is characterized by recurrent unexpected panic attacks, which consist of a discrete period of intense fear or discomfort in which 4 (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes: palpitations, pounding heart, or accelerated heart rate; sweating; trembling or shaking; sensations of shortness of breath or smothering; feeling of choking; chest pain or discomfort; nausea or abdominal distress; feeling dizzy, unsteady, lightheaded, or faint; derealization (feelings of unreality) or depersonalization (being detached from oneself); fear of losing control; fear of dying; paresthesias (numbness or tingling sensations); and chills or hot flushes.

The efficacy of paroxetine hydrochloride for the management of panic disorder with or without agoraphobia has been established by multicenter, double-blind, placebo-controlled studies in adult outpatients who met DSM-IIIR criteria for panic disorder with or without agoraphobia. In a fixed-dose study of 10 weeks' duration in which paroxetine was given in dosages of 10, 20, and 40 mg daily, a substantially greater reduction in panic attack frequency from placebo was noted only in the patients receiving paroxetine 40 mg daily; at the end of the study, 76% of patients receiving paroxetine 40 mg daily were free of panic attacks compared with 44% of those receiving placebo. In 2 studies of 12 weeks' duration employing a flexible dosing schedule, greater improvement was reported in patients receiving paroxetine 10–60 mg daily than in those receiving placebo. In one study, 51% of the paroxetine recipients compared with 32% of the placebo recipients were free of panic attacks at the end of the study, and in the other study which was conducted in patients receiving standardized cognitive behavioral therapy, 33% of patients receiving paroxetine 10–60 mg daily had a reduction in panic attack frequency to 0 or 1 panic attacks during the study period compared with 14% of those receiving placebo. The mean paroxetine dosage for those completing these 2 flexible-dose studies was approximately 40 mg daily.

In these studies, paroxetine was found to be substantially more effective than placebo in the treatment of panic disorder in at least 2 out of 3 measures of panic attack frequency and on the Clinical Global Impression Severity of Illness Scale. The results of the studies conducted to date demonstrate that paroxetine reduces global anxiety, depressive symptoms, phobic avoidance, and improves overall impairment associated with panic disorder.

The efficacy of paroxetine hydrochloride extended-release tablets for the management of panic disorder with or without agoraphobia has been established in multicenter, placebo-controlled, flexible-dosage studies in patients with panic disorder with or without agoraphobia. In 2 studies, paroxetine extended-release tablets were more effective than placebo, but a third study failed to show any benefit compared with placebo.

The efficacy of paroxetine for long-term use (i.e., longer than 12 weeks) has been demonstrated in controlled studies. In a 3-month relapse prevention trial which was an extension of the 10-week, fixed-dose study, patients who were responders to paroxetine were randomized to receive either paroxetine (10, 20, or 40 mg daily) or placebo. The patients receiving long-term therapy with paroxetine relapsed substantially less frequently than those receiving placebo. In another controlled study, patients receiving paroxetine therapy for 1 year demonstrated not only long-term efficacy but also continued improvement. The manufacturers and some clinicians state that panic disorder is a chronic condition; therefore, it is reasonable to continue therapy in responding patients. Dosage adjustment may be necessary to maintain the patient on the lowest effective dosage, and patients should be reassessed periodically to determine the need for continued therapy.

Subgroup analysis in controlled studies for possible age- or gender-related effects on treatment outcome did not suggest any difference in efficacy based on either the age or sex of the patient.

The results of controlled studies suggest that paroxetine is as effective as and better tolerated than clomipramine in the treatment of panic disorder. In addition, paroxetine was found to have a more rapid onset of action than clomipramine in reducing the number of panic attacks in one study.

Unlike imipramine which reduces heart rate variability in patients with panic disorder (a condition associated with decreased heart rate variability and consequently an increased risk of serious cardiovascular problems including sudden cardiac death), paroxetine has been shown to normalize heart rate variability in a limited number of patients with panic disorder. The clinical importance of these findings with regard to potentially decreasing cardiovascular mortality in patients with panic disorder remains to be determined.

Panic disorder can be treated with cognitive and behavioral psychotherapy and/or pharmacologic therapy. There are several classes of drugs that appear to be effective in the pharmacologic management of panic disorder, including tricyclic antidepressants (e.g., imipramine, clomipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine), selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, fluoxetine, sertraline, paroxetine), and benzodiazepines (e.g., alprazolam, clonazepam). When choosing among the available drugs, clinicians should consider their acceptance and tolerability by patients; their ability to reduce or eliminate panic attacks, reduce clinically important anxiety and disability secondary to phobic avoidance, and ameliorate other common comorbid conditions (such as depression); and their ability to prevent relapse during long-term therapy. Because of their better tolerability when com-

pared with other agents (such as the tricyclic antidepressants and benzodiazepines), the lack of physical dependence problems commonly associated with benzodiazepines, and efficacy in panic disorder with comorbid conditions (e.g., depression, other anxiety disorders such as obsessive-compulsive disorder, alcoholism), many clinicians prefer SSRIs as first-line therapy in the management of panic disorder. If SSRI therapy is ineffective or is not tolerated, use of a tricyclic antidepressant or a benzodiazepine is recommended.

■ **Social Phobia** Paroxetine hydrochloride is used in the treatment of social phobia (social anxiety disorder). According to DSM-IV, social phobia is characterized by a marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. Exposure to the feared situation almost invariably provokes anxiety, which may approach the intensity of a panic attack. The feared situations are avoided or endured with intense anxiety or distress. The avoidance, fear, or anxious anticipation of encountering the social or performance situation interferes significantly with the person's daily routine, occupational or academic functioning, or social activities or relationships, or there is marked distress about having the phobias. Lesser degrees of performance anxiety or shyness generally do not require psychotherapy or pharmacologic treatment.

The efficacy of paroxetine hydrochloride in the treatment of social phobia has been established in 3 multicenter, placebo-controlled studies in adult outpatients who met DSM-IV criteria for social phobia. In 2 studies of 12 weeks' duration in which paroxetine was given in dosages ranging from 20–50 mg daily, significant improvement in the Clinical Global Impressions (CGI) Improvement score and Liebowitz Social Anxiety Scale (LSAS) were noted. In these studies, 69 or 77% of paroxetine-treated patients were CGI Improvement responders compared with 29 or 42% of placebo-treated patients. In the third study, paroxetine was given in fixed dosages of 20, 40, or 60 mg daily for 12 weeks. There was significant improvement in the CGI Improvement responder criterion and LSAS Total Score in patients receiving 20 mg daily compared with placebo. Although there were trends in superiority noted in those receiving 40 or 60 mg daily compared with placebo, the results did not reach statistical significance and there was no indication that dosages exceeding 20 mg daily provide any additional benefit.

Subgroup analysis of these controlled studies in adult outpatients with social anxiety disorder did not reveal any evidence of age- or gender-related differences in treatment outcome. Safety and efficacy of paroxetine for the treatment of social phobia in children or adolescents have not been established to date.

■ **Anxiety Disorders** Paroxetine hydrochloride is used in the management of generalized anxiety disorder. According to DSM-IV-TR, generalized anxiety disorder is characterized by excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (e.g., work or school performance). Patients with generalized anxiety disorder find it difficult to control the worry. The anxiety and worry are accompanied by at least 3 of the following somatic symptoms in adults and at least 1 of these symptoms in children: restlessness or feeling keyed up or on edge, being easily fatigued, difficulty concentrating or mind going blank, irritability, muscle tension, and sleep disturbance (e.g., difficulty falling or staying asleep, restless unsatisfying sleep). These symptoms cause clinically important distress or impairment in social, occupational, or other important areas of functioning and are not caused by direct physiologic effects of substances (e.g., medications, drugs of abuse, toxin exposure) or by a general medical condition (e.g., hyperthyroidism). Although patients with generalized anxiety disorder may have another underlying mental disorder (axis I disorder), the focus of the anxiety and worry is unrelated to the latter disorder and does not occur only during the course of a mood, psychotic, or pervasive developmental disorder.

Selective serotonin-reuptake inhibitors (SSRIs) are among several classes of antidepressants recommended by some clinicians as first-line treatment for generalized anxiety disorder because of their safety, tolerability (e.g., lack of physical dependence problems commonly associated with benzodiazepines), and proven efficacy in the treatment of depression and other anxiety disorders (e.g., obsessive-compulsive disorder, panic disorder) that frequently present as comorbid conditions in patients with generalized anxiety disorder. Because an estimated 80% of patients with generalized anxiety disorder will have a comorbid mood disorder (e.g., depression) during their lifetime, an SSRI or a drug that predominantly inhibits serotonin and norepinephrine reuptake (e.g., venlafaxine) is preferred by some clinicians for treatment of patients with long-standing generalized anxiety disorder and in those with several comorbid mood or anxiety disorders. However, the efficacy of antidepressants, including paroxetine, in the management of generalized anxiety disorder in patients with comorbid conditions such as depression has yet to be established, since such patients have been excluded from study entry, and therefore further research is needed.

Efficacy of paroxetine hydrochloride for the management of generalized anxiety disorder has been established in 2 randomized, multicenter, placebo-controlled studies of 8 weeks' duration in adult outpatients who met DSM-IV criteria for generalized anxiety disorder. One study employed fixed paroxetine dosages, and the other employed a flexible dosing schedule. In the flexible-dose study, approximately 62% of patients receiving paroxetine (20–50 mg daily; mean dosage of 26.8 mg daily) had a score of 1 ("very much improved") or 2 ("much improved") on the Clinical Global Impressions (CGI) Global Improvement scale, and approximately 36% of these patients had complete or nearly complete resolution of anxiety (defined as a Hamilton Rating Scale for Anxiety [HAM-A] total score of 7 or less), compared with approximately 47 and 23%, respectively, of patients receiving placebo. These results were similar to those seen in the fixed-dose study, in which a score of 1 or 2 on the CGI Global Improvement scale was attained by 62, 68, or 46%, respectively, and a HAM-A total score of 10 or less was attained by 49, 52, or 33%, respectively, of patients receiving paroxetine 20 or 40 mg daily or placebo. However, in a third study, reductions in HAM-A total score attained by patients receiving flexible dosages of paroxetine (20–50 mg daily; mean dosage of 23.8 mg daily) were not substantially different than those attained by patients receiving placebo. Subgroup analysis of these controlled studies in adult outpatients with generalized anxiety disorder did not reveal any evidence of gender- or race-related differences in treatment outcome.

Systematic evaluation of continuing paroxetine for periods of up to 6 months in patients with generalized anxiety disorder who had responded while taking paroxetine during an 8-week acute treatment phase has demonstrated a benefit of such maintenance therapy. In a double-blind, 24-week relapse prevention trial that was an extension of a single-blind, 8-week acute treatment study, patients who had responded to paroxetine 20–50 mg daily were randomized to receive either paroxetine at the same dosage or placebo. Relapse during the double-blind phase was defined as an increase of 2 or more points on the CGI-Severity of Illness scale to a score of 4 or higher or drug discontinuance due to lack of efficacy. The paroxetine-treated patients experienced a significantly lower relapse rate over the 24-week period compared with those receiving placebo. In addition, 73% of patients receiving a total of 32 weeks of paroxetine therapy achieved remission (defined as a HAM-A total score of 7 or less) compared with about 34% of those who received 8 weeks of therapy and then received 24 weeks of placebo. Because generalized anxiety disorder is a chronic condition, it is reasonable to continue therapy in responding patients. Dosage adjustment may be necessary to maintain patients receiving long-term paroxetine therapy on the lowest effective dosage, and patients should be reassessed periodically to determine the need for continued therapy.

Results of a comparative study indicate that the anxiolytic effects of paroxetine are comparable to those of imipramine, a tricyclic antidepressant, and slightly superior to those of 2′-chlordesmethyldiazepam, a benzodiazepine (not commercially available in the US). In this study, during the first 2 weeks of therapy, 2′-chlordesmethyldiazepam displayed greater anxiolytic efficacy, as measured by HAM-A score, than paroxetine or imipramine; however, following 8 weeks of therapy, a 50% or greater decrease in HAM-A score was attained by 68, 72, or 55% of patients receiving paroxetine, imipramine, or 2′-chlordesmethyldiazepam, respectively. Antidepressants such as paroxetine appear to affect predominantly psychic symptoms, whereas benzodiazepines such as 2′-chlordesmethyldiazepam appear to affect predominately somatic symptoms associated with generalized anxiety disorder.

■ **Posttraumatic Stress Disorder** Paroxetine hydrochloride is used in the treatment of posttraumatic stress disorder (PTSD). PTSD is an anxiety disorder that involves the development of certain characteristic symptoms following personal exposure to an extreme traumatic stressor. According to DSM-IV, PTSD requires exposure to a traumatic event(s) that involved actual or threatened death or serious injury, or threat to the physical integrity of self or others, and the response to the event must involve intense fear, helplessness, or horror (in children the response may be expressed by disorganized or agitated behavior). PTSD is characterized by persistent symptoms of *reexperiencing* the trauma (e.g., intrusive, distressing recollections of the event; recurrent distressing dreams of the event; acting or feeling as if the event were recurring including illusions, hallucinations, or flashbacks; intense distress at exposure to internal or external cues that symbolize or resemble an aspect of the event; physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the event), persistent *avoidance* of stimuli associated with the trauma and numbing of general responsiveness (e.g., efforts to avoid thoughts, feelings, or conversations related to the event; efforts to avoid activities, places, or people that arouse recollections of the event; inability to recall an important aspect of the event; markedly diminished interest or participation in significant activities; feeling of detachment or estrangement from others; restricted emotions and/or range of affect not present before the event; sense of a foreshortened future); and persistent symptoms of *increased arousal* (e.g., difficulty sleeping; irritability/outbursts of anger; difficulty concentrating; hypervigilance; exaggerated startle response). According to DSM-IV, a PTSD diagnosis requires the presence of 1 or more symptoms of *reexperiencing*, 3 or more symptoms of *avoidance*, and 2 or more symptoms of *increased arousal*, all of which must be present for at least 1 month and cause clinically important distress or impairment in social, occupational, or other important areas of functioning. PTSD, like other anxiety disorders, rarely occurs alone, and patients with PTSD often present with comorbid disorders (e.g., major depressive disorder, substance abuse disorders, panic disorder, generalized anxiety disorders, obsessive-compulsive disorder, social phobia); it is unknown whether these comorbid disorders precede or follow the onset of PTSD.

Psychotherapy alone or in combination with pharmacotherapy generally is considered the treatment of choice for PTSD. Pharmacologic therapy may be indicated in addition to psychotherapy for initial treatment of PTSD in patients who have comorbid disorders (e.g., major depressive disorder, bipolar disorder, other anxiety disorders) and also may be indicated in those who do not respond to initial treatment with psychotherapy alone. If pharmacotherapy is indicated in patients with PTSD, selective serotonin-reuptake inhibitors (SSRIs; e.g.,

fluoxetine, paroxetine, sertraline) usually are considered the drugs of choice (except in patients with bipolar disorder who require treatment with mood-stubilizing agents).

Efficacy of paroxetine hydrochloride in the treatment of PTSD has been established in 2 multicenter, placebo-controlled studies of 12 weeks' duration in adult outpatients (66–68% women) with a primary diagnosis (DSM-IV) of PTSD following physical or sexual assault (48–54%), witnessing injury or death (17–19%), serious accident or injury (6–13%), or exposure to combat (5–8%). The mean duration of PTSD for these patients was approximately 13 years and 41 or 40% of patients had secondary depressive disorders or non-PTSD anxiety disorders, respectively. In these studies, patients receiving fixed (20 or 40 mg daily) or flexible (20–50 mg daily; mean: 27.6 mg daily) dosages of paroxetine had substantially greater changes from baseline on the Clinician-Administered PTSD Scale Part 2 (CAPS-2) score, a multi-item instrument that measures 3 aspects of PTSD with the following symptom clusters: reexperiencing/intrusion, avoidance/numbing, and hyperarousal, and were more likely to have a score of 1 (very much improved) or 2 (much improved) on the Clinical Global Impression-Global Improvement Scale (CGI-I) compared with those receiving placebo. Treatment response in the fixed-dose study appeared to be unaffected by patient's gender, type of trauma, duration of PTSD, or severity of baseline PTSD or comorbid conditions. A third study, also a flexible-dose study comparing paroxetine (20–50 mg daily) with placebo, demonstrated paroxetine to be substantially superior to placebo as assessed by improvement from baseline for CAPS-2 total score, but not by proportion of responders on the CGI-I.

Use of paroxetine in the treatment of chronic PTSD did not appear to produce a complete remission in a substantial proportion of patients receiving the drug in clinical studies. Therefore, some clinicians suggest combined use of psychotherapy with pharmacotherapy in order to optimize treatment outcome; however, further studies are needed.

■ **Premenstrual Dysphoric Disorder** Like some other selective serotonin-reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline), paroxetine is used in the treatment of premenstrual dysphoric disorder (previously late luteal phase dysphoric disorder). In women suffering from severe premenstrual dysphoric disorder treated daily for 3 menstrual cycles with paroxetine, maprotiline, or placebo, paroxetine was found to be superior to maprotiline or placebo in improving symptoms associated with this disorder. In women with severe premenstrual dysphoric disorder receiving paroxetine 5–30 mg daily for 10 consecutive menstrual cycles, paroxetine also markedly reduced symptoms (premenstrual irritability, depressed mood, increase in appetite, anxiety/tension). The improvement in symptoms continued throughout the entire treatment period; sedation, dry mouth, and nausea occurred commonly but declined during therapy whereas adverse sexual effects (reduced libido, anorgasmia) persisted. Additional controlled studies are needed to determine whether the efficacy of the drug is sustained during longer-term, maintenance therapy in women with this condition. For further information on use of SSRIs in the treatment of premenstrual dysphoric disorder, see Uses: Premenstrual Dysphoric Disorder, in Fluoxetine Hydrochloride 28:16.04.20.

■ **Premature Ejaculation** Like some other SSRIs, paroxetine has been used with some success in the treatment of premature ejaculation†. In a placebo-controlled study in men with premature ejaculation, paroxetine (20 mg daily for the first week followed by 40 mg daily for 5 additional weeks) produced substantially greater clinical improvement (increased intravaginal ejaculation latency time, increased number of thrusts before ejaculation) than placebo. Nearly all the patients in this study reported some improvement in ejaculatory latency during the first week of paroxetine therapy. In an open study, paroxetine 20 mg daily improved premature ejaculation within about 14 days with all patients studied reporting a longer interval before ejaculation. When dosages of 20 or 40 mg daily were compared in patients with primary premature ejaculation, 20 mg daily was found to be sufficient; further study is needed to determine whether higher dosages may further increase ejaculation latency. In a study comparing paroxetine 20 mg daily for 6 months with paroxetine 20 mg daily for 14 days followed by 10 mg daily for a total of 6 months, both regimens were found to be similarly effective in improving premature ejaculation and were well tolerated. There is some evidence that paroxetine may be more effective than other SSRIs in terms of increasing intravaginal ejaculation latency time.

Additional studies have investigated the use of paroxetine on an "as needed" basis for the treatment of premature ejaculation. In one study, men with premature ejaculation (mean age: 39.5 years; mean pretreatment ejaculatory latency time: 0.3 minutes) were randomized to receive 20 mg of paroxetine or placebo 3–4 hours before planned intercourse; at 4 weeks, the mean ejaculatory latency time was 3.2–3.5 minutes in those receiving the drug compared with 0.45–0.6 minutes in those receiving placebo. However, mean ejaculatory latency time was even longer in another group of men (mean age: 40.5 years; mean pretreatment ejaculatory latency time: 0.5 minutes) who received an initial regimen of paroxetine 10 mg daily for 3 weeks and then received paroxetine 20 mg on an as needed basis for 4 weeks.

Further controlled studies are necessary to confirm these findings, to determine the optimal dosage regimen, and to evaluate the long-term efficacy of paroxetine in patients with this condition. Some clinicians advise that a trial with drug therapy may be particularly useful in patients with premature ejaculation who fail or refuse behavioral or psychotherapeutic treatment or when partners are unwilling to cooperate with such therapy.

■ **Diabetic Neuropathy** Tricyclic antidepressants generally have been considered a mainstay of therapy for the treatment of diabetic neuropathy. However, because of potentially improved patient tolerability, therapy with selective serotonin-reuptake inhibitors (SSRIs) or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., duloxetine, venlafaxine) has been attempted as an alternative. In a controlled study, paroxetine (40 mg daily) was effective in a limited number of patients in substantially reducing the symptoms associated with diabetic neuropathy† and was somewhat less effective but better tolerated than imipramine. Because patients who did not respond as well to paroxetine as to imipramine had lower plasma paroxetine concentrations, it was suggested that dosage adjustment based on plasma concentration monitoring potentially may be useful in the management of this condition. When compared with earlier results obtained with imipramine in the management of diabetic neuropathy, SSRIs such as citalopram, fluoxetine, paroxetine, and sertraline generally appear to be less effective but better tolerated overall. Additional study and experience are needed to elucidate the relative roles of SSRIs versus tricyclic antidepressants, SNRIs, anticonvulsants (e.g., pregabalin, gabapentin), and other forms of treatment in the management of this condition.

■ **Chronic Headache** Paroxetine has been used in a limited number of patients with chronic headache† with some success. In an open study, patients with chronic daily headache unresponsive to previous therapy were treated with paroxetine 10–50 mg daily for 3–9 months; most of the patients showed reductions in the number of headache days per month. Fatigue, insomnia, and urogenital disturbances were the most common adverse effects reported in this study. In a double-blind, crossover study in nondepressed patients with chronic tension-type headache comparing paroxetine (20–30 mg daily) and sulpiride (a dopamine antagonist; not commercially available in the US), both drugs improved headache although sulpiride appeared to provide greater relief. Additional controlled studies are needed to confirm these preliminary findings.

■ **Bipolar Disorder** Paroxetine has been used for the short-term management of acute depressive episodes in patients with bipolar disorder†. While antidepressants such as selective serotonin-reuptake inhibitors (SSRIs) have shown good efficacy in the treatment of unipolar depression, the drugs generally have been studied as adjuncts to mood stabilizing agents such as lithium or valproate in the management of bipolar disorder; antidepressant monotherapy is *not* recommended, given the risk of precipitating a switch into mania. The American Psychiatric Association (APA) currently recommends that paroxetine be reserved for patients who had an inadequate therapeutic response to optimal therapy with first-line agents (i.e., lithium, lamotrigine) or who do not tolerate these drugs. If paroxetine was effective for the management of an acute depressive episode, including during the continuation phase, then maintenance therapy with the drug should be considered to prevent recurrence of major depressive episodes. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Dosage and Administration

■ **Administration** Paroxetine hydrochloride and paroxetine mesylate are administered orally.

Paroxetine hydrochloride conventional tablets, extended-release tablets, and suspension usually are administered once daily in the morning. Since food does not appear to substantially affect GI absorption of paroxetine hydrochloride, the drug generally can be administered without regard to meals; however, administration with food may minimize adverse GI effects. The manufacturer of paroxetine hydrochloride makes no specific recommendations about administration of paroxetine with regard to food.

Paroxetine mesylate conventional tablets are administered once daily, usually in the morning, without regard to meals.

Paroxetine hydrochloride oral suspension should be shaken well just prior to administration of each dose.

Extended-release tablets of paroxetine hydrochloride should be swallowed whole and should *not* be chewed or crushed.

■ **Dosage** Paroxetine is commercially available in the US as paroxetine hydrochloride (e.g., Paxil®, Paxil CR®) and as paroxetine mesylate (i.e., Pexeva®). Conventional tablets of Paxil® and Pexeva® are *not* bioequivalent. The US Food and Drug Administration (FDA) considers paroxetine mesylate (Pexeva®) conventional tablets to be a pharmaceutical *alternative* (as described in section 505[b][2] of the Federal Food, Drug, and Cosmetic Act) and *not* a pharmaceutical (generic) equivalent to paroxetine hydrochloride conventional tablets (e.g., Paxil®), since both contain the same active moiety (paroxetine) but have different salts.

Dosages of paroxetine hydrochloride and paroxetine mesylate are expressed in terms of paroxetine.

Patients receiving paroxetine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications.)

The manufacturers recommend that an interval of at least 2 weeks elapse when switching a patient from a monoamine oxidase (MAO) inhibitor to paroxetine or when switching from paroxetine to an MAO inhibitor. For additional information on potentially serious drug interactions that may occur between paroxetine and MAO inhibitors or other serotonergic agents, see Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.

Clinical experience regarding the optimal timing of switching from other antidepressants to paroxetine therapy is limited. Therefore, care and prudent medical judgment should be exercised when switching from other antidepressants, particularly from long-acting agents (e.g., fluoxetine), to paroxetine. Because some adverse reactions resembling serotonin syndrome have developed when fluoxetine therapy has been abruptly discontinued and therapy with another serotonin-reuptake inhibitor (sertraline) initiated immediately afterward, a washout period may be advisable when transferring a patient from fluoxetine to another SSRI. However, the appropriate duration of the washout period when switching from other serotonin-reuptake inhibitors to paroxetine has not been clearly established. Pending further experience in patients being transferred from therapy with another antidepressant to paroxetine and as the clinical situation permits, it generally is recommended that the previous antidepressant be discontinued according to the recommended guidelines for the specific antidepressant prior to initiation of paroxetine therapy.

Because withdrawal effects may occur (see Cautions: Nervous System Effects and see Chronic Toxicity), abrupt discontinuance of paroxetine should be avoided. The manufacturers and some clinicians recommend that paroxetine therapy be discontinued gradually (e.g., over a period of several weeks) and the patient monitored carefully when paroxetine therapy is discontinued to prevent the possible development of withdrawal reactions. If intolerable symptoms occur following dosage reduction or upon discontinuance of treatment, paroxetine therapy may be reinstituted at the previously prescribed dosage until such symptoms abate. Clinicians may resume dosage reductions at that time but at a more gradual rate.

Major Depressive Disorder For the management of major depressive disorder in adults, the recommended initial dosage of paroxetine is 20 mg daily as conventional tablets or suspension or 25 mg daily as extended-release tablets. If no clinical improvement is apparent, dosage may be increased in increments of 10 mg daily for conventional tablets or suspension or 12.5 mg daily for extended-release tablets at intervals of not less than 1 week up to a maximum of 50 mg daily for conventional tablets or suspension or 62.5 mg daily for extended-release tablets. While a relationship between dosage and antidepressant effect has not been established, efficacy of the drug was demonstrated in clinical trials employing 20–50 mg daily dosages as conventional tablets or suspension and 25–62.5 daily dosages as extended-release tablets. Like with other antidepressants, the full antidepressant effects may be delayed.

While the optimum duration of paroxetine therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). Whether the dosage of paroxetine required to induce remission is identical to the dosage needed to maintain and/or sustain euthymia is unknown. In a controlled study, a paroxetine dosage of 40 mg daily was more effective in preventing recurrences of depression than 20 mg daily in patients with recurrent, unipolar depression. Systematic evaluation of paroxetine hydrochloride has shown that its antidepressant efficacy is maintained for periods of up to 1 year in patients receiving a mean dosage of 30 mg daily as conventional tablets or suspension, which corresponds to a 37.5 mg dosage of paroxetine extended-release tablets. In addition, the drug has been used in some patients for longer periods (e.g., up to 4 years) without apparent loss of clinical effect or increased toxicity. If paroxetine is used for extended periods, dosage should be adjusted so that the patient is maintained on the lowest effective dosage, and the need for continued therapy should be reassessed periodically.

Obsessive-Compulsive Disorder For the management of obsessive-compulsive disorder in adults, the recommended initial dosage of paroxetine is 20 mg daily as conventional tablets or suspension. If no clinical improvement is apparent, dosage may be increased in 10-mg increments at intervals of not less than 1 week. The manufacturers recommend a paroxetine dosage of 40 mg daily in the treatment of obsessive-compulsive disorder. Efficacy of the drug was demonstrated in clinical trials employing paroxetine dosages of 20–60 mg daily. The manufacturers state that paroxetine dosage should not exceed 60 mg daily.

Although the optimum duration of paroxetine therapy required to prevent recurrence of obsessive-compulsive symptoms has not been established to date, the efficacy of paroxetine for long-term use (i.e., longer than 12 weeks) has been demonstrated in a 6-month relapse prevention trial. Patients who received paroxetine relapsed substantially less frequently than those receiving placebo. The manufacturers and many clinicians state that obsessive-compulsive disorder is chronic and requires several months or longer of sustained therapy. Therefore, it is reasonable to continue therapy in responding patients. If paroxetine is used for extended periods, dosage should be adjusted so that the patient is maintained on the lowest effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Panic Disorder For the management of panic disorder in adults, the recommended initial dosage of paroxetine is 10 mg daily as conventional tablets or suspension or 12.5 mg daily as extended-release tablets. Dosage should be increased in 10-mg increments for those receiving conventional tablets or suspension or in 12.5-mg increments for those receiving extended-release tablets at intervals of not less than 1 week. The manufacturers recommend dosages of 40 mg daily for paroxetine conventional tablets or suspension in the treatment of panic disorder. Efficacy of the drug was demonstrated in clinical trials employing 10–60 mg daily as conventional tablets or suspension or 12.5–75 mg daily as extended-release tablets. The manufacturers state that paroxetine dosages should not exceed 60 mg daily for conventional tablets or suspension and 75 mg daily for extended-release tablets.

Although the optimum duration of paroxetine therapy required to prevent recurrence of panic disorder has not been established to date, the efficacy of paroxetine for long-term use (i.e., longer than 12 weeks) has been demonstrated in a 3-month relapse prevention trial. Patients who were treated with paroxetine hydrochloride conventional tablets or suspension (10–40 mg daily) relapsed substantially less frequently than those receiving placebo. The manufacturers and some clinicians state that panic disorder is a chronic condition; therefore, it is reasonable to continue therapy in responding patients. Dosage adjustment may be necessary to maintain the patient on the lowest effective dosage, and patients receiving the drug for extended periods should be reassessed periodically to determine the need for continued therapy.

Social Phobia For the management of generalized social phobia (social anxiety disorder) in adults, the recommended dosage of paroxetine (administered as paroxetine hydrochloride) is 20 mg daily as conventional tablets or suspension or 12.5 mg daily as extended-release tablets. Dosage of the extended-release tablets may be increased in increments of 12.5 mg daily at intervals of not less than 1 week. Efficacy of the drug was demonstrated in clinical trials employing dosages of 20–60 mg daily as conventional tablets or suspension or 12.5–37.5 mg daily as extended-release tablets. The manufacturer of paroxetine hydrochloride states that no additional clinical benefit was observed at dosages exceeding 20 mg daily for conventional tablets or suspension and that the maximum dosage for extended-release tablets should not exceed 37.5 mg daily.

Although the efficacy of paroxetine for long-term therapy (i.e., longer than 12 weeks) has not been demonstrated in controlled studies to date, the manufacturer of paroxetine hydrochloride states that it is reasonable to consider continuation of therapy for a patient who responds to the drug. If paroxetine is used for extended periods, dosage should be adjusted so that the patient is maintained on the lowest effective dosage, and the need for continued therapy should be reassessed periodically.

Anxiety Disorder For the management of generalized anxiety disorder in adults, the recommended initial dosage of paroxetine (administered as paroxetine hydrochloride) is 20 mg daily as conventional tablets or suspension. Although dosages of 20–50 mg daily were effective in clinical studies, there is insufficient evidence to indicate that dosages exceeding 20 mg daily provide additional clinical benefit. Dosage of paroxetine should be increased in 10-mg increments at intervals of not less than 1 week.

The optimum duration of paroxetine therapy for the management of generalized anxiety disorder has not been established to date. Because this disorder is chronic, it is reasonable to continue therapy in responding patients. In general, patients with generalized anxiety disorder usually require at least 8 weeks of treatment to achieve a Hamilton Rating Scale for Anxiety (HAM-A) score of 10 or less, which has been shown to be the score at which specific treatment effects can begin to be distinguished from nonspecific placebo effects. However, available data suggest that some patients may require an extended duration of treatment in order to achieve a HAM-A score of 7–10 or less. In a 32-week, multicenter, relapse-prevention study in outpatients with generalized anxiety disorder and a mean baseline HAM-A score of 26.5, about 34% of patients achieved remission (defined as a HAM-A total score of 7 or less) following 8 weeks of paroxetine therapy compared with 73% of patients following 32 weeks of paroxetine therapy. In addition, patients receiving long-term therapy with the drug relapsed substantially less frequently than those receiving placebo.

Because of the prolonged nature of depressive episodes in patients with generalized anxiety disorder and comorbid depression, some clinicians currently recommend that such patients be treated for at least 12 months to ensure remission of both anxiety and depression. If paroxetine is used for extended periods, dosage should be adjusted so that patients are maintained on the lowest effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Posttraumatic Stress Disorder For the management of posttraumatic stress disorder (PTSD) in adults, the recommended dosage of paroxetine (administered as paroxetine hydrochloride) is 20 mg daily as conventional tablets or suspension. Although efficacy has been established for dosages ranging from 20–50 mg daily, there is insufficient evidence to suggest a greater benefit with 40 mg daily compared with 20 mg daily. If a dosage increase above 20 mg daily is considered necessary, it should be in increments of 10 mg daily at intervals of at least 1 week.

Some clinicians suggest that an adequate trial period for determining the effectiveness of paroxetine in patients with PTSD is 8 weeks; patients who have not achieved at least a 25% reduction in PTSD symptoms at week 8 generally are unlikely to respond to continued paroxetine therapy and use of alternative agents is recommended in such patients. In addition, although the optimum duration of paroxetine therapy required to prevent recurrence of PTSD has not been established to date, some clinicians recommend up to 24 months of drug therapy in patients who achieve good response (i.e., greater than 75% reduction in PTSD symptoms and response maintained for at least 3 months). Although the efficacy of paroxetine for long-term therapy (i.e., longer than 12 weeks) has not been demonstrated in controlled studies to date, PTSD is a chronic condition for which it is reasonable to continue paroxetine therapy as long as a response is maintained. If paroxetine is used for extended periods,

dosage should be adjusted so that the patient is maintained on the lowest possible effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Premenstrual Dysphoric Disorder For the treatment of premenstrual dysphoric disorder (previously late luteal phase dysphoric disorder), the recommended initial dosage of paroxetine (administered as paroxetine hydrochloride) is 12.5 mg daily as extended-release tablets. Dosage should be increased at intervals of not less than 1 week. In clinical trials, both the 12.5-mg and 25-mg daily dosages were shown to be effective.

Efficacy of paroxetine for long-term therapy (i.e., longer than 3 menstrual cycles) has not been demonstrated in controlled studies to date. However, women commonly report that symptoms worsen with age until relieved by the onset of menopause. Therefore, the manufacturer of paroxetine hydrochloride states that it is reasonable to consider continuation of therapy for a patient who responds to the drug. Patients should be periodically reassessed to determine the need for continued treatment.

Premature Ejaculation For the treatment of premature ejaculation†, paroxetine has been given in a dosage of 10–40 mg daily to increase ejaculatory latency time. Alternatively, patients have taken paroxetine on an "as needed" basis for the treatment of premature ejaculation using 20-mg doses of the drug 3–4 hours before planned intercourse. However, one study noted more prolonged ejaculatory latency time if patients received paroxetine in a dosage of 10 mg daily for 3 weeks prior to using 20-mg doses of the drug on an as needed basis.

Diabetic Neuropathy In patients with diabetic neuropathy†, paroxetine has been given in a dosage of 40 mg daily to reduce the symptoms associated with the disease.

Chronic Headache In the management of chronic headache†, paroxetine has been given in a dosage of 10–50 mg daily for 3–9 months to reduce the number of headaches per month.

■ **Dosage in Geriatric and Debilitated Patients** In geriatric or debilitated patients, an initial paroxetine dosage of 10 mg daily as conventional tablets or suspension or 12.5 mg daily as extended-release tablets is recommended; if no clinical improvement is apparent, dosage may be titrated up to a maximum of 40 mg daily (for conventional tablets or suspension) or 50 mg (for extended-release tablets).

■ **Dosage in Renal and Hepatic Impairment** In patients with severe renal or hepatic impairment, an initial paroxetine dosage of 10 mg daily as conventional tablets or suspension or 12.5 mg daily as extended-release tablets is recommended. If no clinical improvement is apparent, dosage may be titrated with caution up to a maximum of 40 mg daily (for conventional tablets or suspension) or 50 mg (for extended-release tablets). (See Pharmacokinetics: Elimination and see Cautions: Precautions and Contraindications.)

■ **Treatment of Pregnant Women during the Third Trimester** Because some neonates exposed to paroxetine and other SSRIs or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed severe complications, consideration may be given to cautiously tapering paroxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Cautions: Pregnancy, Fertility, and Lactation.)

Cautions

The adverse effect profile of paroxetine is similar to that of other selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, sertraline). Paroxetine is commercially available in the US as paroxetine hydrochloride (e.g., Paxil®, Paxil CR®) and as paroxetine mesylate (i.e., Pexeva®). The main clinical studies with paroxetine have been conducted with paroxetine hydrochloride, and the incidences of adverse effects reported in this section are from clinical trials using the hydrochloride salt. Because paroxetine hydrochloride and paroxetine mesylate contain the same active moiety (paroxetine), tolerability is expected to be similar between the 2 different salts. However, direct comparison studies have not been conducted to date, and the possibility that differences in tolerability between paroxetine hydrochloride and paroxetine mesylate may exist should be taken into consideration.

Because paroxetine is a highly selective serotonin-reuptake inhibitor with little or no effect on other neurotransmitters, the incidence of some adverse effects commonly associated with tricyclic antidepressants, such as anticholinergic effects (dry mouth, constipation), cardiovascular effects, drowsiness, and weight gain, is lower in patients receiving paroxetine. However, certain adverse GI (e.g., nausea, anorexia) and nervous system (e.g., somnolence, anxiety, nervousness, insomnia) effects appear to occur more frequently with paroxetine and other SSRIs than with tricyclic antidepressants.

Overall, the adverse effect profile of paroxetine in patients with depression, obsessive-compulsive disorder, panic disorder, social phobia, generalized anxiety disorder, or posttraumatic stress disorder (PTSD) appears to be similar. In controlled studies, the most common adverse effects occurring more frequently in patients receiving paroxetine than in those receiving placebo included nervous system effects such as asthenia, somnolence, dizziness, insomnia, tremor, and nervousness; GI effects such as nausea, decreased appetite, constipation, diarrhea, and dry mouth; impotence, ejaculatory dysfunction (principally ejaculatory delay), and other male genital disorders; female genital disorders (principally anorgasmia or difficulty reaching climax/orgasm); and sweating. The incidence of many of these adverse effects appears to be dose related in patients with depression; however, there was no clear evidence of dose-related adverse events in patients with obsessive-compulsive disorder or social phobia. In addition, there was no clear relationship between the incidence of adverse events and dose except for asthenia, dry mouth, anxiety, decreased libido, tremor, and abnormal ejaculation in the treatment of panic disorder and asthenia, constipation, and abnormal ejaculation in the treatment of generalized anxiety disorder.

Patients receiving paroxetine may develop tolerance to some adverse effects (e.g., nausea, dizziness) with continued therapy (e.g., after 4–6 weeks); however, tolerance is less likely to develop to other adverse effects such as dry mouth, somnolence, and asthenia. During short-term (6 weeks or less) studies, nausea was the most common adverse effect, whereas during long-term studies, headache, sweating, weight gain, and constipation were among the most common. Discontinuance of paroxetine therapy was required in 20% of patients with depression, about 16% of patients with social phobia, about 12% of patients with obsessive-compulsive disorder or PTSD, about 11% of patients with generalized anxiety disorder, and about 9% of patients with panic disorder in clinical trials, principally because of adverse psychiatric (e.g., somnolence, insomnia, agitation, tremor), other nervous system (e.g., dizziness, asthenia), GI (e.g., nausea, vomiting, diarrhea, constipation, dry mouth), or male urogenital (e.g., abnormal ejaculation, impotence) effects or because of sweating.

■ **Nervous System Effects** Somnolence, which appears to be dose related, is among the most common adverse effects of paroxetine, occurring in approximately 23% of depressed patients receiving the drug in short-term controlled clinical trials. Somnolence required discontinuance of therapy in about 2% of patients. Headache occurred in about 18 or 15% of patients receiving paroxetine in short- or long-term controlled clinical trials, respectively. In addition, migraine or vascular headache has been reported in up to 1% or less than 0.1% of paroxetine-treated patients, respectively. Asthenia, which also appears to be dose related, occurred in 15% of depressed patients receiving the drug in short-term controlled clinical trials and required discontinuance of therapy in about 2% of patients.

Dizziness, which appears to be dose related, occurred in about 13% of patients receiving paroxetine in short-term controlled clinical trials. Insomnia occurred in about 13 or 8% of patients receiving the drug in short- or long-term controlled clinical trials, respectively. However, because insomnia is a symptom also associated with depression, relief of insomnia and improvement in sleep patterns may occur when clinical improvement in depression becomes apparent during antidepressant therapy. In clinical trials, less than 2% of patients discontinued paroxetine because of insomnia.

Tremor occurred in about 8%, nervousness or anxiety each in about 5%, paresthesia in about 4%, and agitation in about 2% of patients receiving paroxetine in short-term controlled clinical trials. The incidence of tremor and paresthesia may be dose related. Agitation and tremor each resulted in discontinuance of the drug in about 1% of patients receiving the drug in clinical trials. Drugged feeling or confusion occurred in about 2 or 1% of patients, respectively.

The incidence of seizures during paroxetine therapy appears to be similar to that observed during therapy with most other currently available antidepressants. Seizures, including tonic-clonic (grand mal) seizures, occurred in less than 0.1% of patients receiving paroxetine in clinical trials. (See Cautions: Precautions and Contraindications.) In addition, myoclonus has been reported in about 1% of patients receiving the drug.

Hypomania, mania, manic reaction, and manic-depressive reaction have been reported in approximately 1% of patients receiving paroxetine in short- or long-term controlled clinical trials, which is similar to the incidence reported in patients receiving active control agents (i.e., other antidepressants). The incidence of these adverse effects was 0.3% in unipolar patients receiving placebo. In a subset of patients classified as having bipolar disorder, the incidence of manic episodes was 2.2% in patients receiving paroxetine and 11.6% in patients receiving other antidepressants. (See Cautions: Precautions and Contraindications.) Such reactions have occurred in patients receiving other antidepressant agents and may be caused by antidepressant-induced functional increases in catecholamine activity within the CNS, resulting in a "switch" from depressive to manic behavior. There is some evidence that patients with bipolar disorder may be more likely to experience antidepressant-induced hypomanic or manic reactions than patients without evidence of this disorder. In addition, limited evidence suggests that such reactions may occur more frequently in bipolar depressed patients receiving tricyclics and tetracyclics (e.g., maprotiline, mianserin [not commercially available in the US]) than in those receiving SSRIs (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline). However, further studies are needed to confirm these initial findings.

Amnesia, CNS stimulation, impaired concentration; precipitation or worsening of depression, emotional lability, and vertigo each have been reported in at least 1% of patients receiving paroxetine; however, a causal relationship to the drug has not been established. Abnormal thinking, lack of emotion, neurosis, paralysis, paranoid reaction, alcohol abuse, depersonalization, delirium, euphoria, hallucinations, hostility, ataxia, dyskinesia, hyperkinesia, hypesthesia, hypokinesia, and incoordination have been reported in up to 1% of patients receiving the drug, although these adverse effects have not been definitely attributed to paroxetine.

Extrapyramidal reactions associated with paroxetine, which are uncommon, appear to be a class effect of SSRIs and dose related. Reactions occurring *early* during therapy with the drug may be secondary to preexisting parkinsonian

syndrome and/or concomitant therapy. Paroxetine and other SSRIs have been associated with the development of akathisia, which is characterized by an inner sense of restlessness and psychomotor agitation such as an inability to sit or stand still usually associated with subjective distress. Akathisia is most likely to occur within the first few weeks of therapy with these drugs. Other extrapyramidal symptoms reported in patients receiving paroxetine include dystonia, bradykinesia, cogwheel rigidity, hypertonia, oculogyric crisis (associated with concomitant use of pimozide), tremor, and trismus; however, a causal relationship to the drug has not been established.

Adverse nervous system effects reported in less than 0.1% of patients receiving paroxetine include akinesia, antisocial reaction, aphasia, choreoathetosis, circumoral paresthesias, delusions, drug dependence, dysarthria, fasciculations, gait abnormalities, hyperalgesia, hyperreflexia, decreased reflexes, hysteria, meningitis, myelitis, neurulgia, neuropathy, nystagmus, psychotic depression, stupor, and torticollis; these effects have not been definitely attributed to the drug. Fatigue also has been reported. Although a causal relationship to the drug has not been established, serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions also have been reported rarely in patients receiving paroxetine, other SSRIs, and selective serotonin- und norepinephrine-reuptake inhibitors. (See Cautions: Precautions and Contraindications, Drug Interactions: Serotonergic Drugs, and Acute Toxicity.)

Status epilepticus has been reported during postmarketing surveillance in patients receiving paroxetine, although a causal relationship to the drug has not been established. Guillain-Barré syndrome has been reported rarely in association with paroxetine; however, a causal relationship to the drug has not been clearly established.

Withdrawal Effects Withdrawal syndrome, manifested as dizziness, blurred vision, sweating, nausea, insomnia, tremor, confusion, lethargy, insomnia, sensory disturbances, anxiety or nervousness, headache, paresthesias, hypomanic-like symptoms (including hyperactivity, decreased need for sleep, irritability, agitation, aggressiveness, volatility, explosive vocal und temper outbursts), and ego-dystonic impulsive behavior (including shoplifting, homicidal impulses, suicidal impulses and gestures) following discontinuance of the drug, also has been reported in less than 0.1% of patients receiving paroxetine. Although manifestations of withdrawal generally have been mild, transient and self-limiting, abrupt discontinuance of the drug should be avoided. Some evidence suggests that the risk of withdrawal effects may be somewhat greater with paroxetine than sertraline; fluoxetine appears to be associated with the fewest withdrawal effects, possibly because of its prolonged elimination half-life. Additional clinical experience is necessary to confirm these findings. (See Chronic Toxicity.)

Suicidality The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. Patients, therefore, should be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of paroxetine therapy (i.e., the first few months) and during periods of dosage adjustments. (See Cautions: Precautions and Contraindications, Cautions: Pediatric Precautions, and Acute Toxicity.)

■ **GI Effects** Like other SSRIs (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, sertraline), paroxetine therapy is associated with a relatively high incidence of GI disturbances, principally nausea, dry mouth, and bowel abnormalities. The most frequent adverse effect associated with paroxetine therapy is nausea, which occurred in about 26% of patients receiving the drug in controlled clinical trials. Nausea generally is mild to moderate in severity and usually subsides after a few weeks of continued therapy with the drug. The incidence of nausea appears to be dose related. In clinical trials, nausea required discontinuance of paroxetine in about 3% of patients and was the most frequent adverse effect requiring discontinuance of the drug. Overall, adverse GI effects, principally nausea, required discontinuance of paroxetine therapy in about 6% of patients receiving the drug in clinical trials. While the mechanism(s) of paroxetine-induced GI effects has not been fully elucidated, they appear to arise at least in part because of increased serotonergic activity in the GI tract (which may result in stimulation of small intestine motility and inhibition of gastric and large intestine motility) and possibly because of the drug's effect on central serotonergic type 3 ($5\text{-}HT_3$) receptors.

Dry mouth occurred in about 18%, constipation in about 14%, diarrhea in about 12%, and decreased appetite in about 6% of patients receiving paroxetine in short-term controlled clinical trials. Other adverse GI effects associated with paroxetine therapy include flatulence, which occurred in 4%, and vomiting, which occurred in about 2% of patients receiving the drug in short-term controlled clinical trials. Vomiting generally is mild to moderate in severity and required discontinuance of the drug in about 1% of patients receiving the drug in controlled trials. Oropharyngeal disorders (principally lump or tightness in the throat), taste perversion, and dyspepsia were reported in about 2% and abdominal pain and increased appetite were reported in at least 1% of patients receiving paroxetine. The incidence of constipation, anorexia, decreased appetite, and dry mouth appear to be dose related.

Although a causal relationship to paroxetine has not been established, bruxism, colitis, dysphagia, eructation, gastroenteritis, gingivitis, glossitis, increased salivation, rectal hemorrhage, and ulcerative stomatitis have been reported in up to 1% of patients receiving the drug. Aphthous stomatitis, stomatitis, esophagitis, duodenitis, enteritis, peptic or gastric ulcer, ileus, peritonitis, hematemesis, bloody diarrhea, intestinal obstruction, fecal impaction or incontinence, melena, bulimia, cholelithiasis, tongue discoloration, tongue edema, mouth ulceration, loss of taste, gingival hemorrhage, salivary gland enlargement, and dental caries have been reported in less than 0.1% of patients receiving paroxetine. In addition, laryngismus has been reported during postmarketing surveillance. However, these adverse effects have not been definitely attributed to the drug.

Epidemiologic case-control and cohort design studies have suggested that SSRIs may increase the risk of upper GI bleeding. Although the precise mechanism for this increased risk remains to be clearly established, serotonin release by platelets is known to play an important role in hemostasis, and SSRIs decrease serotonin uptake from the blood by platelets thereby decreasing the amount of serotonin in platelets. In addition, concurrent use of aspirin or other nonsteroidal anti-inflammatory drugs was found to substantially increase the risk of GI bleeding in patients receiving SSRIs in 2 of these studies. Although these studies focused on upper GI bleeding, there is evidence suggesting that bleeding at other sites may be similarly potentiated. Further clinical studies are needed to determine the clinical importance of these findings. (See Cautions: Hematologic Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

■ **Dermatologic and Sensitivity Reactions** Rash, which may be maculopapular or vesiculobullous, has been reported in about 2% of patients receiving paroxetine in short-term controlled clinical trials. Pruritus has been reported in at least 1% of patients receiving the drug. In addition, allergic reactions have been reported in up to 1% of patients in clinical trials, and allergic alveolitis and anaphylaxis have been reported during postmarketing surveillance. However, these adverse effects have not been definitely attributed to paroxetine.

Adverse dermatologic effects reported in up to 1% of patients receiving paroxetine include acne, alopecia, contact dermatitis, dry skin, eczema, herpes simplex, photosensitivity, and urticaria; however, these adverse effects have not been definitely attributed to the drug. Angioedema, erythema nodosum, erythema multiforme, exfoliative dermatitis, fungal dermatitis, furunculosis, herpes zoster, hirsutism, maculopapular rash, seborrhea, skin discoloration, skin hypertrophy, decreased sweating, and skin ulcer have been reported in less than 0.1% of patients receiving the drug. In addition, toxic epidermal necrolysis has been reported rarely.

Sweating occurred in about 11–12% of patients receiving paroxetine in short- or long-term controlled clinical trials and required discontinuance of therapy in approximately 1% of patients. The incidence of sweating appears to be dose related.

■ **Metabolic and Endocrine Effects** Weight gain occurred in at least 1% of patients receiving paroxetine in controlled clinical trials. While clinically important weight loss may occur in some patients, only minimal weight loss (averaging 0.45 kg) generally occurred in up to 17% of patients receiving paroxetine in controlled clinical trials. In addition, while decreased appetite was reported in about 6% of patients receiving paroxetine in short-term clinical trials, the drug, unlike fluoxetine, does not appear to exhibit clinically important anorectic effects.

Ketosis and increased LDH concentrations have also been reported in less than 1% of paroxetine-treated patients, although a causal relationship to the drug has not been established. Thirst has been reported in up to 1% of patients receiving paroxetine, although a causal relationship to the drug has not been established. Adverse effects reported in less than 0.1% of patients receiving the drug include gout, hypercholesterolemia, hyperglycemia, hypoglycemia, and increased creatine kinase (CK, creatine phosphokinase, CPK), gamma globulin and nonprotein nitrogen concentrations; however, these adverse effects also have not been definitely attributed to paroxetine.

Diabetes mellitus, goiter, hyperthyroidism, hypothyroidism, thyroiditis, and symptoms suggestive of prolactinemia and galactorrhea have been reported in less than 0.1% of patients receiving paroxetine; however, these adverse effects have not been definitely attributed to the drug.

■ **Ocular and Otic Effects** Blurred vision, which appears to be dose related, occurred in about 4% of patients receiving paroxetine in controlled clinical trials. Adverse ocular effects reported in up to 1% of patients receiving paroxetine include abnormality of accommodation, conjunctivitis, ocular pain, mydriasis, and keratoconjunctivitis. Although a causal relationship to paroxetine has not been established, amblyopia, blepharitis, diplopia, cataract, conjunctival edema, corneal ulcer, exophthalmos, ocular hemorrhage, glaucoma, photophobia, night blindness, ptosis, retinal hemorrhage, and visual field defect, have been reported in less than 0.1% of patients receiving the drug. Anisocoria and optic neuritis also have been reported in at least one paroxetine-treated patient; these adverse effects have not been definitely attributed to the drug.

Tinnitus occurred in at least 1% of patients receiving paroxetine in controlled clinical trials. Otic pain or otitis media has been reported in up to 1% of patients receiving paroxetine. Deafness, hyperacusis, otitis externa, and parosmia have been reported in less than 0.1% of patients.

■ **Cardiovascular Effects** Paroxetine does not exhibit clinically important anticholinergic activity, and current evidence suggests that paroxetine is less cardiotoxic than most older antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors).

No clinically important changes in vital signs (systolic and diastolic blood

pressure, heart rate) were observed in patients receiving paroxetine in controlled trials. Unlike tricyclic antidepressants, which may cause characteristic ECG changes such as prolongation of PR, QRS, and QT intervals and ST-segment and T-wave abnormalities, clinically important ECG changes have not been reported during controlled clinical trials in paroxetine-treated patients. However, small but statistically significant QRS widening was reported with paroxetine relative to placebo in one study, and ECG changes occasionally have been reported in healthy individuals and patients receiving the drug. In addition, the relative safety of paroxetine in patients with underlying cardiac disease remains to be more fully elucidated.

Palpitation and vasodilation each have been reported in about 3% of patients receiving paroxetine in short-term controlled clinical trials. Unlike tricyclic antidepressants, paroxetine has been associated with hypotension (e.g., orthostatic) infrequently; in short-term controlled clinical trials, orthostatic hypotension occurred in at least 1% of patients receiving the drug. Chest pain also occurred in about 1–2% of patients in such trials. Hypertension, syncope, and tachycardia also have been reported in at least 1% of patients receiving paroxetine. Bradycardia and generalized peripheral and facial edema have been reported in up to 1% of patients receiving the drug, although a definite causal relationship to paroxetine has not been established. Angina pectoris, myocardial ischemia, myocardial infarction, cerebral ischemia, cerebrovascular accident, pallor, congestive heart failure, low cardiac output, arrhythmia nodal, supraventricular or ventricular extrasystoles, atrial fibrillation, heart block, bundle-branch block, pulmonary embolus, thrombosis, phlebitis, and varicose veins have been reported in less than 0.1% of patients receiving paroxetine; these adverse effects have not been definitely attributed to the drug.

In addition, ventricular fibrillation, ventricular tachycardia (including torsades de pointes), and pulmonary hypertension have been reported during postmarketing surveillance; however, these adverse effects have not been definitely attributed to paroxetine.

■ **Musculoskeletal Effects** Myopathy or myalgia occurred in about 2% of patients receiving paroxetine in short-term controlled clinical trials. In addition, arthralgia has been reported in at least 1% of patients receiving the drug. Myasthenia or back pain was reported in about 1% of patients receiving the drug in such trials. Arthritis or neck pain has been reported in up to 1% of patients receiving paroxetine, although a causal relationship to the drug has not been established. Arthrosis, bursitis, myositis, neck rigidity, osteoporosis, generalized spasm, tenosynovitis, and tetany have been reported in less than 0.1% of patients receiving paroxetine; these adverse effects have not been definitely attributed to the drug.

■ **Hematologic Effects** Anemia, eosinophilia, leukocytosis, leukopenia, ecchymosis, and purpura have been reported in up to 1% of patients receiving paroxetine, although a causal relationship to the drug has not been established. Altered platelet function and abnormal bleeding also have been reported. The manufacturers state that there have been several cases of abnormal bleeding (mostly ecchymosis and purpura) and a case of impaired platelet aggregation in patients receiving paroxetine to date. In one woman, widespread bruising developed on the arms, legs, and hips 15 days after paroxetine therapy was begun; the bruising subsided following discontinuance of the drug. In another female patient, spontaneous bruising of the arms and legs and excessive menstrual blood loss developed 2 weeks after starting paroxetine therapy; addition of ascorbic acid 500 mg daily improved the bleeding after 3 weeks but subsequent discontinuance of ascorbic acid led to a gradual recurrence of these symptoms. Similar reactions have been reported in several patients receiving other SSRIs (e.g., fluoxetine, fluvoxamine, sertraline). Although the precise mechanism for these reactions has not been established, it has been suggested that impaired platelet aggregation caused by platelet serotonin depletion and/or increased capillary fragility may contribute to these cases. (See Cautions: GI Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

Although a causal relationship to the drug has not been established, hemolytic anemia, impaired hematopoiesis (including aplastic anemia, pancytopenia, bone marrow aplasia, and agranulocytosis), porphyria, and thrombocytopenia have been reported during postmarketing surveillance in patients receiving paroxetine. Abnormal erythrocytes or lymphocytes; prolonged bleeding time; hypochromic anemia, iron-deficiency anemia, microcytic anemia, or normocytic anemia; eosinophilia, leukoeytosis, lymphocytosis, and monocytosis each have been reported in less than 0.1% of patients receiving paroxetine; these adverse effects have not been definitely attributed to the drug.

■ **Respiratory Effects** Respiratory disorders (principally cold symptoms and upper respiratory infections), pharyngitis and other oropharyngeal disorders (sensation of having a lump or tightness in the throat), increased cough, rhinitis, and sinusitis have been reported in at least 1% of patients receiving paroxetine in short-term controlled clinical trials. Yawning occurred in about 4% of patients receiving the drug.

Adverse effects reported in up to 1% of patients receiving paroxetine include asthma, dyspnea, epistaxis, hyperventilation, bronchitis, pneumonia, and respiratory influenza; however, a causal relationship to the drug has not been established. Other adverse respiratory effects reported in less than 0.1% of patients receiving paroxetine include emphysema, hemoptysis, hiccups, lung fibrosis, pulmonary edema, increased sputum production, stridor, and voice alteration; these adverse effects have not been definitely attributed to the drug. Pulmonary alveolitis has been reported rarely.

■ **Renal, Electrolyte, and Genitourinary Effects** ***Sexual Dysfunction*** Like other SSRIs, adverse effects on sexual function have been reported in both men and women receiving paroxetine. Although changes in sexual desire, sexual performance, and sexual satisfaction often occur as manifestations of a psychiatric disorder, they also may occur as the result of pharmacologic therapy. It is difficult to determine the true incidence and severity of adverse effects on sexual function during paroxetine therapy, in part because patients and clinicians may be reluctant to discuss these effects. Therefore, incidence data reported in product labeling and earlier studies are most likely underestimates of the true incidence of adverse sexual effects. Recent reports indicate that up to 50% of patients receiving SSRIs describe some form of sexual dysfunction during treatment and the actual incidence may be even higher. Results of some (but not all) studies in men and women suggest that paroxetine may be associated with a higher incidence of sexual dysfunction than some other currently available SSRIs.

Ejaculatory disturbances (principally ejaculatory delay), which appear to be dose related, are the most common adverse urogenital effects associated with paroxetine in males, reported by the manufacturer as occurring in about 13–28% of male patients receiving the drug compared with 0–2% of patients receiving placebo in controlled clinical studies for the treatment of depression, obsessive-compulsive disorder, panic disorder, social phobia, generalized anxiety disorder, or posttraumatic stress disorder. Abnormal ejaculation was a reason for drug discontinuance in up to about 5% of patients in these controlled clinical studies. However, the adverse effect of ejaculatory delay has been used for therapeutic benefit in the treatment of premature ejaculation. (See Uses: Premature Ejaculation.)

Decreased libido was reported in 6–15% of male patients receiving paroxetine in controlled clinical studies for the treatment of depression, obsessive-compulsive disorder, panic disorder, social phobia, generalized anxiety disorder, or PTSD compared with 0–5% of males receiving placebo. In these studies, impotence was reported in 2–9% of male patients receiving paroxetine compared with 0–3% of males receiving placebo.

In female patients receiving paroxetine in controlled clinical studies for the treatment of depression, obsessive-compulsive disorder, panic disorder, social phobia, generalized anxiety disorder, or PTSD, decreased libido was reported in 0–9% of those receiving paroxetine compared with 0–2% of women receiving placebo. In these studies, orgasmic disturbances were reported in 2–9% of female patients receiving the drug compared with 0–1% of female patients receiving placebo.

Increased libido has been reported in up to 1% of patients receiving paroxetine. Other reported adverse sexual effects include anorgasmia, erectile difficulties, and delayed orgasm. Priapism also has been reported in male patients receiving the drug.

Results of some (but not all) studies in men and women suggest that paroxetine may be associated with a higher incidence of sexual dysfunction than some other currently available SSRIs, including citalopram and sertraline. Since it is difficult to know the precise risk of sexual dysfunction associated with serotonin-reuptake inhibitors, clinicians should routinely inquire about such possible adverse effects in patients receiving these drugs.

Management of sexual dysfunction caused by SSRI therapy includes waiting for tolerance to develop; using a lower dosage of the drug; using drug holidays; delaying administration of the drug until after coitus; or changing to another antidepressant. Although further study is needed, there is some evidence that adverse sexual effects of SSRIs may be reversed by concomitant use of certain drugs, including buspirone, 5-hydroxytryptamine-2 (5-HT_2) receptor antagonists (e.g., nefazodone), 5-HT_3 receptor inhibitors (e.g., granisetron), or α_2-adrenergic receptor antagonists (e.g., yohimbine), selective phosphodiesterase (PDE) inhibitors (e.g., sildenafil), or dopamine receptor agonists (e.g., amantadine, dextroamphetamine, pemoline [no longer commercially available in the US], methylphenidate). In most patients, sexual dysfunction is fully reversed 1–3 days after discontinuance of the antidepressant.

Other Renal, Electrolyte, and Genitourinary Effects Treatment with SSRIs, including paroxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when the SSRI or SNRI was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Hyponatremia has been reported following paroxetine overdosage in a geriatric patient. Hyponatremia and SIADH in patients receiving SSRIs usually develop an average of 2 weeks after initiating therapy (range: 3–120 days). Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Discontinuance of paroxetine should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. Because geriatric patients may be at increased risk for hyponatremia associated with these drugs, clinicians prescribing paroxetine in such patients should be aware of the possibility that such reactions may occur. In addition, periodic monitoring of serum sodium concentrations (particularly during the first several months) in geriatric patients receiving SSRIs has been recommended by some clinicians.

Hyperkalemia, hypercalcemia, hyperphosphatemia, dehydration, increased BUN, hypocalcemia, and hypokalemia have been reported in less than 0.1% of patients receiving the drug; however, these adverse effects have not been definitely attributed to paroxetine.

Urinary frequency and urinary disorders (principally difficulty with micturition or urinary hesitancy) have been reported in about 3% of patients receiving paroxetine in short-term controlled clinical trials. Although a definite

causal relationship to paroxetine has not been established, amenorrhea, breast pain, menorrhagia, cystitis, urinary tract infection, dysuria, hematuria, nocturia, polyuria, pyuria, urinary incontinence, urinary retention, urinary urgency, and vaginitis have been reported in up to 1% of patients receiving the drug. In addition, spontaneous abortion, breast atrophy, vaginal hemorrhage, metrorrhagia, uterine spasm, oliguria, urethritis, salpingitis, urinary casts, renal calculus, renal pain, nephritis, vaginal candidiasis, female lactation, fibrocystic breast, mastitis, and epididymitis have been reported in less than 0.1% of patients receiving paroxetine; however, these adverse effects have not been definitely attributed to paroxetine. Breast enlargement also has been reported in some women receiving chronic therapy with paroxetine or other selective serotonin-reuptake inhibitors. In one study, approximately 40% of patients receiving either selective serotonin-reuptake inhibitors or venlafaxine reported some degree of breast enlargement; most patients with breast enlargement also experienced weight gain, and serum prolactin concentrations were increased in the paroxetine-treated women in this study.

In addition, acute renal failure and eclampsia also have been reported during postmarketing surveillance in patients receiving paroxetine; however, these adverse effects have not been definitely attributed to the drug.

■ **Hepatic Effects** Abnormal liver function test results, including elevations in serum ALT (SGOT) and AST (SGPT) concentrations, have been reported in up to 1% of patients receiving paroxetine, and rarely have been a reason for drug discontinuance. Elevated serum alkaline phosphatase concentrations, bilirubinemia, hepatitis, ascites, and jaundice have been reported in less than 0.1% of patients receiving the drug. In addition, death resulting from liver necrosis and substantially elevated serum aminotransferase (transaminase) concentrations associated with severe liver dysfunction have been reported rarely.

■ **Other Adverse Effects** Fever, influenza-like symptoms, infections, and trauma occurred in at least 2% of patients receiving paroxetine. In addition, chills, influenza, lymphadenopathy, and malaise have been reported in up to 1% of patients receiving the drug. Adrenergic syndrome, cellulitis, lymphedema, moniliasis, pelvic pain, and sepsis have been reported in less than 0.1% of patients receiving the drug, but a definite causal relationship to paroxetine has not been established. Pancreatitis also has been reported during postmarketing surveillance in association with paroxetine; however, a causal relationship to the drug has not been clearly established.

■ **Precautions and Contraindications** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Cautions: Pediatric Precautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older. It is currently unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior, as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. If a decision is made to discontinue therapy, paroxetine dosage should be tapered as rapidly as is feasible but with recognition of the risks of abrupt discontinuance. (See Dosage and Administration: Dosage.) FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Potentially life-threatening serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions have been reported with SSRIs, including paroxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) alone, but particularly with concurrent administration of other serotonergic drugs (including serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"]), drugs that impair the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), or antipsychotic agents or other dopamine antagonists. Manifestations of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. Patients receiving paroxetine should be monitored for the development of serotonin syndrome or NMS-like signs and symptoms.

Concurrent or recent (i.e., within 2 weeks) therapy with MAO inhibitors used for treatment of depression is contraindicated in patients receiving paroxetine. If concurrent therapy with paroxetine and a 5-HT_1 receptor agonist (triptan) is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated. Concomitant use of paroxetine and serotonin precursors (e.g., tryptophan) is not recommended. If signs and symptoms of serotonin syndrome or NMS develop during therapy, treatment with paroxetine and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated. (See Drug Interactions: Serotonergic Drugs.)

Because clinical experience with paroxetine in patients with concurrent systemic disease, including cardiovascular disease, hepatic impairment, or renal impairment, is limited, caution should be exercised when paroxetine is administered to patients with any systemic disease or condition that may alter metabolism of the drug or adversely affect hemodynamic function. (See Dosage and Administration: Dosage.)

Because paroxetine may cause mydriasis, the drug should be used with caution in patients with angle-closure glaucoma.

Paroxetine should be used with caution in patients with severe renal or hepatic impairment, since increased plasma concentrations of the drug may occur in such patients. (See Pharmacokinetics: Elimination and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Although current evidence suggests that paroxetine is less cardiotoxic than most older antidepressant agents (see Cautions: Cardiovascular Effects), the safety of paroxetine in patients with a recent history of myocardial infarction or unstable cardiovascular disease has not been adequately evaluated to date.

Because of the potential for adverse drug interactions, the manufacturers recommend that patients receiving paroxetine be advised to notify their clinician if they are taking or plan to take nonprescription (over-the-counter) or prescription medications or alcohol-containing beverages or preparations. Although paroxetine has not been shown to potentiate the impairment of mental and motor skills caused by alcohol, the manufacturers recommend that patients be advised to avoid alcohol while receiving the drug.

Paroxetine generally is less sedating than most other currently available antidepressants and does not appear to produce substantial impairment of cognitive or psychomotor function nor to potentiate psychomotor impairment induced by other CNS depressants. However, patients should be cautioned that paroxetine may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle), particularly at dosages of 40 mg or more daily, and to avoid such activities until they experience how the drug affects them. In addition, the possibility that paroxetine may potentiate other (i.e., nonpsychomotor) adverse nervous system effects of CNS depressants should be considered.

The manufacturers recommend that patients receiving paroxetine be advised that while they may notice improvement within 1–4 weeks after starting therapy, they should continue therapy with the drug as directed by their physician.

Seizures have been reported in patients receiving therapeutic dosages of paroxetine. Because of limited experience with paroxetine in patients with a history of seizures, the drug should be used with caution in such patients and should be discontinued if seizures occur.

Activation of mania and hypomania has occurred in patients receiving therapeutic dosages of paroxetine. The drug should be used with caution in patients with a history of mania. (See Cautions: Nervous System Effects.)

Paroxetine and other SSRIs have been associated with the development of akathisia, which is characterized by an inner sense of restlessness and psychomotor agitation such as an inability to sit or stand still usually associated with subjective distress. Akathisia is most likely to occur within the first few weeks of therapy with these drugs.

Treatment with SSRIs, including paroxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In

many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when paroxetine was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Signs and symptoms of hyponatremia include headache, difficulty concentrating, memory impairment, confusion, weakness, and unsteadiness, which may lead to falls; more severe and/or acute cases have been associated with hallucinations, syncope, seizures, coma, respiratory arrest, and death. Discontinuance of paroxetine should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. (See Cautions: Renal, Electrolyte, and Genitourinary Effects and see also Cautions: Geriatric Precautions.)

The manufacturers state that there have been several cases of abnormal bleeding (mostly ecchymosis and purpura) and a case of impaired platelet aggregation in patients receiving paroxetine. (See Cautions: Hematologic Effects.)

Because paroxetine is the active moiety in both paroxetine mesylate conventional tablets (Pexeva®) and commercially available paroxetine hydrochloride preparations (e.g., Paxil®, nonproprietary [generic] preparations), concurrent administration of paroxetine hydrochloride and paroxetine mesylate should be avoided.

Paroxetine is contraindicated in patients concurrently receiving pimozide. (See Drug Interactions: Pimozide.)

Paroxetine is contraindicated in patients concomitantly receiving thioridazine. (See Drugs Metabolized by Cytochrome P-450 [CYP] 2D6 under Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes.)

Paroxetine hydrochloride is contraindicated in patients concurrently receiving linezolid. (See Monoamine Oxidase Inhibitors under Drug Interactions: Serotonergic Drugs.)

Paroxetine also is contraindicated in patients hypersensitive to the drug or any ingredient in the formulation.

■ **Pediatric Precautions** Safety and efficacy of paroxetine in children younger than 18 years of age have not been established.

Paroxetine has not demonstrated efficacy in several placebo-controlled trials in 752 children and adolescents with major depressive disorder. Adverse effects reported in at least 2% of the paroxetine-treated pediatric patients in these trials and that occurred at least twice as frequently as in pediatric patients receiving placebo included emotional lability (including self-harm, suicidal thoughts, attempted suicide, crying, and mood fluctuations), hostility, decreased appetite, tremor, sweating, hyperkinesias, and agitation. Upon discontinuance of paroxetine in these pediatric trials following a taper phase regimen, adverse events that occurred in at least 2% of the paroxetine-treated pediatric patients and occurred at least twice as frequently as in pediatric patients receiving placebo included emotional lability (including suicidal ideation, suicide attempt, mood changes, and tearfulness), nervousness, dizziness, nausea, and abdominal pain.

In June 2003, the United Kingdom (UK) regulatory agency warned clinicians to avoid the off-label use of paroxetine for the treatment of depression in children younger than 18 years of age. This action was taken in response to concern about a possible association between selective serotonin-reuptake inhibitors and suicidal behavior, which includes a broad range of symptoms ranging from episodes of self-harm to attempted suicide. Proprietary data examined by the UK regulatory agency showed a slight increase in suicidal behavior among patients who were randomly assigned to selective serotonin-reuptake inhibitor treatment, as compared with subjects who received placebo.

The US Food and Drug Administration (FDA) determined that the available data at that time were not sufficient either to establish or to rule out an association between the use of these drugs and increased suicidal thoughts or actions by pediatric patients. However, following the results of independent classification and analysis of the suicidal events and behaviors observed in controlled studies, FDA now warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. The risk of suicidality for these drugs was identified in a pooled analysis of data from a total of 24 short-term (4–16 weeks), placebo-controlled studies of 9 antidepressants (i.e., paroxetine, bupropion, citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, sertraline, venlafaxine) in over 4400 children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders. The analysis revealed a greater risk of adverse events representing suicidal behavior or thinking (suicidality) during the first few months of treatment in pediatric patients receiving antidepressants than in those receiving placebo. However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

The risk of suicidality in the FDA's pooled analysis differed across the different psychiatric indications, with the highest incidence observed in the major depressive disorder studies. In addition, although there was considerable variation in risk among the antidepressants, a tendency toward an increase in suicidality risk in younger patients was found for almost all drugs studied. It is currently unknown whether the suicidality risk in pediatric patients extends to longer-term use (i.e., beyond several months).

As a result of this analysis and public discussion of the issue, FDA has directed manufacturers of all antidepressants to add a boxed warning to the labeling of their products to alert clinicians of this suicidality risk in children and adolescents and to recommend appropriate monitoring and close observation of patients receiving these agents. (See Cautions: Precautions and Contraindications.) The drugs that are the focus of the revised labeling are all drugs included in the general class of antidepressants, including those that have not been studied in controlled clinical trials in pediatric patients, since the available data are not adequate to exclude any single antidepressant from an increased risk. In addition to the boxed warning and other information in professional labeling on antidepressants, FDA currently recommends that a patient medication guide explaining the risks associated with the drugs be provided to the patient each time the drugs are dispensed. Caregivers of pediatric patients whose depression is persistently worse or who are experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality during antidepressant therapy should consult their clinician regarding the best course of action (e.g., whether the therapeutic regimen should be changed or paroxetine discontinued). *Patients should not discontinue use of paroxetine without first consulting their clinician; it is very important that paroxetine not be abruptly discontinued (see Dosage and Administration: Dosage), as withdrawal effects may occur.*

Anyone considering the use of paroxetine in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need.

■ **Geriatric Precautions** While safety and efficacy of paroxetine in geriatric patients have not been established specifically, 17% of patients (approximately 700) receiving the drug for depression in clinical trials were 65 years of age or older. Although no overall differences in efficacy or the adverse effect profile of paroxetine were observed between geriatric and younger patients and other clinical experience revealed no evidence of age-related differences, pharmacokinetic studies have revealed a decreased clearance of paroxetine in geriatric patients. (See Pharmacokinetics: Elimination.) For this reason, the manufacturers and some clinicians recommend initiating paroxetine therapy in patients 65 years of age or older at a lower dosage than in younger patients. (See Dosage and Administration: Dosage in Geriatric or Debilitated Patients.)

Geriatric patients appear to be more likely than younger patients to develop paroxetine-induced hyponatremia and transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Therefore, clinicians prescribing paroxetine in geriatric patients should be aware of the possibility that such reactions may occur. Periodic monitoring (especially during the first several months) of serum sodium concentrations in geriatric patients receiving the drug has been recommended by some clinicians.

In studies comparing paroxetine and various tricyclic antidepressants, including amitriptyline, clomipramine, and doxepin, in geriatric patients, paroxetine was at least as effective and as well tolerated as or better tolerated than tricyclic antidepressants. In addition, serum anticholinergicity of paroxetine was found to be substantially lower than that of nortriptyline in geriatric depressed patients; complaints of dry mouth and tachycardia also occurred more frequently in nortriptyline-treated patients than in those receiving paroxetine. These findings indicate that, at therapeutic plasma concentrations, paroxetine has approximately 20% the anticholinergic potential of nortriptyline in older patients. Overall, paroxetine was less frequently associated with dry mouth, somnolence, constipation, tachycardia, or confusion than tricyclic antidepressants, although certain adverse effects (e.g., nausea, diarrhea, headache) were more common with paroxetine. In geriatric patients with depression, paroxetine appears to be at least as effective as fluoxetine.

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Cautions: Precautions and Contraindications.)

As with other psychotropic drugs, geriatric patients receiving antidepressants appear to have an increased risk of hip fracture. Despite the fewer cardiovascular and anticholinergic effects associated with selective serotonin-reuptake inhibitors (SSRIs), these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered to be at increased risk of falls and appropriate measures should be taken.

■ **Mutagenicity and Carcinogenicity** Paroxetine was not mutagenic in several in vitro tests including the bacterial mutation assay, mouse lymphoma mutation assay, and unscheduled DNA synthesis assay. The drug also was not mutagenic in tests for cytogenetic aberrations in vivo in mouse bone marrow, in vitro in human lymphocytes, and in a dominant lethal test in rats.

Studies to determine the carcinogenic potential of paroxetine were performed in mice receiving oral dosages of 1, 5, and 25 mg/kg daily and in rats receiving dosages of 1, 5, and 20 mg/kg daily for 2 years. In mice, the maximum dosage was up to approximately 2.4 times the maximum human dose for depression, social anxiety disorder, generalized anxiety disorder, and PTSD on a mg/m^2 basis. In rats, the maximum dosage was up to approximately 3.9 times the maximum human dose for depression on a mg/m^2 basis. Because the maximum recommended human dosage for depression, social anxiety disorder, generalized anxiety disorder, and PTSD is slightly lower than that for obses-

sive-compulsive disorder (50 versus 60 mg daily, respectively), the dosages used in these carcinogenicity studies were only about 2 and 3.2 times the maximum recommended human dosage for obsessive-compulsive disorder in mice and rats, respectively. A substantially greater number of male rats in the high-dose group had reticulum cell sarcomas (1/100, 0/50, 0/50, and 4/50 for control, low-, middle-, and high-dose groups, respectively), and a substantially increased linear trend across dose groups was evident for the occurrence of lymphoreticular tumors in male rats. Female rats were not affected. Although there was a dose-related increase in the number of tumors in mice, there was no drug-related increase in the number of mice with tumors. The relationship of these findings to human exposure to paroxetine is not known.

■ **Pregnancy, Fertility, and Lactation** Some neonates exposed to paroxetine and other selective serotonin-reuptake inhibitors (SSRIs) or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed complications that occasionally have been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special care nurseries. Such complications can arise immediately upon delivery and usually last for several days or up to 2–4 weeks. Clinical findings reported to date in the neonates have included respiratory distress, cyanosis, apnea, seizures, temperature instability or fever, feeding difficulty, dehydration, excessive weight loss, vomiting, hypoglycemia, hypotonia, hypertonia, hyperreflexia, tremor, jitteriness, irritability, lethargy, reduced or lack of reaction to pain stimuli, and constant crying. These clinical features appear to be consistent with either a direct toxic effect of the SSRI or SNRI or, possibly, a drug withdrawal syndrome. It should be noted that, in some cases, the clinical picture was consistent with serotonin syndrome (see Drug Interactions: Serotonergic Drugs). When treating a pregnant woman with paroxetine during the third trimester of pregnancy, the clinician should carefully consider the potential risks and benefits of such therapy. Consideration may be given to cautiously tapering paroxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Dosage: Treatment of Pregnant Women during the Third Trimester in Dosage and Administration.)

FDA states that decisions about management of depression in pregnant women are challenging and that the patient and her clinician must carefully consider and discuss the potential benefits and risks of SSRI therapy during pregnancy for the individual woman. Two recent studies provide important information on risks associated with discontinuing or continuing antidepressant therapy during pregnancy.

The first study, which was prospective, naturalistic, and longitudinal in design, compared the potential risk of relapsed depression in pregnant women with a history of major depressive disorder who discontinued or attempted to discontinue antidepressant (SSRIs, tricyclic antidepressants, or others) therapy during pregnancy compared with that in women who continued antidepressant therapy throughout their pregnancy; all women were euthymic while receiving antidepressant therapy at the beginning of pregnancy. In this study, women who discontinued antidepressant therapy were found to be 5 times more likely to have a relapse of depression during their pregnancy than were women who continued to receive their antidepressant while pregnant, suggesting that pregnancy does not protect against a relapse of depression.

The second study suggests that infants exposed to SSRIs in late pregnancy may have an increased risk of persistent pulmonary hypertension of the newborn (PPHN), which is associated with substantial neonatal morbidity and mortality. Persistent pulmonary hypertension of the newborn occurs at a rate of 1–2 neonates per 1000 live births in the general population in the US. In this retrospective case-control study of 377 women whose infants were born with persistent pulmonary hypertension of the newborn and 836 women whose infants were born healthy, the risk for developing persistent pulmonary hypertension of the newborn was approximately sixfold higher for infants exposed to SSRIs after the twentieth week of gestation compared with infants who had not been exposed to SSRIs during this period. The study was too small to compare the risk of persistent pulmonary hypertension of the newborn associated with individual SSRIs, and the findings have not been confirmed. Although the risk of persistent pulmonary hypertension of the newborn identified in this study still is low (6–12 cases per 1000) and further study is needed, the findings add to concerns from previous reports that infants exposed to SSRIs late in pregnancy may experience adverse serotonergic effects.

Reproduction studies in rats receiving oral paroxetine dosages of 50 mg/kg daily and in rabbits receiving 6 mg/kg daily during organogenesis have been conducted. These dosages correspond to approximately 9.7 and 2.2 times the maximum recommended human dose for depression, social anxiety disorder, generalized anxiety disorder, and PTSD and approximately 8.1 and 1.9 times the maximum recommended human dose for obsessive-compulsive disorder on a mg/m^2 basis in rats and rabbits, respectively. Although these studies have not revealed evidence of teratogenicity, an increase in pup deaths was observed in rats during the first 4 days of lactation when dosing occurred during the last trimester of gestation and continued throughout lactation. This effect occurred at a dose of 1 mg/kg daily, which corresponds to 0.19 times the maximum recommended human dose for depression, social anxiety disorder, generalized anxiety disorder, and PTSD and 0.16 times the maximum recommended human dose for obsessive-compulsive disorder on a mg/m^2 basis. The no-effect dose for rat pup mortality has not been determined and the cause of these deaths is not known.

Preliminary analyses from 2 epidemiologic studies have shown that infants born to women exposed to paroxetine during the first trimester of pregnancy had an increased risk of cardiovascular malformations, principally ventricular and atrial septal defects. In one of these studies using Swedish national registry data, infants born to 6896 women exposed to antidepressants during the first trimester of pregnancy were evaluated; 5175 of the infants born to 5123 of these women were exposed to SSRIs, including 822 infants born to 815 women reporting first trimester use of paroxetine. An analysis of these data indicated that infants exposed to paroxetine during early pregnancy had an increased risk of cardiovascular malformations (principally ventricular and atrial septal defects) compared to the entire registry population. The rate of cardiovascular malformations following early pregnancy exposure to paroxetine was approximately 2% compared with 1% in the entire registry population. An analysis of the data from the same paroxetine-exposed infants revealed no increase in the overall risk of congenital malformations.

A separate retrospective cohort epidemiologic study using U.S. United Healthcare data evaluated 5956 infants born to women dispensed paroxetine (822 infants born to 815 women) or other antidepressants during the first trimester of pregnancy showed a trend toward an increased risk for cardiovascular malformations for paroxetine compared with other antidepressants. The prevalence of cardiovascular malformations following first trimester dispensing was 1.5% for paroxetine compared with 1% for other antidepressants; most of the observed cardiovascular malformations (in 9 out of 12 paroxetine-exposed infants) were ventricular septal defects. This study also demonstrated an increased risk of overall major congenital malformations (inclusive of cardiovascular malformations) for paroxetine compared with other antidepressants; the prevalence of all congenital malformations following first trimester exposure was 4% for paroxetine compared with 2% for other antidepressants.

In addition, a smaller study examining pregnancy outcomes in pregnant women exposed to paroxetine or fluoxetine who contacted two teratogen information services in Israel and Italy reported a higher overall rate of congenital malformations in infants exposed to paroxetine in the first trimester compared with infants in the control group with exposures to drugs not known to be teratogenic (5.1% and 2.6%, respectively). A higher rate of cardiovascular anomalies was also observed in the paroxetine group (1.9%) compared with the control group (0.6%) in this study. Similar trends were reported in the fluoxetine group but these did not achieve statistical significance.

Previous epidemiologic studies of pregnancy outcome following first trimester exposure to SSRIs, including paroxetine, had not revealed evidence of an increased risk of major congenital malformations. In a prospective, controlled, multicenter study, maternal use of SSRIs (paroxetine, fluvoxamine, sertraline) in a limited number of pregnant women did not appear to increase the risk of congenital malformation, miscarriage, stillbirth, or premature delivery when used during pregnancy at recommended dosages. Birth weight and gestational age in neonates exposed to the drugs were similar to those in the control group. In addition, an increased risk of major congenital malformations was not observed in infants in 2 small, case-control studies based on prospectively gathered epidemiologic data collected in women exposed to paroxetine during the first trimester of pregnancy. In another small study based on medical records review, the incidence of congenital anomalies reported in infants born to women who were treated with paroxetine and other SSRIs during pregnancy was comparable to that observed in the general population.

Based on the conflicting preliminary findings reported to date from the available studies, the manufacturer of paroxetine hydrochloride states that it is unclear whether a causal relationship exists between these congenital malformations and maternal paroxetine exposure. However, the available data indicates that the individual risk of a mother having an infant with a cardiovascular malformation following first trimester paroxetine exposure is approximately 1/50, compared with an expected rate for such defects of approximately 1/100 infants in the general population. In general, septal defects range from those that are symptomatic and require surgical intervention to those that are asymptomatic and may resolve spontaneously. The final results of recent studies and additional data relating to the use of paroxetine during pregnancy will be analyzed further once they become available to better characterize the risk for congenital malformations with paroxetine.

The manufacturers of paroxetine state that if a woman becomes pregnant while receiving paroxetine, she should be informed of the potential hazard to the fetus. Unless the potential benefits to the mother justify continuing treatment, consideration should be given to either discontinuing paroxetine therapy or switching to another antidepressant. For women who intend to become pregnant or are in their first trimester of pregnancy, the manufacturer of paroxetine hydrochloride states that paroxetine should only be initiated after consideration of the other available treatment options.

The effect of paroxetine on labor and delivery is not known. However, there have been postmarketing reports of premature births in pregnant women who have received paroxetine or other selective serotonin-reuptake inhibitors.

Reproduction studies in rats receiving paroxetine dosages of 15 mg/kg daily, which corresponds to 2.9 times the highest recommended human daily dose for depression, social anxiety disorder, generalized anxiety disorder, and PTSD and 2.4 times the highest recommended human daily dose for obsessive-compulsive disorder on a mg/m^2 basis, revealed evidence of a reduced pregnancy rate. In toxicity studies performed for 2–52 weeks in male rats receiving paroxetine, irreversible lesions in the reproductive tract were reported. These lesions consisted of vacuolation of epididymal tubular epithelium in male rats receiving paroxetine dosages of 50 mg/kg daily (9.8 times the highest recommended human daily dose in major depressive disorder, social anxiety disorder, and generalized anxiety disorder and 8.2 times the highest recommended hu-

man daily dose in obsessive-compulsive disorder and panic disorder on a mg/m² basis). In male rats receiving paroxetine dosages of 25 mg/kg daily (4.9 times the highest recommended human daily dose in major depressive disorder, social anxiety disorder, and generalized anxiety disorder and 4.1 times the highest recommended human daily dose in obsessive-compulsive disorder and panic disorder on a mg/m² basis), atrophic changes in the seminiferous tubules of the testes with arrested spermatogenesis were observed.

Paroxetine is distributed into human milk. (See Pharmacokinetics: Distribution.) Paroxetine should be used with caution in nursing women, and women should be advised to notify their clinician if they plan to breast-feed.

Drug Interactions

■ **Serotonergic Drugs** Use of selective serotonin-reuptake inhibitors (SSRIs) such as paroxetine concurrently or in close succession with other drugs that affect serotonergic neurotransmission may result in serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions. Manifestations of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). Although the syndrome appears to be relatively uncommon and usually mild in severity, serious and potentially life-threatening complications, including seizures, disseminated intravascular coagulation, respiratory failure, and severe hyperthermia, as well as death occasionally have been reported. In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. The precise mechanism of these reactions is not fully understood; however, they appear to result from excessive serotonergic activity in the CNS, probably mediated by activation of serotonin 5-HT_{1A} receptors. The possible involvement of dopamine and 5-HT_2 receptors also has been suggested, although their roles remain unclear.

Serotonin syndrome most commonly occurs when 2 or more drugs that affect serotonergic neurotransmission are administered either concurrently or in close succession. Serotonin syndrome also has been reported when paroxetine was given together with another drug that impairs the hepatic metabolism of paroxetine. Serotonergic agents include those that increase serotonin synthesis (e.g., the serotonin precursor tryptophan), stimulate synaptic serotonin release (e.g., some amphetamines, dexfenfluramine [no longer commercially available in the US], fenfluramine [no longer commercially available in the US]), inhibit the reuptake of serotonin after release (e.g., SSRIs, selective serotonin- and norepinephrine-reuptake inhibitors [SNRIs], tricyclic antidepressants, trazodone, dextromethorphan, meperidine, tramadol), decrease the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), have direct serotonin postsynaptic receptor activity (e.g., buspirone), or nonspecifically induce increases in serotonergic neuronal activity (e.g., lithium salts). Selective agonists of serotonin (5-hydroxytryptamine; 5-HT) type 1 receptors ("triptans") and dihydroergotamine, agents with serotonergic activity used in the management of migraine headache, and St. John's wort (*Hypericum perforatum*) also have been implicated in several cases of serotonin syndrome.

The combination of SSRIs and MAO inhibitors may result in serotonin syndrome or NMS-like reactions. Such reactions also have been reported in patients receiving SSRIs concomitantly with tryptophan, lithium, dextromethorphan, sumatriptan, dihydroergotamine, or antipsychotics or other dopamine antagonists. In rare cases, serotonin syndrome reportedly has occurred in patients receiving the recommended dosage of a single serotonergic agent (e.g., clomipramine) or during accidental overdosage (e.g., sertraline intoxication in a child). Some other drugs that have been implicated in precipitating symptoms suggestive of serotonin syndrome or NMS-like reactions include buspirone, bromocriptine, dextropropoxyphene, fentanyl, linezolid, methylenedioxymethamphetamine (MDMA; "ecstasy"), selegiline (a selective MAO-B inhibitor), and sibutramine (an SNRI used for the management of obesity). Other drugs that have been associated with the syndrome but for which less convincing data are available include carbamazepine and pentazocine.

Clinicians should be aware of the potential for serious, possibly fatal reactions associated with serotonin syndrome or NMS-like reactions in patients receiving 2 or more drugs that affect serotonergic neurotransmission, even if no such interactions with the specific drugs have been reported to date in the medical literature. Pending further accumulation of data, drugs that affect serotonergic neurotransmission should be used cautiously in combination and such combinations should be avoided whenever clinically possible. Serotonin syndrome may be more likely to occur when initiating therapy with a serotonergic agent, increasing the dosage, or following the addition of another serotonergic agent. Some clinicians state that patients who have experienced serotonin syndrome may be at higher risk for recurrence of the syndrome upon reinitiation of serotonergic drugs. Pending further experience in such cases, some clinicians recommend that therapy with serotonergic agents be limited following recovery. In cases in which the potential benefit of the drug is thought to outweigh the risk of serotonin syndrome, lower potency agents and reduced dosages should be used, combination serotonergic therapy should be avoided, and patients should be monitored carefully for manifestations of serotonin syndrome. If signs and symptoms of serotonin syndrome or NMS develop during therapy, treatment with paroxetine and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated.

For further information on serotonin syndrome, including manifestations and treatment, see Serotonin Syndrome under Drug Interactions: Serotonergic Drugs, in Fluoxetine Hydrochloride 28:16.04.20.

Monoamine Oxidase Inhibitors Potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions have been reported in patients receiving SSRIs in combination with an MAO inhibitor. Such reactions also have been reported in patients who recently have discontinued an SSRI and have been started on an MAO inhibitor. While there are no human data to date demonstrating such interactions with paroxetine, limited data from animal studies evaluating the effects of concomitant use of paroxetine and an MAO inhibitor suggest that these drugs may act synergistically to elevate blood pressure and produce behavioral excitation.

Because of the potential risk of serotonin syndrome or NMS-like reactions, concomitant use of paroxetine and MAO inhibitors is contraindicated. At least 2 weeks should elapse between discontinuance of MAO inhibitor therapy and initiation of paroxetine therapy and vice versa.

Linezolid. Linezolid, an anti-infective agent that is a nonselective and reversible MAO inhibitor, has been associated with drug interactions resulting in serotonin syndrome, including some associated with SSRIs, and potentially may also cause NMS-like reactions. The manufacturer of paroxetine mesylate states that the drug should be used with caution in patients receiving linezolid, and some manufacturers of paroxetine hydrochloride state that concurrent administration with linezolid is contraindicated. The manufacturer of linezolid states that, unless patients are carefully observed for signs and/or symptoms of serotonin syndrome, the drug should not be used in patients receiving SSRIs. Some clinicians suggest that linezolid only be used with caution and close monitoring in patients concurrently receiving SSRIs, and some suggest that SSRI therapy should be discontinued before linezolid is initiated and not reinitiated until 2 weeks after linezolid therapy is completed.

Moclobemide. Moclobemide (not commercially available in the US), a selective and reversible MAO-A inhibitor, has been associated with serotonin syndrome, and such reactions have been fatal in several cases in which the drug was given in combination with the SSRI citalopram or with clomipramine. Pending further experience with such combinations, some clinicians recommend that concurrent therapy with moclobemide and SSRIs be used only with extreme caution and that these drugs should have been discontinued for some time (depending on the elimination half-lives of the drug and its active metabolites) before initiating moclobemide therapy.

Selegiline. Selegiline, a selective MAO-B inhibitor used in the management of parkinsonian syndrome, has been reported to cause serotonin syndrome when used concomitantly with SSRIs (e.g., fluoxetine, paroxetine, sertraline). Although selegiline is a selective MAO-B inhibitor at therapeutic dosages, the drug appears to lose its selectivity for the MAO-B enzyme at higher dosages (e.g., those exceeding 10 mg/kg), thereby increasing the risk of serotonin syndrome in patients receiving higher dosages of the drug either alone or in combination with other serotonergic agents. The manufacturer of selegiline recommends avoiding concurrent selegiline and SSRI therapy. In addition, the manufacturer of selegiline recommends that at least 2 weeks elapse between discontinuance of selegiline and initiation of SSRI therapy.

Isoniazid. Isoniazid, an antituberculosis agent, appears to have some MAO-inhibiting activity. In addition, iproniazid (not commercially available in the US), another antituberculosis agent structurally related to isoniazid that also possesses MAO-inhibiting activity, reportedly has resulted in serotonin syndrome in at least 2 patients when given in combination with meperidine. Pending further experience, clinicians should be aware of the potential for serotonin syndrome when isoniazid is given in conjunction with SSRI therapy (such as paroxetine) or other serotonergic agents.

Other Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors Concomitant administration of paroxetine with other SSRIs or SNRIs potentially may result in serotonin syndrome or NMS-like reactions and is therefore not recommended.

Antipsychotic Agents and Other Dopamine Antagonists Concomitant use of antipsychotic agents and other dopamine antagonists with paroxetine rarely may result in potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions. If signs and symptoms of serotonin syndrome or NMS occur, treatment with paroxetine and any concurrently administered antidopaminergic or serotonergic agents should be immediately discontinued and supportive and symptomatic treatment initiated. (See Drugs Metabolized by Cytochrome P-450 [CYP] 2D6 under Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes and see Drug Interactions: Clozapine and see Drug Interactions: Pimozide.)

Tryptophan and Other Serotonin Precursors As with other serotonin-reuptake inhibitors, an interaction between paroxetine and tryptophan, a serotonin precursor, may occur during concurrent use. Adverse reactions reported to date during concomitant therapy resembled serotonin syndrome and have consisted principally of headache, nausea, sweating, and dizziness. Because of the potential risk of serotonin syndrome or NMS-like reactions, concurrent use of tryptophan or other serotonin precursors should be avoided in patients receiving paroxetine.

Sibutramine Because of the possibility of developing potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions, sibutramine should be used with caution in patients receiving paroxetine.

5-HT₁ Receptor Agonists ("Triptans") Weakness, hyperreflexia, and incoordination have been reported rarely during postmarketing surveillance

in patients receiving sumatriptan concomitantly with an SSRI (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline). Oral or subcutaneous sumatriptan and SSRIs were used concomitantly in some clinical studies without unusual adverse effects. However, an increase in the frequency of migraine attacks and a decrease in the effectiveness of sumatriptan in relieving migraine headache have been reported in a patient receiving subcutaneous injections of sumatriptan intermittently while undergoing fluoxetine therapy.

Clinicians prescribing 5-HT_1 receptor agonists, SSRIs, and SNRIs should consider that triptans often are used intermittently and that either the 5-HT_1 receptor agonist, SSRI, or SNRI may be prescribed by a different clinician. Clinicians also should weigh the potential risk of serotonin syndrome or NMS-like reactions with the expected benefit of using a triptan concurrently with SSRI or SNRI therapy. If concomitant treatment with paroxetine and a triptan is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, dosage increases, and following the addition of other serotonergic agents. Patients receiving concomitant triptan and SSRI or SNRI therapy should be informed of the possibility of serotonin syndrome or NMS-like reactions and advised to immediately seek medical attention if they experience signs or symptoms of these syndromes.

Fentanyl Because cases of serotonin syndrome have been reported in patients concurrently receiving fentanyl and SSRIs, including paroxetine, clinicians should be aware of this potential interaction and monitor patients receiving these drugs in combination for possible signs and symptoms of serotonin syndrome.

Tramadol and Other Serotonergic Drugs Because of the potential risk of serotonin syndrome or NMS-like reactions, caution is advised whenever SSRIs, including paroxetine, and SNRIs are concurrently administered with other drugs that may affect serotonergic neurotransmitter systems, including tramadol and St. John's wort (*Hypericum perforatum*).

■ **Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes** The metabolism and pharmacokinetics of paroxetine may be affected by a number of drugs that induce (e.g., phenobarbital) or inhibit (e.g., cimetidine, tricyclic antidepressants), drug-metabolizing enzymes.

Drugs Metabolized by Cytochrome P-450 (CYP) 2D6 Paroxetine, like many other antidepressants (e.g., other SSRIs, many tricyclic antidepressants), is metabolized by the drug-metabolizing cytochrome P-450 (CYP) 2D6 isoenzyme (debrisoquine hydroxylase). In addition, like many other drugs metabolized by CYP2D6, paroxetine inhibits the activity of CYP2D6 and potentially may increase plasma concentrations of concomitantly administered drugs that also are metabolized by this isoenzyme. Although similar interactions are possible with other SSRIs, there is considerable variability among the drugs in the extent to which they inhibit CYP2D6; fluoxetine and paroxetine appear to be more potent in this regard than sertraline. In most patients (greater than 90%), the CYP2D6 isoenzyme is saturated early during paroxetine therapy. At steady state when the CYP2D6 pathway is essentially saturated, paroxetine is cleared by alternative cytochrome P-450 isoenzymes which, unlike CYP2D6, show no evidence of saturation.

Concomitant administration of paroxetine with risperidone, a CYP2D6 substrate, was evaluated in one study. In 10 patients with schizophrenia or schizoaffective disorder stabilized on risperidone therapy (4–8 mg daily) who also received paroxetine (20 mg daily) for 4 weeks, mean plasma concentrations of risperidone increased approximately fourfold, mean plasma concentrations of 9-hydroxyrisperidone (the active metabolite of risperidone) decreased by approximately 10%, and concentrations of the active moiety (the sum of the plasma concentrations of risperidone and 9-hydroxyrisperidone) increased by approximately 1.4 fold. These drugs were generally well tolerated when administered concurrently, with the exception of one patient who developed parkinsonian symptoms. Although the precise mechanism for this interaction remains to be fully established, it appears that paroxetine may impair the elimination of risperidone, principally by inhibiting CYP2D6-mediated 9-hydroxylation and, to a lesser extent, by simultaneously affecting the further metabolism of 9-hydroxyrisperidone or other pathways of risperidone biotransformation. Pending further accumulation of data, some clinicians recommend careful clinical observation and possible monitoring of plasma risperidone concentrations when paroxetine and risperidone are given concurrently. Consideration also should be given to using a lower initial dosage of paroxetine (10–20 mg daily) since the inhibitory effect of paroxetine on CYP2D6 is concentration dependent.

The steady-state pharmacokinetics of atomoxetine were altered when the drug was administered at a dosage of 20 mg twice daily concurrently with paroxetine 20 mg daily in healthy adults who were extensive CYP2D6 metabolizers. Concurrent administration with paroxetine increased maximum plasma atomoxetine concentrations threefold to fourfold and steady-state area under the plasma concentration curve was increased sixfold to eightfold compared with administration of atomoxetine alone. The pharmacokinetics of paroxetine were not altered. The manufacturers of paroxetine and atomoxetine recommend that atomoxetine be administered at a reduced dosage when the drugs are administered concurrently.

Concomitant use of paroxetine with other drugs metabolized by CYP2D6 has not been systematically studied. The extent to which this potential interaction may become clinically important depends on the extent of inhibition of CYP2D6 by the antidepressant and the therapeutic index of the concomitantly administered drug. The drugs for which this potential interaction is of greatest concern are those that are metabolized principally by CYP2D6 and have a narrow therapeutic index, such as tricyclic antidepressants, class IC antiarrhythmics (e.g., propafenone, flecainide, encainide), risperidone, and some phenothiazines (e.g., perphenazine, thioridazine).

In one study, chronic dosing of paroxetine (20 mg once daily) under steady-state conditions increased single-dose desipramine (100 mg) peak plasma concentrations, AUC, and elimination half-life by an average of approximately two-, five-, and threefold, respectively. (See Drug Interactions: Tricyclic and Other Antidepressants.)

Administration of perphenazine in patients receiving paroxetine 20 mg daily for 10 days increased plasma concentrations and the adverse CNS effects of perphenazine. This interaction appears to result principally from paroxetine-induced inhibition of the CYP2D6 isoenzyme. Pending further experience with combined therapy, a reduction in perphenazine dosage may be necessary to prevent adverse CNS effects in patients receiving paroxetine.

For information on a potential interaction between paroxetine and metoprolol, see Drug Interactions: β-Adrenergic Blocking Agents.

Concurrent use of paroxetine with other drugs metabolized by CYP2D6, including certain antidepressants (e.g., nortriptyline, amitriptyline, imipramine, desipramine, fluoxetine), phenothiazines (e.g., perphenazine), and class IC antiarrhythmics, or drugs that inhibit CYP2D6 should be approached with caution. Because concomitant use of paroxetine and thioridazine may result in increased plasma concentrations of the phenothiazine and increase the risk of serious, potentially fatal, adverse cardiac effects (e.g., ventricular arrhythmias, sudden death), thioridazine should not be used concomitantly with paroxetine (see Cautions: Precautions and Contraindications). The manufacturer of paroxetine states that concurrent use of a drug metabolized by CYP2D6 may necessitate the administration of dosages of the other drugs that are lower than those usually prescribed. Furthermore, whenever paroxetine therapy is discontinued (and plasma concentrations of the drug are decreased) during concurrent therapy with another drug metabolized by CYP2D6, an increased dosage of the concurrently administered drug may be necessary.

Drugs Metabolized by Cytochrome P-450 (CYP) 3A4 Although paroxetine can inhibit the cytochrome P-450 (CYP) 3A4 isoenzyme, results of in vitro and in vivo studies indicate that the drug is a much less potent inhibitor of this enzyme than many other drugs. In an in vivo drug interaction study, concomitant administration of paroxetine and the cytochrome P-450 3A4 substrate, terfenadine (no longer commercially available in the US), had no effect on the pharmacokinetics of terfenadine. In another in vivo interaction study, ketoconazole, which is a potent inhibitor of CYP3A4 activity, was found to be at least 100 times more potent than paroxetine as an inhibitor of the metabolism of several substrates for this enzyme, including terfenadine, astemizole (no longer commercially available in the US), cisapride, triazolam, and cyclosporine. Based on the assumption that the relationship between paroxetine's inhibitory activity in vitro and its lack of effect on terfenadine's clearance in vivo predicts its effect on other CYP3A4 substrates, the manufacturer states that these data suggest that the extent of paroxetine's inhibition of CYP3A4 activity is unlikely to be of clinical importance.

Drugs Metabolized by Other Cytochrome P-450 Isoenzymes Unlike fluvoxamine, in vitro data indicate that paroxetine does not substantially inhibit the CYP1A2 isoenzyme, which is responsible for the metabolism of caffeine and numerous other substances.

Cimetidine Cimetidine is known to inhibit many cytochrome P-450 oxidative enzymes and can affect the pharmacokinetics of paroxetine. In a study in which oral paroxetine (30 mg once daily) was given for 4 weeks, steady-state plasma paroxetine concentrations were increased by approximately 50% during concomitant use of oral cimetidine (300 mg 3 times daily) for the final week. The possible effects of paroxetine on the pharmacokinetics of cimetidine have not been studied. If paroxetine and cimetidine are used concurrently, dosage adjustment of paroxetine after the initial 20-mg dose should be guided by clinical effect.

Phenobarbital Phenobarbital is known to induce many cytochrome P-450 oxidative enzymes and can affect the pharmacokinetics of paroxetine. Following administration of a single 30-mg oral dose of paroxetine in individuals who had achieved steady-state serum phenobarbital concentrations (100 mg of phenobarbital daily for 14 days), the AUC and elimination half-life of paroxetine were reduced by an average of 25 and 38%, respectively, compared with administration of paroxetine alone. The influence of paroxetine on the pharmacokinetics of phenobarbital has not been studied to date. Since paroxetine exhibits nonlinear pharmacokinetics, the results of this study may not apply in situations in which both drugs are administered chronically. The manufacturer of paroxetine states that initial dosage adjustment of paroxetine is not considered necessary in patients receiving phenobarbital, and any subsequent dosage adjustment should be guided by clinical effect.

■ **Tricyclic and Other Antidepressants** The extent to which SSRI interactions with tricyclic antidepressants may pose clinical problems depends on the degree of inhibition and the pharmacokinetics of the serotonin-reuptake inhibitor involved. In one study, daily dosing of paroxetine (20 mg once daily) under steady-state conditions increased single-dose desipramine (100 mg) peak plasma concentrations, AUC, and elimination half-life by an average of approximately 2-, 5-, and 3-fold, respectively. This interaction appears to result from paroxetine-induced inhibition of CYP2D6. Thus, the manufacturers recommend that caution be exercised during concomitant use of tricyclics with

paroxetine since paroxetine may inhibit the metabolism of the tricyclic antidepressant. In addition, plasma tricyclic concentrations may need to be monitored and the dosage of the tricyclic reduced during concomitant use. (See Drugs Metabolized by Cytochrome P-450 [CYP] 2D6 under Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes.)

Clinical experience regarding the optimal timing of switching from other antidepressants to paroxetine therapy is limited. Therefore, care and prudent medical judgment should be exercised when switching from other antidepressants to paroxetine. (See Dosage and Administration: Dosage and see also Drug Interactions: Serotonergic Drugs.)

■ **Lithium** In a multiple-dose study, there was no evidence of a pharmacokinetic or pharmacodynamic interaction between lithium and paroxetine. However, because there is little clinical experience with combined therapy and because lithium may enhance the serotonergic effects of paroxetine, potentially resulting in serotonin syndrome or NMS-like reactions, concurrent use of lithium and paroxetine should be undertaken with caution. (See Drug Interactions: Serotonergic Drugs.)

■ **Protein-bound Drugs** Because paroxetine is highly protein bound, the drug theoretically could be displaced from binding sites by, or it could displace from binding sites, other protein-bound drugs such as oral anticoagulants or digitoxin (no longer commercially available in the US). In vitro studies to date have shown that paroxetine has no effect on the protein binding of 2 highly protein-bound drugs, phenytoin and warfarin; however, preliminary data suggest that there may be a pharmacodynamic interaction between paroxetine and warfarin. Pending further accumulation of data, patients receiving paroxetine concomitantly with any highly protein-bound drug should be observed for potential adverse effects associated with combined therapy. (See Warfarin under Drug Interactions: Drugs Affecting Hemostasis.)

■ **Drugs Affecting Hemostasis** ***Warfarin*** In vitro data have shown that paroxetine has no effect on the protein binding of warfarin. However, preliminary data suggest that there may be a pharmacodynamic interaction between these drugs that causes an increased bleeding diathesis while the prothrombin time remains unchanged. An increase in mild but clinically important bleeding was observed in healthy individuals receiving paroxetine and warfarin for several days. Because of limited clinical experience to date, the concurrent use of paroxetine and warfarin should be undertaken with caution. (See Drug Interactions: Protein-bound Drugs.)

Other Drugs that Interfere with Hemostasis Epidemiologic case-control and cohort design studies that have demonstrated an association between selective serotonin-reuptake inhibitor therapy and an increased risk of upper GI bleeding also have shown that concurrent use of aspirin or other nonsteroidal anti-inflammatory drugs substantially increases the risk of GI bleeding. Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated. The precise mechanism for this increased risk remains to be clearly established; however, serotonin release by platelets is known to play an important role in hemostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets, thereby decreasing the amount of serotonin in platelets. Patients receiving paroxetine should be cautioned about the concomitant use of drugs that interfere with hemostasis, including aspirin and other nonsteroidal anti-inflammatory agents.

■ **Digoxin** The steady-state pharmacokinetics of paroxetine were not altered when administered concurrently with digoxin at steady state. The mean AUC of digoxin at steady state decreased by 15% in the presence of paroxetine. Because there is limited clinical experience to date, the manufacturers state that combined therapy with paroxetine and digoxin should be undertaken with caution.

■ **Alcohol** Paroxetine has not been shown to potentiate the impairment of mental and motor skills caused by alcohol. However, the drug's ability to reduce alcohol consumption in animals and humans suggests that there may be a serotonergically mediated, pharmacodynamic interaction between paroxetine and alcohol within the CNS. The manufacturers recommend that patients be advised to avoid alcohol while receiving paroxetine.

■ **Benzodiazepines** Under steady-state conditions, diazepam does not appear to affect the pharmacokinetics of paroxetine. The effect of paroxetine on diazepam pharmacokinetics has not been evaluated to date. Paroxetine does not appear to potentiate the CNS depressant effects of diazepam, lorazepam, or oxazepam.

■ **Clozapine** Concomitant use of SSRIs such as paroxetine in patients receiving clozapine can increase plasma concentrations of the antipsychotic agent. In a study in schizophrenic patients receiving clozapine under steady-state conditions, initiation of paroxetine therapy resulted in only minor changes in plasma concentrations of clozapine and its metabolites; however, initiation of fluvoxamine therapy resulted in increases that were threefold compared with baseline. In other published reports, concomitant use of clozapine and SSRIs (fluvoxamine, paroxetine, sertraline) resulted in modest increases (less than twofold) in clozapine and metabolite concentrations. The manufacturer of clozapine states that caution should be exercised and patients closely monitored if clozapine is used in patients receiving SSRIs, and a reduction in clozapine dosage should be considered. (See Antipsychotic Agents and Other Dopamine Antagonists under Drug Interactions: Serotonergic Drugs.)

■ **Pimozide** In a controlled study, concurrent administration of a single 2-mg dose of pimozide in healthy individuals receiving paroxetine (dosage titrated up to 60 mg daily) was associated with mean increases in the AUC and peak plasma concentrations of pimozide of 151 and 62%, respectively, compared with pimozide given alone. Because of the narrow therapeutic index of pimozide and its known ability to prolong the QT interval, concurrent administration of paroxetine and pimozide is contraindicated. (See Antipsychotic Agents and Other Dopamine Antagonists under Drug Interactions: Serotonergic Drugs.)

■ **Electroconvulsive Therapy** The effects of paroxetine in conjunction with electroconvulsive therapy (ECT) have not been systematically evaluated to date in clinical studies.

■ **β-Adrenergic Blocking Agents** In a study in which propranolol (80 mg twice daily) was given orally for 18 days, the steady-state plasma concentrations of propranolol were not affected when paroxetine (30 mg once daily) was used concurrently during the last 10 days. The manufacturers state that the effect(s) of propranolol on paroxetine have not been systematically evaluated.

Severe hypotension has been reported following the initiation of paroxetine therapy in a patient who had been receiving chronic metoprolol therapy. Metoprolol is metabolized by the CYP2D6 isoenzyme and paroxetine is known to potently inhibit this enzyme. Pending further experience with this combination, caution should be exercised when paroxetine and metoprolol are used concomitantly.

■ **Phenytoin** In vitro studies to date have shown that paroxetine has no effect on the protein binding of phenytoin. When a single 30-mg oral dose of paroxetine was administered in individuals in whom steady-state plasma phenytoin concentrations (300 mg once daily for 14 days) had been achieved, the AUC and elimination half-life of paroxetine were reduced by an average of 50 and 35%, respectively, compared with paroxetine administered alone. In another study, when a single 300-mg oral dose of phenytoin was administered to individuals in whom steady-state plasma paroxetine concentrations (30 mg once daily for 14 days) had been achieved, the AUC of phenytoin was slightly reduced (by an average of 12%) compared with phenytoin administered alone. However, because both paroxetine and phenytoin exhibit nonlinear pharmacokinetics, these studies may not address the case in which both drugs are given chronically. Elevated plasma phenytoin concentration has been reported in one patient 4 weeks after concurrent therapy with paroxetine and phenytoin. Pending further experience, the manufacturers state that initial dosage adjustments are not considered necessary during concurrent use and that any subsequent adjustments in dosage should be guided by clinical effects.

■ **Theophylline** Elevated serum theophylline concentrations associated with paroxetine therapy have been reported. Although this interaction has not been systematically studied to date, the manufacturers recommend that serum concentrations of theophylline be monitored during concomitant paroxetine therapy.

■ **Procyclidine** Multiple oral doses of paroxetine (30 mg once daily) have increased the steady-state AUC, peak concentrations, and trough concentrations of procyclidine (5 mg once daily) by 35, 37, and 67%, respectively, compared with procyclidine alone at steady state. If anticholinergic effects are observed in patients receiving concurrent therapy with these drugs, the manufacturers recommend that the procyclidine dosage be reduced.

■ **Antacids** Limited data indicate that antacids do not substantially interfere with the absorption of paroxetine following oral administration.

■ **Fosamprenavir and Ritonavir** Concurrent administration of fosamprenavir and ritonavir with paroxetine substantially decreased plasma paroxetine concentrations. The manufacturers recommend that dosage adjustments in patients receiving these drugs concurrently be guided by clinical effect (tolerability and efficacy).

Acute Toxicity

Limited information is available on the acute toxicity of paroxetine.

■ **Pathogenesis** The acute lethal dose of paroxetine in humans is not known.

■ **Manifestations** In general, overdosage of paroxetine may be expected to produce effects that are extensions of the drug's pharmacologic and adverse effects. Overdosages of paroxetine may result in somnolence, coma, nausea, tremor, tachycardia, confusion, vomiting, and dizziness. Other signs and symptoms observed in patients who received overdosages of paroxetine alone or in combination with other substances include mydriasis, convulsions (including status epilepticus), ventricular arrhythmias (including torsades de pointes), hypertension, aggressive reactions, syncope, hypotension, stupor, bradycardia, dystonia, rhabdomyolysis, symptoms of hepatic dysfunction (including hepatic failure, hepatic necrosis, jaundice, hepatitis, and hepatic steatosis), serotonin syndrome, manic reactions, myoclonus, acute renal failure, and urinary retention.

The manufacturers state that, since introduction of paroxetine in the US, 48 fatalities involving overdosages of paroxetine alone or in combination with other substances have been reported worldwide. In 145 nonfatal overdosages, most patients recovered without sequelae. One patient recovered after ingesting 2 g of paroxetine (33 times the maximum recommended daily dosage).

In a geriatric woman who ingested 360 mg of paroxetine, the initial sign

of overdosage was excessive vomiting; hyponatremia developed 5 days later and was associated with somnolence, confusion, muscle spasms, dehydration, and slow reflexes. Ecchymoses and myxedema also were observed in this patient.

In 28 children aged 10.5 months to 17 years of age who ingested an overdosage of paroxetine alone, less sedation and fewer adverse cardiovascular effects were observed when compared with tricyclic antidepressant overdosage. In children 5 years of age and younger, ingestions of 120 mg or less of paroxetine were treated with GI evacuation and minimal supportive care with favorable outcomes. In children 12 years of age and younger who ingested 600–800 mg of the drug alone, most of the patients remained asymptomatic.

■ **Treatment** Because fatalities and severe toxicity have been reported following paroxetine overdosage, particularly in large overdosage and when taken with other drugs or alcohol, some clinicians recommend that any overdosage involving the drug be managed aggressively. Because suicidal ingestion often involves more than one drug, clinicians treating paroxetine overdosage should be alert to possible manifestations caused by drugs other than paroxetine. The manufacturers specifically caution about patients who are currently receiving or recently have taken paroxetine who might ingest either accidentally or intentionally excessive quantities of a tricyclic antidepressant. In such cases, accumulation of both the tricyclic and its active metabolite may increase the possibility of clinically important sequelae and lengthen the time needed for close medical supervision. (See Drug Interactions: Tricyclic and Other Antidepressants.)

Clinicians also should consider the possibility of serotonin syndrome or NMS-like reactions in patients presenting with similar clinical features and a recent history of paroxetine ingestion and/or ingestion of other serotonergic and/or antipsychotic agents or other dopamine antagonists. (See Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.)

Management of paroxetine overdosage generally involves symptomatic and supportive care. A patent airway should be established and maintained, and adequate oxygenation and ventilation should be ensured. An ECG should be taken and monitoring of cardiac function should be instituted if there is any evidence of abnormality. Frequent vital sign monitoring and close observation of the patient is necessary. There is no specific antidote for paroxetine intoxication.

Following recent (i.e., within 4 hours) ingestion of a potentially toxic amount of paroxetine and in the absence of signs and symptoms of cardiac toxicity, the stomach should be emptied immediately by inducing emesis or by gastric lavage. If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of gastric contents. Since administration of activated charcoal (which may be used in conjunction with sorbitol) may be as or more effective than induction of emesis or gastric lavage, its use has been recommended either in the initial management of paroxetine overdosage or following induction of emesis or gastric lavage in patients who have ingested a potentially toxic quantity of the drug. In the past, the manufacturer of paroxetine hydrochloride suggested that 20–30 g of activated charcoal be administered following gastric evacuation every 4–6 hours during the first 24–48 hours following ingestion.

Because of the large volume of distribution of paroxetine and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion are unlikely to be effective in removing substantial amounts of paroxetine from the body.

Clinicians should consult a poison control center for additional information on the management of paroxetine overdosage.

Chronic Toxicity

Paroxetine has not been studied systematically in animals or humans to determine whether therapy with the drug is associated with abuse, tolerance, or physical dependence.

The clinical trials conducted with paroxetine did not reveal any tendency for drug-seeking behavior. However, withdrawal syndrome, manifested as dizziness, sensory disturbances, blurred vision, sweating, nausea, insomnia, tremor, confusion, lethargy, insomnia, nervousness or anxiety, headache, paresthesias, hypermanic-like symptoms (including hyperactivity, decreased need for sleep, irritability, agitation, aggressiveness, volatility, explosive vocal and temper outbursts), and egodystonic impulsive behavior (including shoplifting, homicidal impulses, suicidal impulses and gestures), has been reported following discontinuance of paroxetine therapy. Such reactions may emerge after abrupt discontinuance or intermittent noncompliance with therapy and, less frequently, when the dosage is reduced. Although manifestations of withdrawal generally have been mild, transient, and self-limiting, patients should be carefully monitored when paroxetine therapy is discontinued and abrupt discontinuance of the drug should be avoided. (See Dosage and Administration: Dosage:)

Some evidence suggests that the risk of withdrawal effects may be somewhat greater with paroxetine than with sertraline; fluoxetine appears to associated with the fewest withdrawal effects, possibly due at least in part to its prolonged elimination half-life. Additional clinical experience is necessary to confirm these findings.

Experience with paroxetine and with other serotonin-reuptake inhibitors suggests that a withdrawal syndrome may occur within several days following abrupt discontinuance of these drugs. The most commonly observed manifestations are those that resemble influenza, such as fatigue, GI complaints (e.g., nausea), dizziness or lightheadedness, tremor, anxiety, insomnia, chills, sweating, and incoordination. Other reported manifestations include memory impairment, paresthesia, shock-like sensations, headache, palpitations, agitation, and aggression. Although the mechanism(s) for such withdrawal reactions is not fully understood, it has been suggested that they may be caused by a sudden decrease in serotonin availability at the synapse or cholinergic rebound; other neurotransmitters (e.g., dopamine, norepinephrine, GABA) also may be involved. These manifestations may in some cases be mistaken for physical illness or relapse into depression, but generally appear to be self-limiting and improve over one to several weeks. Manifestations of withdrawal also may be improved by restarting therapy with paroxetine or another antidepressant with a similar pharmacologic profile. Paroxetine therapy should be discontinued gradually (e.g., over a period of several weeks) to prevent the possible development of withdrawal reactions.

As with other CNS-active drugs, clinicians should carefully evaluate patients for a history of substance abuse prior to initiating paroxetine therapy. If paroxetine therapy is initiated in patients with a history of substance abuse, such patients should be monitored closely for signs of misuse or abuse of the drug (e.g., development of tolerance, use of increasing doses, drug-seeking behavior).

Pharmacology

The pharmacology of paroxetine is complex and in many ways resembles that of other antidepressant agents, particularly those agents (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, sertraline, clomipramine, trazodone) that predominantly potentiate the pharmacologic effects of serotonin (5-HT). Like other selective serotonin-reuptake inhibitors (SSRIs), paroxetine is a potent and highly selective reuptake inhibitor of serotonin and has little or no effect on other neurotransmitters.

■ **Nervous System Effects** The precise mechanism of antidepressant action of paroxetine is unclear, but the drug has been shown to selectively inhibit the reuptake of serotonin at the presynaptic neuronal membrane. Paroxetine-induced inhibition of serotonin reuptake causes increased synaptic concentrations of serotonin in the CNS, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission. Like other SSRIs (e.g., citalopram, fluoxetine, fluvoxamine, sertraline), paroxetine appears to have only very weak effects on the reuptake of norepinephrine or dopamine and does not exhibit clinically important anticholinergic, antihistaminic, or adrenergic (α_1, α_2, β) blocking activity at usual therapeutic dosages.

Although the mechanism of antidepressant action of antidepressant agents may involve inhibition of the reuptake of various neurotransmitters (i.e., serotonin, norepinephrine) at the presynaptic neuronal membrane, it has been suggested that postsynaptic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of antidepressant agents. During long-term therapy with most antidepressants (e.g., tricyclic antidepressants, monoamine oxidase [MAO] inhibitors), these adaptive changes mainly consist of subsensitivity of the noradrenergic adenylate cyclase system in association with a decrease in the number of β-adrenergic receptors; such effects on noradrenergic receptor function are commonly referred to as "down regulation". However, in an animal study, long-term administration of paroxetine was not shown to downregulate noradrenergic receptors in the CNS as has been observed with many other clinically effective antidepressants. In addition, some antidepressants (e.g., amitriptyline) reportedly decrease the number of serotonergic (5-HT) binding sites following chronic administration.

The precise mechanism of action that is responsible for the efficacy of paroxetine in the treatment of obsessive-compulsive disorder is unclear. However, because of the potency of clomipramine and SSRIs (e.g., citalopram, fluoxetine, fluvoxamine, sertraline) in inhibiting serotonin reuptake and their efficacy in the treatment of obsessive-compulsive disorder, a serotonin hypothesis has been developed to explain the pathogenesis of the condition. The hypothesis postulates that a dysregulation of serotonin is responsible for obsessive-compulsive disorder and that paroxetine and these other agents are effective because they correct this imbalance. Although the available evidence supports the serotonergic hypothesis of obsessive-compulsive disorder, additional studies are necessary to confirm this hypothesis.

The exact mechanism of action of paroxetine in panic disorder, social phobia, or generalized anxiety disorder has not been fully elucidated but appears to involve inhibition of reuptake of serotonin at the presynaptic membrane.

Animal data indicate that serotonergic mechanisms also appear to be involved at least in part in a number of other pharmacologic effects associated with SSRIs, such as decreased food intake and altered food selection as well as decreased alcohol intake.

Serotonergic Effects Paroxetine is a highly selective inhibitor of serotonin reuptake at the presynaptic neuronal membrane. Paroxetine-induced inhibition of serotonin reuptake causes increased synaptic concentrations of the neurotransmitter, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission.

Data from in vitro studies suggest that paroxetine is more potent than citalopram, clomipramine, fluoxetine, fluvoxamine, and sertraline as a serotonin-reuptake inhibitor. Unlike some other serotonin-reuptake inhibitors, the metabolites of paroxetine have been shown to possess no more than 2% of the potency

of the parent compound as inhibitors of serotonin reuptake; therefore, they are unlikely to contribute to the clinical activity of the drug.

At therapeutic dosages in humans, paroxetine has been shown to inhibit the reuptake of serotonin into platelets.

Effects on Other Neurotransmitters Like other serotonin-reuptake inhibitors, paroxetine has been shown to have little or no activity in inhibiting the reuptake of norepinephrine. Paroxetine appears to have only very weak activity on neuronal reuptake of dopamine. In addition, paroxetine does not inhibit monoamine oxidase (MAO).

Unlike tricyclic and some other antidepressants, paroxetine does not exhibit clinically important anticholinergic, α- or β-adrenergic blocking, or antihistaminic activity at usual therapeutic dosages. As a result, the incidence of adverse effects commonly associated with blockade of muscarinic cholinergic receptors (e.g., dry mouth, blurred vision, urinary retention, constipation, confusion), α-adrenergic receptors (e.g., orthostatic hypotension), and histamine H_1- and H_2-receptors (e.g., sedation) is lower in paroxetine-treated patients than tricyclic-treated patients. In vitro studies have demonstrated that paroxetine does not possess clinically important affinity for α_1- or α_2-adrenergic, β- adrenergic, histaminergic (H_1-, GABA, benzodiazepine, or dopamine D_2-receptors.

Although paroxetine has demonstrated weak affinity for muscarinic cholinergic receptors in vitro and has caused mydriasis in vivo, these effects generally occurred only at dosages greatly exceeding those required for increasing serotonergic activity in the CNS. Limited data indicate that mydriasis may also be serotonergically mediated. In addition, serum anticholinergicity of paroxetine was found to be substantially lower than that of nortriptyline in depressed geriatric patients in one study; complaints of dry mouth and tachycardia also occurred more frequently in the nortriptyline-treated patients than in those treated with paroxetine. These findings indicate that, at therapeutic plasma concentrations, paroxetine has approximately 20% the anticholinergic potential of nortriptyline in older patients. Therefore, it appears unlikely that paroxetine will produce adverse anticholinergic events when given in the usual recommended dosage.

Effects on Sleep Like tricyclic and most other antidepressants, paroxetine suppresses rapid eye movement (REM) sleep. Some evidence suggests that the drug may suppress REM sleep in a dose-dependent manner. Although not clearly established, there is some evidence that the REM-suppressing effects of antidepressant agents may contribute to the antidepressant activity of these drugs. While the precise mechanism has not been fully elucidated, results of animal studies indicate that paroxetine's effects on REM sleep may be serotonergically mediated.

In some studies, paroxetine prolonged REM latency, increased awakenings, increased stage 1 sleep, and/or reduced actual sleep time and sleep efficiency. In one study, administration of single, 40-mg doses of paroxetine in the morning increased sleep latency; however, the drug did not affect sleep latency when given at bedtime. In addition, sleep maintenance parameters (such as nocturnal wake time, total sleep time, and sleep efficiency) deteriorated in a dose-dependent manner both when a single dose of the drug was given in the morning and when given as a single 30-mg dose at bedtime. Overall, the changes in sleep observed with paroxetine are relatively small and are unlikely to be of clinical importance during prolonged administration. In addition, the changes noted with paroxetine are similar to those reported with other SSRIs and suggest an alerting effect on sleep that has not been shown to adversely affect sleep quality.

Effects on EEG Limited data currently are available regarding the effects of paroxetine on the EEG. In animals, EEG studies have revealed an activating effect associated with slight behavioral arousal and weak locomotor stimulation at dosages higher than those required to inhibit serotonin reuptake in the CNS. EEG changes in healthy individuals receiving single, 70-mg oral doses of paroxetine revealed a decrease in delta and theta activity and an increase in beta activity; these changes were still evident after 72 hours. Overall, available data in humans suggest that paroxetine generally does not produce clinically relevant changes on the EEG.

Effects on Psychomotor Function Paroxetine generally does not appear to cause clinically important sedation and generally does not interfere with psychomotor performance. Controlled studies in healthy young individuals and in patients with major depression did not demonstrate any adverse effects on psychomotor performance in those receiving 20-mg doses of the drug. No adverse effects on psychomotor performance or cognitive function were observed in healthy men older than 60 years of age who received single and repeated doses of paroxetine 20 mg in a controlled study; in some tests (e.g., critical flicker fusion thresholds), paroxetine improved information processing ability. In a controlled study evaluating the effects of paroxetine (20 or 40 mg administered daily for 8 days) on psychomotor performance and car driving in healthy males, the 20-mg dosage was found to have no effect while the 40-mg dosage was not found to affect road tracking but slightly impaired performance in some psychomotor tests in a persistent manner. Further study is needed to clarify whether paroxetine may adversely affect psychomotor performance at dosages of 40 mg daily or more.

■ **Cardiovascular Effects** No clinically important changes in vital signs (systolic and diastolic blood pressure, heart rate, temperature) were observed in patients receiving paroxetine in controlled trials. Paroxetine also appears to have little effect on the ECG. In controlled studies, paroxetine did not produce clinically important changes in heart rate, cardiac conduction, or other ECG parameters in patients receiving the drug. In depressed patients with stable ischemic heart disease, paroxetine did not substantially affect blood pressure or conduction intervals and did not produce sustained effects on heart rate, heart rhythm, or indexes of heart rate variability. However, a small but statistically significant QRS widening relative to placebo was reported in one study, and ECG changes occasionally have been reported in healthy individuals and patients receiving the drug. In addition, the relative safety of paroxetine in patients with underlying cardiac disease, particularly those with severe cardiovascular disease and immediately following a myocardial infarction, remains to be more fully elucidated.

Paroxetine did not demonstrate any substantial change in cardiovascular autonomic function tests (such as heart rate variability) in a limited number of depressed patients receiving the drug for 14 days. On the other hand, paroxetine has been shown to increase heart rate variability in a limited number of patients with panic disorder, a condition associated with decreased heart rate variability and consequently an increased risk of serious cardiovascular problems including sudden cardiac death.

■ **Effects on Appetite and Body Weight** Paroxetine appears to possess some anorexigenic activity, although to a lesser degree than certain other serotonergic agents (e.g., fenfluramine [no longer commercially available in the US], fluoxetine, sertraline, zimelidine). Limited data from animal studies suggest that fenfluramine is the most effective inhibitor of food intake followed by fluoxetine, then sertraline, and then paroxetine. Although the precise mechanism has not been clearly established, results from animal studies indicate that the appetite-inhibiting action of these antidepressants may result at least in part from serotonin-reuptake blockade and enhancement of serotonin release thereby increasing serotonin availability at the neuronal synapse.

While clinically important weight loss may occur in some patients receiving paroxetine, only minimal weight loss (averaging 0.45 kg) generally occurred in patients receiving the drug in controlled clinical trials. In addition, while decreased appetite was reported in about 6% of patients receiving paroxetine in short-term clinical trials, the drug, unlike fluoxetine, does not appear to exhibit clinically important anorectic effects. (See Cautions: Metabolic and Endocrine Effects.)

■ **Neuroendocrine Effects** Limited data currently are available regarding the effects of paroxetine on the endocrine system. Elevated serum prolactin concentrations have been reported in some women receiving chronic paroxetine therapy.

Pharmacokinetics

Paroxetine is commercially available in the US as paroxetine hydrochloride (e.g., Paxil®, Paxil CR®) and as paroxetine mesylate (i.e., Pexeva®). Conventional tablets of Paxil® and Pexeva® are *not* bioequivalent. The U.S. Food and Drug Administration (FDA) considers paroxetine mesylate (Pexeva®) conventional tablets to be a pharmaceutical *alternative* (as described in section 505[b][2] of the Federal Food, Drug, and Cosmetic Act) and not a pharmaceutical (generic) equivalent to paroxetine hydrochloride conventional tablets (e.g., Paxil®), since both contain the same active moiety (paroxetine) but have different salts.

In all human studies described in the Pharmacokinetics section, paroxetine was administered as either the hydrochloride or the mesylate salt; dosages and concentrations are expressed in terms of paroxetine.

■ **Absorption** Paroxetine hydrochloride appears to be slowly but well absorbed from the GI tract following oral administration. Although the oral bioavailability of paroxetine hydrochloride in humans has not been fully elucidated to date, the manufacturer states that paroxetine is completely absorbed after oral dosing of a solution of the hydrochloride salt. However, the relative proportion of an oral dose that reaches systemic circulation unchanged appears to be relatively small because paroxetine undergoes extensive first-pass metabolism. The oral tablets and suspension of paroxetine hydrochloride reportedly are bioequivalent.

Paroxetine mesylate is completely absorbed following oral administration of the tablets.

Food does not substantially affect the absorption of paroxetine. In one study, no substantial differences in pharmacokinetic parameters were noted when paroxetine hydrochloride was administered under fasting and nonfasting conditions or with a low- or high-fat diet, milk, water, or antacids. In another study, administration of a single dose of paroxetine hydrochloride with food resulted in a 6% increase in the area under the concentration-time curve (AUC), a 29% increase in peak plasma concentrations of the drug, and a decrease in the time to peak plasma concentrations from 6.4 to 4.9 hours.

In healthy males receiving one 30-mg tablet of paroxetine (administered as paroxetine hydrochloride) once daily for 30 days, steady-state plasma paroxetine concentrations were achieved after approximately 10 days in most patients, although achievement of steady-state concentrations may take substantially longer in some patients. At steady-state, mean peak plasma paroxetine concentrations of 61.7 ng/mL occurred after an average of 5.2 hours following oral administration; corresponding mean trough concentrations of 30.7 ng/mL were reported. However, wide interindividual variation in peak plasma concentrations of paroxetine has been observed in both single- and multiple-dose studies. In geriatric individuals receiving multiple daily doses of 20–40 mg daily of paroxetine (administered as paroxetine hydrochloride), trough plasma concentrations were 70–80% higher than trough concentrations in nongeriatric

individuals. In another multiple-dose study, mean steady-state trough concentrations were approximately 3 times higher in geriatric individuals than in younger adults receiving paroxetine (administered as paroxetine hydrochloride) 20 mg daily, although there was considerable overlap between the 2 groups. Therefore, the manufacturers and some clinicians recommend that paroxetine be administered in a reduced dosage (i.e., 10 mg daily) initially in geriatric patients. (See Cautions: Geriatric Precautions and see Dosage and Administration: Dosage in Geriatric and Debilitated Patients.)

In healthy males receiving one 30-mg tablet of paroxetine (administered as paroxetine mesylate) once daily for 24 days, steady-state plasma paroxetine concentrations were achieved after approximately 13 days in most patients, although achievement of steady-state concentrations may take substantially longer in some patients. At steady-state, mean peak plasma paroxetine concentrations of 81.3 ng/mL occurred after an average of 8.1 hours following oral administration of paroxetine mesylate tablets; corresponding mean trough concentrations of 43.2 ng/mL were reported.

When compared with administration of a single dose of paroxetine hydrochloride, steady-state peak and trough paroxetine concentrations following multiple dosing were approximately 6 and 14 times higher than would be expected from single-dose values. In addition, steady-state drug exposure based on AUC (0–24 hour) was about 8 times greater than would have been predicted based on the single-dose data in these individuals. When compared with administration of a single dose of paroxetine mesylate, steady-state peak and trough paroxetine concentrations following multiple dosing were approximately 7 and 10 times higher than would be expected from single-dose values. In addition, steady-state drug exposure based on AUC (0–24 hour) was about 8 and 10 times greater than would have been predicted based on the single-dose data in these individuals receiving the hydrochloride and mesylate salts of paroxetine, respectively. The manufacturers attributed this excess accumulation to the fact that one of the enzymes that metabolizes paroxetine, the cytochrome P-450 isoenzyme CYP2D6, is saturable.

In steady-state, dose-proportionality studies involving geriatric and nongeriatric patients receiving 20–40 and 20–50 mg daily of paroxetine (administered as paroxetine hydrochloride), respectively, some nonlinearity was observed in both groups, which also suggests a saturable metabolic pathway. When compared with trough paroxetine concentrations after 20 mg of the drug daily, trough concentrations after 40 mg daily were approximately 2–3 times higher than doubled.

As with other serotonin-reuptake inhibitors, the relationship between plasma paroxetine concentrations and the therapeutic and/or toxic effects of the drug has not been clearly established.

■ **Distribution** Distribution of paroxetine and its metabolites into human body tissues and fluids has not been fully characterized. However, limited pharmacokinetic data suggest that the parent drug, which is highly lipophilic, and some of its metabolites are widely distributed throughout body tissues, including the CNS. Only 1% of paroxetine remains in plasma.

Although the apparent volume of distribution of paroxetine has not been determined in humans, values ranging from 3.1–28 L/kg have been reported in animal studies. The drug crosses the blood-brain barrier in humans and animals.

In vitro, approximately 95 and 93% of paroxetine is bound to plasma proteins at plasma concentrations of 100 and 400 ng/mL, respectively. Under usual clinical conditions, plasma paroxetine concentrations would be less than 400 ng/mL. In vitro, paroxetine does not alter the plasma protein binding of 2 other highly protein-bound drugs, phenytoin and warfarin.

Paroxetine is distributed into human milk. In one lactating woman receiving paroxetine (administered as paroxetine hydrochloride) 20 mg daily for 1 week, the concentration of paroxetine in breast milk was 7.6 ng/mL 4 hours after the daily dose; no adverse effects were observed in the infant during lactation. Based on an estimated weight-adjusted dose to the infant of 0.34% of the maternal dose, the exposure of infants during breastfeeding appears to be lower for paroxetine and fluvoxamine than for fluoxetine; however, further study is needed to clarify the clinical importance of these findings.

■ **Elimination** The elimination half-life of paroxetine when administered as paroxetine hydrochloride averages approximately 21–24 hours, although there is wide interpatient variation with half-lives (ranging from 7–65 hours in one study). In healthy males receiving one 30-mg tablet of paroxetine (administered as paroxetine mesylate) once daily for 24 days, the mean paroxetine half-life was 33.2 hours. In geriatric individuals, elimination half-life of paroxetine (administered as paroxetine hydrochloride) may be increased (e.g., to about 36 hours).

The exact metabolic fate of paroxetine has not been fully elucidated; however, paroxetine is extensively metabolized, probably in the liver. The principal metabolites are polar and conjugated products of oxidation and methylation, which are readily cleared by the body. Conjugates with glucuronic acid and sulfate predominate, and the principal metabolites have been isolated and identified. The metabolites of paroxetine have been shown to possess no more than 2% of the potency of the parent compound as inhibitors of serotonin reuptake; therefore, they are essentially inactive.

Like some other serotonin-reuptake inhibitors, paroxetine is partially metabolized by the drug metabolizing isoenzyme CYP2D6 (a cytochrome P-450 isoenzyme implicated in sparteine/debrisoquine polymorphism). Saturation of this enzyme at dosages used clinically appears to account for the nonlinearity of paroxetine kinetics observed with increasing dosage and duration of treatment. The role of the CYP2D6 enzyme in paroxetine metabolism also suggests potential drug-drug interactions. (See Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes.)

Following oral administration, paroxetine and its metabolites are excreted in both urine and feces. Following oral administration of a single, 30-mg dose of paroxetine (administered as paroxetine hydrochloride) as an oral solution (not commercially available), approximately 64% of the dose was excreted in the urine within 10 days; unchanged paroxetine accounted for 2% of the dose and metabolites accounted for the remaining 62% of the dose. During the same period, approximately 36% of the dose was eliminated in feces (probably via the bile), mostly as metabolites and less than 1% as the parent drug.

The effect of age on the elimination of paroxetine has not been fully elucidated. In healthy geriatric adults, hepatic clearance of paroxetine was mildly impaired leading to slower elimination and increased plasma concentrations of the drug. (See Pharmacokinetics: Absorption.) Studies in depressed, geriatric patients confirm these findings with higher steady-state concentrations and longer elimination half-lives reported compared with younger individuals. These results suggest that older patients may be more susceptible to saturation of hepatic metabolic activity resulting in nonlinear kinetics and higher plasma concentrations occurring at lower dosages of paroxetine. Therefore, the manufacturers and some clinicians recommend that paroxetine initially be administered in a reduced dosage in geriatric patients. (See Cautions: Geriatric Precautions and see Dosage and Administration: Dosage in Geriatric and Debilitated Patients.)

Because paroxetine is extensively metabolized by the liver, hepatic impairment can affect the elimination of the drug. In cirrhotic patients with moderate hepatic impairment who received a single 20-mg dose of paroxetine (administered as paroxetine hydrochloride), no significant difference in plasma paroxetine concentrations and pharmacokinetic parameters was observed when compared with corresponding data in healthy individuals. However, accumulation potentially may occur in patients receiving multiple daily doses of paroxetine. The manufacturers state that patients with impaired hepatic function have approximately twofold higher peak plasma concentrations and AUC values. Therefore, the manufacturers recommend that paroxetine be administered in a reduced dosage initially in patients with severe hepatic impairment; caution also should be exercised when increasing the dosage of paroxetine in such patients. (See Cautions: Precautions and Contraindications and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

The effect of renal impairment on the pharmacokinetics of paroxetine has not been fully evaluated to date. Following oral administration of multiple daily doses of paroxetine as paroxetine hydrochloride in patients with creatinine clearances less than 30 mL/minute, mean plasma concentrations of paroxetine were approximately 4 times greater than those seen in healthy individuals. In patients with creatinine clearances of 30–60 mL/minute, peak plasma concentrations and AUC values were approximately twofold higher when compared with healthy individuals. The influence of renal impairment in patients receiving multiple daily doses of paroxetine has not been evaluated to date. Pending further accumulation of data, the manufacturers and some clinicians recommend that paroxetine be administered in a reduced dosage initially in patients with severe renal impairment. (See Cautions: Precautions and Contraindications and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Because of the large volume of distribution of paroxetine and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion are unlikely to be effective in removing substantial amounts of paroxetine from the body.

Chemistry and Stability

■ **Chemistry** Paroxetine, a selective serotonin-reuptake inhibitor (SSRI) antidepressant agent, is a phenylpiperidine-derivative. Paroxetine differs structurally from other SSRIs (e.g., citalopram, fluoxetine, sertraline) and also differs structurally and pharmacologically from other currently available antidepressants (e.g., tricyclic antidepressants, monoamine oxidase inhibitors).

Paroxetine is commercially available in the US as the hydrochloride and mesylate salts. Paroxetine hydrochloride occurs as an odorless, off-white powder and has a solubility of 5.4 mg/mL in water. The drug has a pK_a of approximately 9.9. Paroxetine mesylate also occurs as an odorless, off-white powder but has a solubility of more than 1 g/mL in water.

The commercially available extended-release tablets of paroxetine hydrochloride contain the drug in a biodegradable polymeric delivery system, consisting of a hydrophilic core surrounded by a biodegradable barrier layer. This delivery system is designed to release the drug gradually over a period of 4–5 hours after ingestion; in addition, an enteric coating delays the release of drug until after the extended-release tablet has left the stomach.

■ **Stability** Paroxetine hydrochloride conventional tablets should be stored at 15–30°C. The oral suspension and extended-release tablets of paroxetine hydrochloride should be stored at or below 25°C. When stored as directed, paroxetine hydrochloride conventional tablets and oral suspension have an expiration date of 3 and 2 years following the date of manufacture, respectively.

Paroxetine mesylate conventional tablets should be stored at a temperature of 25°C but may be exposed to temperatures ranging from 15–30°C; the tablets should be protected from humidity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Paroxetine Hydrochloride

Oral		
Suspension	10 mg (of paroxetine) per 5 mL	Paxil®, GlaxoSmithKline
Tablets, extended-release, film-coated	12.5 mg (of paroxetine)	Paxil CR®, GlaxoSmithKline
	25 mg (of paroxetine)	Paxil CR®, GlaxoSmithKline
	37.5 mg (of paroxetine)	Paxil CR®, GlaxoSmithKline
Tablets, film-coated	10 mg (of paroxetine)*	Paroxetine Hydrochloride Film-coated Tablets
		Paxil® (scored), GlaxoSmithKline
	20 mg (of paroxetine)*	Paroxetine Hydrochloride Film-coated Tablets
		Paxil® (scored), GlaxoSmithKline
	30 mg (of paroxetine)*	Paroxetine Hydrochloride Film-coated Tablets
		Paxil®, GlaxoSmithKline
	40 mg (of paroxetine)*	Paroxetine Hydrochloride Film-coated Tablets
		Paxil®, GlaxoSmithKline

*Available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Paroxetine Mesylate

Oral		
Tablets, film-coated	10 mg (of paroxetine)	Pexeva®, JDS Pharmaceuticals
	20 mg (of paroxetine)	Pexeva® (scored), JDS Pharmaceuticals
	30 mg (of paroxetine)	Pexeva®, JDS Pharmaceuticals
	40 mg (of paroxetine)	Pexeva®, JDS Pharmaceuticals

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Sertraline Hydrochloride

■ Sertraline, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant agent.

Uses

■ **Major Depressive Disorder** Sertraline is used in the treatment of major depressive disorder. A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features, alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, Drug Interactions: Tricyclic and Other Antidepressants, and Drug Interactions: Lithium.)

The efficacy of sertraline for the acute treatment of major depression has been established by 2 placebo-controlled studies in adult outpatients who met DSM-III criteria for major depression. In the first study of 8 weeks' duration, sertraline was administered with flexible dosing in a range of 50–200 mg daily; the mean daily dosage for patients completing the study was 145 mg daily. In the second study of 6 weeks' duration, sertraline was administered in fixed doses of 50, 100, and 200 mg daily. Overall, these 2 studies demonstrated that sertraline was superior to placebo in improving scores on the Hamilton Depression Rating Scale and the Clinical Global Impression Severity and Improvement Scales. However, the second study was not readily interpretable regarding whether there was a dose-response relationship for the drug's efficacy.

In a third study, depressed outpatients who had responded by the end of an initial 8-week open treatment phase to sertraline 50–200 mg daily were randomized to continue sertraline in the same dosage range or placebo for 44 weeks in a double-blind manner. The mean daily dosage of sertraline in those who completed this long-term study was 70 mg daily, and the relapse rate in the sertraline-treated patients was substantially lower than in those who received placebo.

An analysis of these 3 controlled studies for possible gender-related effects on treatment outcome did not suggest any difference in efficacy based on the gender of the patient.

While the optimum duration of sertraline therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). The efficacy of sertraline in maintaining an antidepressant response for up to 1 year without increased toxicity has been demonstrated in a controlled setting. The manufacturers state that the usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically. (See Dosage and Administration: Dosage.)

The manufacturers state that the drug's antidepressant efficacy in hospital settings has not been adequately studied to date.

As with certain other antidepressants, the possibility that sertraline may precipitate hypomanic or manic attacks in patients with bipolar or other major affective disorder should be considered. Sertraline is *not* approved for use in treating bipolar depression in adults.

Considerations in Choosing an Antidepressant A variety of antidepressant drugs is available for the treatment of major depressive disorder, including selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., desvenlafaxine, duloxetine, venlafaxine), tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine, tranylcypromine), and other antidepressants (e.g., bupropion, maprotiline, nefazodone, trazodone). Most clinical studies have shown that the antidepressant effect of usual dosages of sertraline in patients with depression is greater than that of placebo and comparable to that of usual dosages of tricyclic antidepressants (e.g., amitriptyline), other SSRIs (e.g., fluoxetine), and other antidepressants (e.g., nefazodone). In geriatric patients with major depression, sertraline appears to be as effective as amitriptyline. The onset of action of sertraline appears to be comparable to that of tricyclic antidepressants.

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months of therapy or during periods of dosage adjustment. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Importance of informing patients of potential risk of serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions, particularly with concurrent use of escitalopram and 5-HT_1 receptor agonists (also called triptans), tramadol, tryptophan, other serotonergic agents, or antipsychotic agents. Importance of immediately contacting clinician if signs and symptoms of these syndromes develop (e.g., restlessness, hallucinations, loss of coordination, fast heart beat, increased body temperature, muscle stiffness, labile blood pressure, diarrhea, coma, nausea, vomiting, confusion).

Risk of psychomotor impairment; importance of exercising caution while operating hazardous machinery, including driving a motor vehicle, until the drug's effects on the individual are known.

Importance of patients being aware that withdrawal effects may occur when stopping escitalopram, especially with abrupt discontinuance of the drug.

Risks associated with concomitant use of escitalopram with alcohol or racemic citalopram.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs or herbal supplements, as well as any concomitant illnesses (e.g., bipolar disorder) or personal or family history of suicidality or bipolar disorder. Risk of bleeding associated with concomitant use of escitalopram with aspirin or other nonsteroidal anti-inflammatory agents, warfarin, or other drugs that affect coagulation.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of advising patients that, although they may notice improvement with escitalopram therapy within 1–4 weeks, they should continue therapy as directed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[a] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Escitalopram Oxalate

Oral		
Solution	5 mg (of escitalopram) per 5 mL	**Lexapro®**, Forest
Tablets, film-coated	5 mg (of escitalopram)	**Lexapro®**, Forest
	10 mg (of escitalopram)	**Lexapro®** (scored), Forest
	20 mg (of escitalopram)	**Lexapro®** (scored), Forest

Fluoxetine Hydrochloride

■ Fluoxetine, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant.

Uses

Fluoxetine is used in the treatment of major depressive disorder, obsessive-compulsive disorder, premenstrual dysphoric disorder, and bulimia nervosa. In addition, fluoxetine has been used for the treatment of depression associated with bipolar disorder†; obesity†; anorexia nervosa†; panic disorder† with or without agoraphobia; myoclonus†; cataplexy†; alcohol dependence†; and premature ejaculation†.

■ **Major Depressive Disorder** Fluoxetine is used in the treatment of major depressive disorder. The efficacy of fluoxetine for long-term use (i.e., longer than 5–6 weeks) as an antidepressant has not been established by controlled studies, but the drug has been used in some patients for substantially longer periods (e.g., up to 4 years or longer) without apparent loss of clinical effect or increased toxicity. If fluoxetine is used for extended periods, the need for continued therapy should be reassessed periodically.

A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features, alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, see Drug Interactions: Tricyclic and Other Antidepressants, and see Drug Interactions: Lithium.)

Efficacy of fluoxetine for the management of major depression has been established principally in outpatient settings; the drug's antidepressant efficacy in hospital or institutional settings has not been adequately studied to date. Most patients evaluated in clinical studies with fluoxetine had major depressive episodes of at least moderate severity, had no evidence of bipolar disorder, and had experienced either single or recurrent episodes of depressive illness. Limited evidence suggests that mildly depressed patients may respond less well to fluoxetine than moderately depressed patients. There also is some evidence that patients with atypical depression (which usually is characterized by atypical signs and symptoms such as hypersomnia and hyperphagia), a history of poor response to prior antidepressant therapy, chronic depressive symptomatology with or without episodic worsening of depressive symptoms, a longer duration of depression in the current episode, and/or a younger age of onset of depression may be more likely to respond to fluoxetine than to tricyclic antidepressant therapy.

Considerations in Choosing Antidepressants A variety of antidepressant drugs are available for the treatment of major depressive disorder, including selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., desvenlafaxine, duloxetine, venlafaxine), tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine, tranylcypromine), and other antidepressants (e.g., bupropion, maprotiline, nefazodone, trazodone). Most clinical studies have shown that the antidepressant effect of usual dosages of fluoxetine in patients with moderate to severe depression is greater than that of placebo and comparable to that of usual dosages of tricyclic antidepressants, maprotiline, other selective serotonin-reuptake inhibitors (e.g., paroxetine, sertraline), and other antidepressants (e.g., trazodone). Fluoxetine appears to be

as effective as tricyclic antidepressants in reducing most of the signs and symptoms associated with major depressive disorder, including depression, anxiety, cognitive disturbances, and somatic symptoms. However, in some studies, the drug did not appear to be as effective as tricyclic antidepressants or trazodone in reducing sleep disturbances associated with depression. In geriatric patients with major depressive disorder, fluoxetine appears to be as effective as and to cause fewer overall adverse effects than doxepin. The onset of action of fluoxetine appears to be comparable to that of tricyclic antidepressants, although the onset of action has been variably reported to be somewhat faster or slower than that of tricyclic antidepressants in some studies.

Because response rates in patients with major depression are similar for most currently available antidepressants, the choice of antidepressant agent for a given patient depends principally on other factors such as potential adverse effects, safety or tolerability of these adverse effects in the individual patient, psychiatric and medical history, patient or family history of response to specific therapies, patient preference, quantity and quality of available clinical data, cost, and relative acute overdose safety. No single antidepressant can be recommended as optimal for all patients because of substantial heterogeneity in individual responses and in the nature, likelihood, and severity of adverse effects. In addition, patients vary in the degree to which certain adverse effects and other inconveniences of drug therapy (e.g., cost, dietary restrictions) affect their preferences.

In the large-scale Sequenced Treatment Alternatives to Relieve Depression (STAR*D) effectiveness trial, patients with major depressive disorder who did not respond to or could not tolerate therapy with one SSRI (citalopram) were randomized to switch to extended-release ("sustained-release") bupropion, sertraline, or extended-release venlafaxine as a second step of treatment (level 2). Remission rates as assessed by the 17-item Hamilton Rating Scale for Depression (HRSD-17) and the Quick Inventory of Depressive Symptomatology—Self Report (QIDS-SR-16) were approximately 21 and 26% for extended-release bupropion, 18 and 27% for sertraline, and 25 and 25% for extended-release venlafaxine therapy, respectively; response rates as assessed by the QIDS-SR-16 were 26, 27, and 28% for extended-release bupropion, sertraline, and extended-release venlafaxine therapy, respectively. These results suggest that after unsuccessful initial treatment of depressed patients with an SSRI, approximately 25% of patients will achieve remission after therapy is switched to another antidepressant, and either another SSRI (e.g., sertraline) or an agent from another class (e.g., bupropion, venlafaxine) may be reasonable alternative antidepressants in patients not responding to initial SSRI therapy.

Patient Tolerance Considerations. Because of differences in the adverse effect profile between selective serotonin-reuptake inhibitors and tricyclic antidepressants, particularly less frequent anticholinergic effects, cardiovascular effects, and weight gain with selective serotonin-reuptake inhibitors, these drugs may be preferred in patients in whom such effects are not tolerated or are of potential concern. The decreased incidence of anticholinergic effects associated with fluoxetine and other selective serotonin-reuptake inhibitors compared with tricyclic antidepressants is a potential advantage, since such effects may result in discontinuance of the drug early during therapy in unusually sensitive patients. In addition, some anticholinergic effects may become troublesome during long-term tricyclic antidepressant therapy (e.g., persistent dry mouth may result in tooth decay). Although selective serotonin-reuptake inhibitors share the same overall tolerability profile, certain patients may tolerate one drug in this class better than another. In an open study, most patients who had discontinued fluoxetine therapy because of adverse effects subsequently tolerated sertraline therapy. Antidepressants other than selective serotonin-reuptake inhibitors may be preferred in patients in whom certain adverse GI effects (e.g., nausea, anorexia) or nervous system effects (e.g., anxiety, nervousness, insomnia, weight loss) are not tolerated or are of concern, since such effects appear to occur more frequently with fluoxetine and other drugs in this class.

Pediatric Considerations. The clinical presentation of depression in children and adolescents can differ from that in adults and generally varies with the age and developmental stages of the child. Younger children may exhibit behavioral problems such as social withdrawal, aggressive behavior, apathy, sleep disruption, and weight loss; adolescents may present with somatic complaints, self esteem problems, rebelliousness, poor performance in school, or a pattern of engaging in risky or aggressive behavior.

Data from controlled clinical studies evaluating various antidepressant agents in children and adolescents are less extensive than with adults, and many of these studies have methodologic limitations (e.g., nonrandomized or uncontrolled, small sample size, short duration, nonspecific inclusion criteria). However, there is some evidence that the response to antidepressants in pediatric patients may differ from that seen in adults, and caution should be used in extrapolating data from adult studies when making treatment decisions for pediatric patients. Results of several studies evaluating tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline) in preadolescent and adolescent patients with major depression indicate a lack of overall efficacy in this age group.

Based on the lack of efficacy data regarding use of tricyclic antidepressants and MAO inhibitors in pediatric patients and because of the potential for life-threatening adverse effects associated with the use of these drugs, many experts consider selective serotonin-reuptake inhibitors, including fluoxetine, the drugs of choice when antidepressant therapy is indicated for the treatment of major depressive disorder in children and adolescents. However, the US Food and Drug Administration (FDA) states that, while efficacy of fluoxetine has been established in pediatric patients, efficacy of other newer antidepressants (i.e., citalopram, desvenlafaxine, duloxetine, escitalopram, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, venlafaxine) was not conclusively established in clinical trials in pediatric patients with major depressive disorder. In addition, FDA now warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) FDA currently states that anyone considering using an antidepressant in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications.)

Geriatric Considerations. The response to antidepressants in depressed geriatric patients without dementia is similar to that reported in younger adults, but depression in geriatric patients often is not recognized and is not treated. In geriatric patients with major depressive disorder, SSRIs appear to be as effective as tricyclic antidepressants (e.g., amitriptyline) but may cause fewer overall adverse effects than these other agents. Geriatric patients appear to be especially sensitive to anticholinergic (e.g., dry mouth, constipation, vision disturbance), cardiovascular, orthostatic hypotensive, and sedative effects of tricyclic antidepressants. The low incidence of anticholinergic effects associated with fluoxetine and other SSRIs compared with tricyclic antidepressants is a potential advantage in geriatric patients, since such effects (e.g., constipation, dry mouth, confusion, memory impairment) may be particularly troublesome in these patients. However, SSRI therapy may be associated with other troublesome adverse effects (e.g., nausea and vomiting, agitation and akathisia, parkinsonian adverse effects, sexual dysfunction, weight loss, hyponatremia). Some clinicians state that SSRIs including fluoxetine may be preferred for treating depression in geriatric patients in whom the orthostatic hypotension associated with many antidepressants (e.g., tricyclics) potentially may result in injuries (such as severe falls). However, despite the fewer cardiovascular and anticholinergic effects associated with SSRIs, these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered at increased risk of falls and appropriate measures should be taken. In addition, clinicians prescribing SSRIs in geriatric patients should be aware of the many possible drug interactions associated with these drugs, including those involving metabolism of the drugs through the cytochrome P-450 system. (See Drug Interactions.)

Patients with dementia of the Alzheimer's type (Alzheimer's disease, presenile or senile dementia) often present with depressive symptoms, such as depressed mood, appetite loss, insomnia, fatigue, irritability, and agitation. Most experts recommend that patients with dementia of the Alzheimer's type who present with clinically important and persistent depressive symptoms be considered as candidates for pharmacotherapy even if they fail to meet the criteria for a major depressive syndrome. The goals of such therapy are to improve mood, functional status (e.g., cognition), and quality of life. Treatment of depression also may reduce other neuropsychiatric symptoms associated with depression in patients with dementia, including aggression, anxiety, apathy, and psychosis. Although patients may present with depressed mood alone, the possibility of more extensive depressive symptomatology should be considered. Therefore, patients should be evaluated and monitored carefully for indices of major depression, suicidal ideation, and neurovegetative signs since safety measures (e.g., hospitalization for suicidality) and more vigorous and aggressive therapy (e.g., relatively high dosages, multiple drug trials) may be needed in some patients.

Although placebo-controlled trials of antidepressants in depressed patients with concurrent dementia have shown mixed results, the available evidence and experience with the use of antidepressants in patients with dementia of the Alzheimer's type and associated depressive manifestations indicate that depressive symptoms (including depressed mood alone and with neurovegetative changes) in such patients are responsive to antidepressant therapy. In some patients, cognitive deficits may partially or fully resolve during antidepressant therapy, but the extent of response will be limited to the degree of cognitive impairment that is directly related to depression. SSRIs such as fluoxetine, citalopram, escitalopram, paroxetine, or sertraline are generally considered as first-line agents in the treatment of depressed patients with dementia since they are usually better tolerated than some other antidepressants (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). Some possible alternative agents to SSRIs include bupropion, mirtazapine, and venlafaxine. Some geriatric patients with dementia and depression may be unable to tolerate the antidepressant dosages needed to achieve full remission. When a rapid antidepressant response is not critical, some experts therefore recommend a very gradual dosage increase to increase the likelihood that a therapeutic dosage of the SSRI or other antidepressant will be reached and tolerated. In a randomized, double-blind study comparing fluoxetine and amitriptyline in a limited number of patients with major depression complicating Alzheimer's disease, fluoxetine and amitriptyline were found to be equally effective; however, fluoxetine was better tolerated.

Cardiovascular Considerations. The relatively low incidence of adverse cardiovascular effects, including orthostatic hypotension and conduction disturbances, associated with fluoxetine and other selective serotonin-reuptake inhibitors may be advantageous in patients in whom cardiovascular effects associated with tricyclic antidepressants may be hazardous. However, most

clinical studies of fluoxetine for the management of depression did not include individuals with cardiovascular disease (e.g., those with a recent history of myocardial infarction or unstable heart disease), and further experience in such patients is necessary to confirm the reported relative lack of cardiotoxicity with the drug. (See Cautions: Precautions and Contraindications.)

Sedative Considerations. Because fluoxetine and other SSRIs generally are less sedating than some other antidepressants (e.g., tricyclics), some clinicians state that these drugs may be preferable in patients who do not require the sedative effects associated with many antidepressant agents; however, an antidepressant with more prominent sedative effects (e.g., trazodone) may be preferable in some patients (e.g., those with insomnia).

Suicidal Risk Considerations. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidal thinking and behavior (suicidality) in certain patients during the early phases of treatment. FDA states that antidepressants increased the risk of suicidality in short-term studies in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) It currently is unknown whether the suicidality risk extends to longer-term antidepressant use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression. Because the risk of suicidality in depressed patients may persist until substantial remission of depression occurs, appropriate monitoring and close observation of patients of all ages who are receiving antidepressant therapy are recommended. (See Cautions: Precautions and Contraindications.)

Dosing Interval Considerations. Fluoxetine can be administered once weekly as delayed-release capsules for continuing management of major depressive disorder. Whether the weekly regimen is equivalent to daily therapy with conventional preparations for preventing relapse has not been established. In a double-blind study in adults who responded to daily fluoxetine therapy for major depressive disorder, the relapse rate for continuing therapy with fluoxetine 20-mg conventional capsules administered daily, fluoxetine 90-mg delayed-release capsules administered once weekly, or placebo was 26, 37, or 50%, respectively.

Other Considerations. Fluoxetine has been effective for the treatment of depression in adults with human immunodeficiency virus (HIV) infection. In one randomized, placebo-controlled study, analysis of patients who completed the study showed a statistically significant benefit in patients receiving fluoxetine compared with those receiving placebo. However, results of intent-to-treat analysis did not show a statistically significant benefit in those receiving the antidepressant, possibly because of a high attrition rate and substantial placebo response. There was no evidence that the degree of immunosuppression affected the response to antidepressant therapy.

Fluoxetine has been effective when used in combination with lithium in a limited number of patients with refractory depression who had not responded to prior therapy (including tricyclic antidepressants and MAO inhibitors administered alone or in combination with lithium), suggesting that lithium may potentiate the antidepressant activity of fluoxetine. (See Drug Interactions: Lithium.) In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) level 2 trial, patients with major depressive disorder who did not respond to or could not tolerate therapy with citalopram (another SSRI) were randomized to receive either extended-release ("sustained-release") bupropion or buspirone therapy in addition to citalopram. Although both extended-release bupropion and buspirone were found to produce similar remission rates, extended-release bupropion produced a greater reduction in the number and severity of symptoms and a lower rate of drug discontinuance than buspirone in this large-scale, effectiveness trial. These results suggest that augmentation of SSRI therapy with extended-release bupropion may be useful in some patients with refractory depression.

Fluoxetine has been used safely for the management of depression in at least one patient with established susceptibility to malignant hyperthermia, suggesting that the drug may be useful in depressed patients susceptible to malignant hyperthermia and in whom tricyclics and MAO inhibitors are potentially hazardous; however, additional experience is necessary to confirm this preliminary finding.

Because fluoxetine possesses anorectic and weight-reducing properties, some clinicians state that the drug may be preferred in obese patients and/or patients in whom the increase in appetite, carbohydrate craving, and weight gain associated with tricyclic antidepressant therapy may be undesirable (e.g., potentially hazardous to the patient's health; result in possible discontinuance of or noncompliance with therapy). However, the possibility that some patients with concurrent eating disorders or those who may desire to lose weight may misuse fluoxetine for its anorectic and weight-reducing effects should be considered. (See Uses: Eating Disorders and also see Chronic Toxicity.)

■ **Obsessive-Compulsive Disorder** Fluoxetine is used in the treatment of obsessive-compulsive disorder in adults and pediatric patients 7 years of age and older when the obsessions or compulsions cause marked distress, are time consuming, or interfere substantially with social or occupational functioning. Obsessions are recurrent and persistent ideas, thoughts, impulses, or images that, at some time during the disturbance, are experienced as intrusive and inappropriate (i.e., "ego dystonic") and that cause marked anxiety or distress but that are not simply excessive worries about real-life problems. Compulsions are repetitive, intentional behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) performed in response to an obsession or according to rules that must be applied rigidly (e.g., in a stereotyped fashion). Although the behaviors or acts are aimed at preventing or reducing distress or preventing some dreaded event or situation, they either are not connected in a realistic manner with what they are designed to neutralize or prevent or are clearly excessive. At some time during the course of the disturbance, the patient, if an adult, recognizes that the obsessions or compulsions are excessive or unreasonable; children may not make such a recognition.

The efficacy of fluoxetine for the management of obsessive-compulsive disorder has been established in several multicenter, placebo-controlled studies, including 2 studies of 13 weeks' duration in adults and one study of 13 weeks' duration in children and adolescents 7–17 years of age. Patients in these studies had moderate to severe obsessive-compulsive disorder with average baseline total scores on the Yale-Brown Obsessive-Compulsive Scale (YBOCS) of 22–26 in adults and 25–26 in children and adolescents (measured on the Children's Yale-Brown Obsessive-Compulsive Scale [CY-BOCS]).

In 2 fixed-dose studies of 13 weeks' duration, adults receiving fluoxetine dosages of 20, 40 and 60 mg daily experienced substantially greater reductions in the YBOCS total score than those receiving placebo. Mean reductions in total scores on the YBOCS in fluoxetine-treated patients were approximately 4–6 units in one study and 4–9 units in the other study compared with a 1-unit reduction in patients receiving placebo. In these 2 studies, a positive clinical response (much or very much improved on the Clinical Global Impressions improvement scale) occurred in 36–47 or 11% of patients receiving fluoxetine or placebo, respectively. While there was no indication of a dose-response relationship for effectiveness in one study, a dose-response relationship was observed in the other study, with numerically better responses in patients receiving 40 or 60 mg of fluoxetine daily compared with those receiving 20 mg of the drug daily. No age- or gender-related differences in outcome were noted in either of these studies.

In another randomized, placebo-controlled study of 13 weeks' duration, children and adolescents 7–17 years of age with obsessive-compulsive disorder who received mean fluoxetine dosages of approximately 25 mg daily (range: 10–60 mg daily) demonstrated substantially greater reductions in the CY-BOCS total score than those receiving placebo. In this study, a positive clinical response (much or very much improved on the Clinical Global Impressions improvement scale) occurred in approximately 55–58 or 9–19% of patients receiving fluoxetine or placebo, respectively. In addition, 49% of patients who received fluoxetine were classified as responders (i.e., patients with a 40% or greater reduction in their CY-BOCS total score from baseline) compared with 25% of those who received placebo. Subgroup analyses on outcome did not suggest any differential responsiveness on the basis of age or gender.

Results from comparative studies to date suggest fluoxetine and other selective serotonin-reuptake inhibitors (SSRIs; e.g., fluvoxamine, paroxetine, sertraline) are as effective or somewhat less effective than clomipramine in the management of obsessive-compulsive disorder. In a pooled analysis of separate short-term (10–13 weeks) studies comparing clomipramine, fluoxetine, fluvoxamine, or sertraline with placebo, clomipramine was calculated as being more effective (as determined by measures on the YBOC scale) than SSRIs, although all drugs were superior to placebo.

Many clinicians consider an SSRI (e.g., fluoxetine, fluvoxamine, paroxetine, sertraline) or clomipramine to be the drugs of choice for the pharmacologic treatment of obsessive-compulsive disorder. The decision whether to initiate therapy with an SSRI or clomipramine often is made based on the adverse effect profile of these drugs. For example, some clinicians prefer clomipramine in patients who may not tolerate the adverse effect profile of SSRIs (nausea, headache, overstimulation, sleep disturbances) while SSRIs may be useful alternatives in patients unable to tolerate the adverse effects associated with clomipramine therapy (anticholinergic effects, cardiovascular effects, sedation). Consideration of individual patient characteristics (age, concurrent medical conditions), pharmacokinetics of the drug, potential drug interactions, and cost of therapy may also influence decisions regarding use of SSRIs or clomipramine as first-line therapy in patients with obsessive-compulsive disorder. Although not clearly established, it has been suggested that the mechanism of action of fluoxetine and other drugs (e.g., clomipramine) used in the management of obsessive-compulsive disorder may be related to their serotonergic activity.

Other Disorders with an Obsessive-Compulsive Component

Experience in a limited number of patients suggests that fluoxetine also reduces obsessive-compulsive symptoms associated with Tourette's disorder† (Gilles de la Tourette's syndrome); however, the drug did not appear to be effective in suppressing motor and vocal tics associated with the condition.

Trichotillomania† (an urge to pull out one's hair) has some features in common with those of obsessive-compulsive disorder and some studies have suggested that antiobsessional agents such as SSRIs and clomipramine may be useful in treating this condition. Successful treatment with fluoxetine has been reported in some patients with trichotillomania, including in 2 short-term, open studies in which dosages of up to 80 mg daily were given. However, fluoxetine's efficacy in the management of this disorder was not demonstrated in 2 double-blind, placebo-controlled, crossover studies. In addition, behavioral therapy was found to be more effective than fluoxetine in treating trichotillomania in a short-term, controlled study. Further studies are needed to more

clearly determine the role of fluoxetine and other serotonin-reuptake blockers in the management of this condition.

■ **Premenstrual Dysphoric Disorder** Fluoxetine is used in the treatment of premenstrual dysphoric disorder (previously late luteal phase dysphoric disorder). DSM-IV criteria for premenstrual dysphoric disorder (PMDD) require that in most menstrual cycles of the previous year at least 5 of the following 11 symptoms must have been present for most of the time during the last week of the luteal phase (with at least one of the symptoms being the first 4 listed): marked depressed mood, feelings of hopelessness, or self-deprecating thoughts; marked anxiety, tension, feelings of being "keyed up" or on "edge"; marked affective lability (e.g., feeling suddenly sad or tearful or increased sensitivity to rejection); persistent and marked anger or irritability or increased interpersonal conflicts; decreased interest in usual activities (e.g., work, school, friends, hobbies); a subjective sense of difficulty in concentrating; lethargy, easy fatigability, or marked lack of energy; marked change in appetite, overeating, or specific food cravings; hypersomnia or insomnia; a subjective sense of being overwhelmed or out of control; and other physical symptoms, such as breast tenderness or swelling, headaches, joint or muscle pain, or a sensation of "bloating" or weight gain. Such symptoms should begin to remit within a few days of the onset of menses (follicular phase) and are always absent in the week following menses. The presence of this cyclical pattern of symptoms must be confirmed by at least 2 consecutive months of prospective daily symptom ratings. PMDD should be distinguished from the more common premenstrual syndrome (PMS) by prospective daily ratings and the strict criteria listed above.

There is some evidence that serotonergic agents (e.g., fluoxetine, paroxetine) have greater efficacy compared with non-serotonergic agents (e.g., bupropion, maprotiline) in relieving the physical and/or emotional symptoms of PMDD. In published studies, the response rates to fluoxetine therapy in women with PMDD appear to be similar to those described in patients with depression, panic disorder, and obsessive-compulsive disorder. However, unlike the onset of action of fluoxetine in other psychiatric conditions (6–8 weeks), some clinicians have observed a rapid onset of response to fluoxetine (approximately 2–4 weeks) in women with PMDD, suggesting that the mechanism of action of these agents in PMDD is not mediated by the drug's antidepressant or anti-obsessive effects. In addition, use of fluoxetine in the treatment of PMDD does not appear to produce the sustained remission typically seen in the treatment of major depressive disorder. PMDD symptoms recur soon after discontinuance of fluoxetine therapy (e.g., within 2 menstrual cycles), even in women who have received the drug for more than 1 year. It has been suggested that a past history of major depression may be associated with a partial or absent response to lower dosages of fluoxetine therapy. Because patients on oral contraceptives were excluded from most clinical studies to date, efficacy of fluoxetine used in conjunction with oral contraceptives for the treatment of PMDD has not been determined.

The efficacy of fluoxetine for the management of PMDD has been established in 3 randomized, placebo-controlled (1 intermittent- and 2 continuous-dosing) studies of 3 or 6 months' duration in adult women who met DSM-III-R or DSM-IV criteria for PMDD. One study involved over 300 women (20–40 years of age) who were randomized to receive either fluoxetine (at fixed dosages of 20 or 60 mg daily) or placebo continuously throughout the full menstrual cycle, beginning on the first day of their cycle. In this study, fixed doses of fluoxetine were shown to be substantially more effective than placebo in decreasing the mean total of 3 visual analog scale scores (tension, irritability, dysphoria); total scores decreased by 36–39% on 20 or 60 mg of fluoxetine and 7% on placebo. However, marked (greater than 50% reduction from baseline) improvement in total luteal phase visual analog scale scores occurred only in 18% of patients receiving 60 mg of fluoxetine and in 6 or 4% of those receiving 20 mg of fluoxetine or placebo, respectively. Fluoxetine therapy appeared to be well tolerated in patients receiving dosages of 20 mg daily, but approximately 33% of women receiving 60 mg daily discontinued the drug because of adverse reactions and 86% of those receiving this dosage who remained in the study reported one or more adverse effects attributable to the drug.

In a second double-blind, placebo-controlled, crossover study, women with PMDD who received flexible doses of fluoxetine (20–60 mg daily; mean dosage of 27 mg daily) throughout the menstrual cycle for a total of 3 cycles had an average visual analog scale total score (follicular to luteal phase increase) that was 3.8 times lower than that of patients receiving placebo. However, results of another double-blind, parallel study indicated that the response rate in women receiving fluoxetine 20 mg daily or bupropion 300 mg daily continuously for 2 cycles was not substantially superior to placebo on the Clinical Global Impressions scale.

The efficacy of intermittent dosing (defined as initiation of daily dosage 14 days prior to the anticipated onset of menstruation and continuing through the first full day of menses) was established in a double-blind, parallel group study of 3 months' duration. In this study, women receiving intermittent dosing of 20 mg daily dosages of fluoxetine had substantially greater improvements on the Daily Record of Severity of Problems, a patient-rated instrument that mirrors the diagnostic criteria for PMDD as identified in the DSM-IV, than those receiving placebo. Further studies are needed to evaluate the comparative efficacy of continuous and intermittent dosing regimens.

■ **Eating Disorders** Fluoxetine is used in the treatment of bulimia nervosa; the drug also has been used in a limited number of patients with other eating disorders (e.g., anorexia nervosa).

Although DSM-IV criteria provide guidelines for establishing a diagnosis of a specific eating disorder, the symptoms frequently occur along a continuum between those of anorexia nervosa and bulimia nervosa. The primary features in both anorexia nervosa and bulimia nervosa are weight preoccupation and excessive self-evaluation (i.e., disturbed perception) of body weight and shape, and many patients exhibit a mixture of both anorexic and bulimic behaviors.

The American Psychiatric Association (APA) states that psychiatric management forms the foundation of treatment for patients with eating disorders and should be instituted for all patients in combination with other specific treatment modalities (e.g., nutritional rehabilitation and pharmacotherapy). Because patients with eating disorders often exhibit comorbid conditions and/or associated psychiatric features that may compromise clinical outcome, treatment programs should identify and address all comorbid conditions before initiating therapy. Clinicians should recognize that patients with concurrent diabetes mellitus often underdose their insulin in order to lose weight, and that pregnant patients with disturbed eating behaviors (e.g., inadequate nutritional intake, binge eating, purging, abuse of teratogenic medications) may be at high risk for fetal or maternal complications. Results from several studies indicate that patients with associated psychiatric features such as substance abuse/dependence or personality disorder may require longer-term therapy than those without these comorbid conditions. Although the presence of depression at initial presentation has no predictive value for treatment outcome, many clinicians suggest that severe depression can impair the patient's involvement in and/or response to psychotherapy, and such patients should receive initial pharmacologic therapy to improve mood symptoms.

Bulimia Nervosa Fluoxetine is used in the management of binge-eating and self-induced vomiting behaviors in patients with moderate to severe bulimia nervosa (e.g., at least 3 bulimic episodes per week for 6 months).

According to DSM-IV, bulimia nervosa is characterized by recurrent episodes of binge eating and recurrent inappropriate compensatory behaviors to prevent weight gain (e.g., self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; excessive exercise) and binge eating and compensatory behaviors both occur at least twice a week for 3 months.

Treatment strategies for bulimia nervosa include psychosocial interventions, nutritional counseling and rehabilitation, and pharmacotherapy. The primary goals in treating bulimia nervosa are to reduce binge eating and purging. Although antidepressants initially were used only in bulimic patients who were clinically depressed, evidence from recent studies indicates that nondepressed patients also respond to these agents, and that the presence of depression is not predictive of therapeutic response. Therefore, antidepressants are included as one component of initial treatment regimens for patients with bulimia nervosa. Because selective serotonin-reuptake inhibitors have a more favorable adverse effects profile, these drugs usually are preferred and may be especially useful for patients with symptoms of depression, anxiety, obsessions, or certain impulse disorder symptoms or for those who previously failed to achieve optimal response to psychosocial therapy. Other antidepressants also may be used to reduce the symptoms of binge eating and purging and help prevent relapse. However, the APA cautions against the use of tricyclic antidepressants in patients who are suicidal and cautions against use of MAO inhibitors in those with chaotic binge eating and purging.

The APA states that in patients who fail to respond to initial antidepressant therapy, it may be necessary to assess whether the patient has taken the drug shortly before vomiting or to determine whether effective drug concentrations have been achieved. Although only limited data are available regarding use of antidepressants for maintenance therapy, there appears to be a high rate of relapse during the treatment phase and an even higher rate following discontinuance of therapy. However, limited data indicate that the rate of relapse appears to correlate with the time at which drug therapy is initiated. In one small, open-label study, patients who received drug treatment within 13 weeks of diagnosis were more likely to exhibit sustained recovery during the first year than those who did not receive pharmacotherapy. Furthermore, continuing cognitive behavior therapy following discontinuance of drug therapy appears to prevent relapse in patients with bulimia nervosa. Additional study is needed to determine the effects of sequential use of psychotherapy and pharmacotherapy in the treatment of bulimia nervosa.

The efficacy of fluoxetine for the management of bulimia nervosa has been established in several multicenter, placebo-controlled studies, including 2 studies of 8 weeks' duration (using fluoxetine dosages of 20 or 60 mg daily) and one study of 16 weeks' duration (using fluoxetine dosages of 60 mg once daily) in patients with moderate to severe bulimia nervosa with median binge eating and self-induced vomiting of 7–10 and 5–9 times a week, respectively. In these studies, fluoxetine given in dosages of 60 mg daily (but not in dosages of 20 mg daily) was substantially more effective than placebo in reducing the number of binge-eating and self-induced vomiting episodes weekly. The superiority of fluoxetine compared with placebo was evident as early as within 1 week of therapy and persisted throughout each study period. The drug-related reduction in bulimic episodes appeared to be independent of baseline depression as assessed by the Hamilton Depression Rating Scale. The beneficial effect of fluoxetine therapy (compared with placebo), as measured by median reductions in the frequency of bulimic behaviors at the end of therapy compared with baseline, ranged from 1–2 and 2–4 episodes per week for binge eating and self-induced vomiting, respectively. The magnitude of clinical effect was related to baseline frequency of bulimic behaviors since greater reductions in such behaviors were observed in patients with higher baseline frequencies. Although binge eating and purging resolved completely in some patients who received

fluoxetine therapy, the majority of fluoxetine-treated patients only experienced a partial reduction in the frequency of bulimic behaviors.

In an uncontrolled study in patients with bulimia nervosa, fluoxetine substantially reduced the frequency of binge eating and self-induced vomiting but did not affect bodily dissatisfaction in patients receiving 60–80 mg of the drug for 4 weeks; in several patients, therapeutic effects of the drug appeared to be maintained during chronic therapy. In another uncontrolled study, fluoxetine reduced the frequency of binge eating and self-induced vomiting in several patients with bulimia nervosa who were unresponsive to previous therapy with imipramine. The drug also reportedly improved bulimic symptoms, expanded food preferences, and resulted in weight gain in one underweight patient with anorexia nervosa and bulimia who was unresponsive to or unable to tolerate previous therapy for her eating disorder (including tricyclic antidepressants, monoamine oxidase inhibitors, bupropion, nomifensine, or lithium). In addition, fluoxetine used in combination with lithium was effective in improving bulimic symptoms in a patient with major depression and bulimia who was unresponsive to prior therapy.

The efficacy of fluoxetine for long-term use in the treatment of bulimia nervosa has been established in a placebo-controlled study of up to 52 weeks' duration in patients who responded to an initial single-blind, 8-week acute treatment phase with fluoxetine 60 mg daily for bulimia nervosa. In this study, fluoxetine decreased the likelihood of relapse and improved the clinical outcome. However, symptoms of bulimia gradually worsened over time in patients in both the fluoxetine and placebo groups in this study, suggesting that fluoxetine alone may not be an adequate maintenance treatment after acute response in some patients with bulimia nervosa. Additional management strategies, such as psychotherapy, may be required to augment or to sustain initial improvement in this condition.

Pending further accumulation of data, most clinicians recommend that antidepressant therapy, including fluoxetine, be continued for at least 6–12 months in patients with bulimia nervosa before attempting to discontinue therapy. If fluoxetine is used for extended periods, the need for continued therapy with the drug should be reassessed periodically.

Anorexia Nervosa Fluoxetine has been used in a limited number of patients with anorexia nervosa†. According to DSM-IV, anorexia nervosa is characterized by refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected or failure to make expected weight gain during periods of growth, leading to body weight less than 85% of that expected); intense fear of gaining weight or becoming fat (even though underweight); disturbance in the perception of body weight and shape, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight; and amenorrhea in postmenarchal females (i.e., absence of at least 3 consecutive menstrual cycles). Patients with anorexia nervosa often exhibit depressive (e.g., depressed mood, social withdrawal, irritability, insomnia, and diminished interest in sex) and obsessive-compulsive symptoms that may be associated with or exacerbated by undernutrition.

The APA recommends that a program of nutritional rehabilitation, including vitamin (e.g., potassium and phosphorus) supplementation, be established for all patients who are significantly underweight. The APA states that pharmacologic measures (e.g., antidepressants) may be considered in patients with anorexia nervosa to maintain weight and normal eating behaviors; to treat psychiatric symptoms associated with the disorder (e.g., depression, anxiety, or obsessive-compulsive symptoms); and to prevent relapse. However, such therapy should not be used as the sole or primary treatment for anorexia nervosa. Because associated psychiatric symptoms of anorexia nervosa (e.g., depression) often improve with weight gain, the APA states that the decision to initiate antidepressant therapy should be deferred until weight gain has been restored, and that the choice of an antidepressant agent depends on the remaining symptoms. According to the APA, selective serotonin-reuptake inhibitors commonly are considered in patients with anorexia nervosa whose depressive, obsessive, or compulsive symptoms persist in spite of or in the absence of weight gain.

Although there are few well-controlled, clinical studies of antidepressants for the treatment of anorexia nervosa, data from one study indicate that weight-restored patients with anorexia nervosa who received fluoxetine (40 mg daily) after hospital discharge had less weight loss, depression, and fewer rehospitalizations for anorexia nervosa during the subsequent year than those who received placebo. However, it should be noted that fluoxetine has been misused for its anorectic and weight-reducing effects in a patient with a history of chronic depression, anorexia nervosa, and laxative abuse who was receiving the drug for the treatment of depression; therefore, the misuse potential of fluoxetine in depressed patients with concurrent eating disorders or in other patients who may desire to lose weight should be considered. (See Chronic Toxicity.)

■ **Panic Disorder** Fluoxetine is used in the treatment of panic disorder with or without agoraphobia. Panic disorder is characterized by the occurrence of unexpected panic attacks and associated concern about having additional attacks, worry about the implications or consequences of the attacks, and/or a clinically important change in behavior related to the attacks.

According to DSM-IV, panic disorder is characterized by recurrent unexpected panic attacks, which consist of a discrete period of intense fear or discomfort in which 4 (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes: palpitations, pounding heart, or accelerated heart rate; sweating; trembling or shaking; sensations of shortness of breath or smothering; feeling of choking; chest pain or discomfort; nausea or abdominal distress; feeling dizzy, unsteady, lightheaded, or faint; derealization (feelings of unreality) or depersonalization (being detached from oneself); fear of losing control; fear of dying; paresthesias (numbness or tingling sensations); and chills or hot flushes.

The efficacy of fluoxetine for the management of panic disorder with or without agoraphobia has been established by 2 randomized, double-blind, placebo-controlled studies in adult outpatients who met DSM-IV criteria for panic disorder with or without agoraphobia. These studies were of 12 weeks' duration and used a flexible dosing schedule. Fluoxetine therapy in both studies was initiated in a dosage of 10 mg daily for the first week and then the dosage was escalated to 20–60 mg daily depending on clinical response and tolerability. In these studies, 42–62% of patients receiving fluoxetine were free from panic attacks at week 12 compared with 28–44% of those receiving placebo. The mean fluoxetine dosage in one of these studies was approximately 30 mg daily.

The optimum duration of fluoxetine therapy required to prevent recurrence of panic disorder has not been established to date. The manufacturer states that the efficacy of fluoxetine for long-term use (i.e., longer than 12 weeks) has not been demonstrated in controlled studies. However, in a 10-week, placebo-controlled, fixed-dose study, patients responding to fluoxetine 10 or 20 mg daily were randomized to receive continued therapy with their previous fluoxetine dosage or placebo during a 6-month continuation phase. The patients who received an additional 6 months of fluoxetine therapy in this study demonstrated continued clinical improvement. The manufacturer and some clinicians state that panic disorder is a chronic condition and requires several months or longer of sustained therapy. Therefore, it is reasonable to continue therapy in responding patients. The manufacturer recommends, however, that patients be reassessed periodically to determine the need for continued therapy.

Panic disorder can be treated with cognitive and behavioral psychotherapy and/or pharmacologic therapy. There are several classes of drugs that appear to be effective in the pharmacologic management of panic disorder, including tricyclic antidepressants (e.g., imipramine, clomipramine), monamine oxidase (MAO) inhibitors (e.g., phenelzine), selective serotonin-reuptake inhibitors (SSRIs), and benzodiazepines (e.g., alprazolam, clonazepam). When choosing among the available drugs, clinicians should consider their acceptance and tolerability by patients; their ability to reduce or eliminate panic attacks, reduce clinically important anxiety and disability secondary to phobic avoidance, and ameliorate other common comorbid conditions (such as depression); and their ability to prevent relapse during long-term therapy. Because of their better tolerability when compared with other agents (such as the tricyclic antidepressants and benzodiazepines), the lack of physical dependence problems commonly associated with benzodiazepines, and efficacy in panic disorder with comorbid conditions (e.g., depression, other anxiety disorders such as obsessive-compulsive disorder, alcoholism), many clinicians prefer SSRIs as first-line therapy in the management of panic disorder. If SSRI therapy is ineffective or is not tolerated, use of a tricyclic antidepressant or a benzodiazepine is recommended.

■ **Bipolar Disorder** Fluoxetine has been used for the short-term treatment of acute depressive episodes† in a limited number of patients with bipolar depression† (bipolar disorder, depressed). In one poorly controlled study, fluoxetine was more effective than imipramine, and each drug was more effective than placebo in the management of depression in patients with bipolar disorder; fluoxetine appeared to be particularly effective in reducing anxiety and somatic symptoms in these patients. However, because the drug has been reported to cause manic reactions in some patients, the possibility that hypomanic or manic attacks may be precipitated in patients with bipolar disorder must be considered. In addition, some experts have reported an association between use of antidepressants and the development of rapid cycling and mixed affective states in patients with bipolar disorder, suggesting that such use may worsen the overall course of bipolar disorder in these patients. Consequently, the American Psychiatric Association (APA) does not recommend use of antidepressant monotherapy in patients with bipolar disorder. Initiation or optimization of dosages of maintenance agents (i.e., lithium, lamotrigine) are considered first-line therapies for the management of acute episodes of depression in patients with bipolar disorder. While the addition of either lamotrigine, bupropion, or paroxetine currently is recommended as the next step for patients who fail to respond to optimum dosages of maintenance agents, the APA states that other SSRIs (e.g., fluoxetine) can be used as an alternative to these agents. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Fluoxetine also is used in combination with olanzapine for the treatment of acute depressive episodes in patients with bipolar disorder. In 2 randomized, double-blind studies of 8 weeks' duration comparing a fixed combination of fluoxetine and olanzapine (Symbyax®) with olanzapine monotherapy and placebo, the fixed combination (flexible daily dosages of 6 mg olanzapine and 25 or 50 mg of fluoxetine or of 12 mg of olanzapine and 50 mg of fluoxetine) was more effective than olanzapine monotherapy (5–20 mg daily) or placebo in improvement in depressive symptoms as assessed by the Montgomery-Asberg Depression Rating Scale (MADRS). Although the manufacturer states that efficacy beyond 8 weeks' duration remains to be established, patients have received the fixed combination for up to 24 weeks in clinical trials. Clinicians who elect to extend therapy beyond 8 weeks should reevaluate the risks and benefits of continued therapy periodically.

■ **Obesity** Fluoxetine has been used in a limited number of patients for the short-term management of exogenous obesity†. In a controlled study, obese

(i.e., more than 20% overweight), nondepressed individuals receiving fluoxetine (average dosage: 64.9 mg daily), benzphetamine hydrochloride (average dosage: 97 mg daily), or placebo concurrently with reduced food intake and increased exercise for 8 weeks lost an average of about 4.8, 4, and 1.7 kg, respectively. Fluoxetine-treated patients who usually experienced carbohydrate cravings reportedly lost more weight during this study than those who did not experience such cravings. (See Pharmacology: Effects on Appetite and Body Weight.)

In a study evaluating the safety of fluoxetine therapy in the management of exogenous obesity, the drug was generally well tolerated. The adverse effect profile of the drug in nondepressed obese patients appeared to differ somewhat from that in depressed patients receiving similar dosages of the drug; obese patients reportedly had a higher incidence of fatigue and a lower incidence of nausea, anxiety, and tremor. Unlike amphetamines, the potential for addiction to or abuse of fluoxetine appears to be minimal (see Chronic Toxicity), and tolerance to the drug's anorectic and weight-reducing effects has not been reported to date following short-term administration. However, long-term studies are necessary to fully determine whether tolerance develops during chronic fluoxetine therapy and to fully establish the relative efficacy and safety of fluoxetine in the management of exogenous obesity.

■ **Cataplexy** Fluoxetine has been used for the symptomatic management of cataplexy† in a limited number of patients with cataplexy and associated narcolepsy. In one study, the drug appeared to be as effective as clomipramine in reducing the number of cataplexy attacks in patients concurrently receiving CNS stimulants (e.g., dextroamphetamine) for the symptomatic management of associated narcolepsy.

■ **Alcohol Dependence** Like some other selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, zimeldine [not commercially available in the US]), fluoxetine has been used in the management of alcohol dependence†. However, studies of SSRIs have generally shown modest effects on alcohol consumption. In a limited number of early-stage problem drinkers (who drank an average of about 8 drinks daily prior to therapy), alcohol consumption was reduced by an average of 17% in patients receiving 60 mg of fluoxetine daily; however, response showed considerable interindividual variability, and alcohol consumption was not altered substantially in problem drinkers receiving 40 mg of the drug daily. It has been suggested that the clinical effects of SSRIs in the management of alcohol dependence may only be transient. In patients with mild to moderate alcohol dependence, alcohol consumption is substantially decreased for only the first 1–4 weeks of fluoxetine therapy or first 12 weeks of citalopram therapy. Additional study is required to fully determine the safety and efficacy of fluoxetine in the management of alcohol dependence. (See Pharmacology: Effects on Alcohol Intake and also see Drug Interactions: Alcohol.)

■ **Myoclonus** Fluoxetine has been used for the management of intention myoclonus†, including postanoxic action myoclonus† and progressive action myoclonus†, in a limited number of patients. Although fluoxetine alone was not effective in improving myoclonus, speech abnormalities, gait abnormalities, or overall performance on neurological examination in such patients, the drug did appear to potentiate the therapeutic effects of combined oxitriptan (l-5-hydroxytryptophan, l-5HTP) and carbidopa therapy in some patients. In addition, fluoxetine reportedly reduced the dosage requirement of oxitriptan and the incidence of adverse GI effects (e.g., diarrhea, abdominal cramps) associated with such therapy. Fluoxetine used in combination with oxitriptan also has exhibited antimyoclonic activity in animals. (See Pharmacology: Other Effects.) However, because toxic effects have been reported in some patients concurrently receiving fluoxetine and tryptophan, a serotonergic agent that is structurally similar to oxitriptan (see Tryptophan and Other Serotonin Precursors under Drug Interactions: Serotonergic Drugs), further study and experience are needed to fully determine the safety and efficacy of combined therapy with fluoxetine and oxitriptan-carbidopa in the management of intention myoclonus.

■ **Premature Ejaculation** Like some other SSRIs, fluoxetine has been used with some success in the treatment of premature ejaculation†. In a placebo-controlled study, fluoxetine produced substantial improvements compared with placebo in time to ejaculation and was well tolerated in most patients. However, in a comparative study, patients receiving either clomipramine or sertraline reported a greater increase in mean intravaginal ejaculation latency time and a greater patient sexual satisfaction rating than those receiving either fluoxetine or placebo. Although the mechanism of action of SSRIs in delaying ejaculation is unclear, it has been suggested that these drugs may be particularly useful in patients who fail or refuse behavioral or psychotherapeutic treatment or when partners are unwilling to cooperate with such therapy.

Dosage and Administration

■ **Administration** Fluoxetine hydrochloride is administered orally without regard to meals.

Fluoxetine hydrochloride conventional capsules, tablets, and solution are administered once or twice daily; the delayed-release capsules are administered once weekly. For the initial management of depression, obsessive-compulsive disorder, premenstrual dysphoric disorder, or bulimia nervosa, the drug generally is administered once daily in the morning. If the dosage exceeds 20 mg daily, the manufacturer and some clinicians state that fluoxetine should be administered in 2 divided doses daily (preferably in the morning and at noon). However, limited evidence suggests that no clinically important differences in either the efficacy or incidence of adverse effects exist with once-daily (in the morning) versus twice-daily (in the morning and at noon) administration of the drug. If sedation occurs during fluoxetine therapy, administering the second dose at bedtime rather than at noon may be useful. Because fluoxetine and its principal active metabolite have relatively long half-lives, the drug has been administered less frequently than once daily (e.g., every 2–7 days), particularly during maintenance therapy. Fluoxetine delayed-release capsules are administered once weekly as maintenance therapy in the management of major depressive disorder in patients who have responded to daily administration of the drug. Some clinicians have suggested that conventional fluoxetine preparations administered less frequently than once daily (i.e., three 20-mg capsules once weekly) may also be effective as maintenance therapy in the management of major depressive disorder, but such dosing regimens should be considered investigational at this time and require additional study to confirm their safety and efficacy.

Because of the prolonged elimination of fluoxetine and its active metabolite from the body, missing a dose of the drug once steady-state concentrations have been achieved is unlikely to result in substantial alterations in plasma fluoxetine or norfluoxetine concentrations.

■ **Dosage** Dosage of fluoxetine hydrochloride is expressed in terms of fluoxetine.

In titrating dosage of or discontinuing fluoxetine therapy, the prolonged elimination half-life of fluoxetine and norfluoxetine should be considered. Several weeks will be required before the full effect of such alterations is realized.

The manufacturers and some clinicians recommend that an interval of at least 5 weeks elapse between discontinuance of fluoxetine therapy and initiation of monoamine oxidase (MAO) inhibitor therapy, and that at least 2 weeks elapse following discontinuance of an MAO inhibitor prior to initiation of fluoxetine therapy. For additional information on potentially serious drug interactions that may occur between fluoxetine and MAO inhibitors or other serotonergic agents, see Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.

Withdrawal symptoms, including dysphoric mood, irritability, agitation, dizziness, anxiety, confusion, headache, lethargy, emotional lability, insomnia, hypomania, and sensory disturbances (e.g., paresthesias such as electric shock sensations), have been reported following discontinuance of fluoxetine and other selective serotonin-reuptake inhibitors (SSRIs), particularly upon abrupt discontinuance. While these events are generally self-limiting, there have been reports of serious discontinuance symptoms. If fluoxetine is to be discontinued, the manufacturer recommends that the dosage be tapered gradually and the patient closely monitored for these manifestations. Abrupt discontinuance should be avoided whenever possible. If intolerable symptoms occur following a decrease in the dosage or upon discontinuance of therapy, fluoxetine therapy may be reinstituted at the previously prescribed dosage. Subsequently, the clinician may continue decreasing the dosage but at a more gradual rate. Plasma concentrations of fluoxetine and norfluoxetine (the principal metabolite) decline gradually after cessation of therapy, which may minimize the risk of withdrawal symptoms.

Patients receiving fluoxetine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications.)

Major Depressive Disorder Adult Dosage. For the management of major depression, the recommended initial dosage of fluoxetine in adults is 20 mg daily. However, some clinicians suggest that fluoxetine therapy be initiated with lower dosages (e.g., 5 mg daily or 20 mg every 2 or 3 days). Although symptomatic relief may be apparent within the first 1–3 weeks of fluoxetine therapy, optimum antidepressant effect usually requires at least 4 weeks or more of therapy with the drug. If insufficient clinical improvement is apparent after several weeks of fluoxetine therapy at 20 mg daily, an increase in dosage may be considered. Efficacy of fluoxetine for major depression was demonstrated in clinical trials employing 10–80 mg daily. Studies comparing fluoxetine 20, 40, and 60 mg daily to placebo indicate that a dosage of 20 mg daily is sufficient to obtain a satisfactory response in most adults with major depression. Fluoxetine dosages up to 80 mg daily have been administered in some patients, and dosages as low as 5 mg daily may be effective in some patients with depression. In addition, in a study in moderately depressed patients, increasing the dosage of fluoxetine from 20 mg to 40 or 60 mg daily did not result in substantial improvement in depression but was associated with an increase in certain adverse effects (e.g., nausea, anxiety, diarrhea, dry mouth, weight loss). The manufacturer states that the maximum dosage of fluoxetine in adults with major depression should not exceed 80 mg daily; however, somewhat higher dosages (e.g., 100–120 mg daily) occasionally have been used in patients who did not respond adequately to lower dosages.

When fluoxetine hydrochloride delayed-release capsules are used for the continuing management of major depressive disorder, the recommended dosage of fluoxetine is 90 mg once weekly beginning 7 days after the last dose of fluoxetine 20 mg daily. If a satisfactory response is not maintained with once weekly administration, consideration may be given to reestablishing a daily dosage schedule.

As with the use of fluoxetine for other indications, lower dosages or less frequent dosing regimens should be considered for geriatric patients, patients with concurrent disease, and patients receiving multiple concomitant drug therapies.

Pediatric Dosage. For the management of major depressive disorder in children and adolescents 8–18 years of age, the recommended initial dosage of fluoxetine is 10 or 20 mg daily. If therapy is initiated at 10 mg daily, it can be increased after 1 week to 20 mg daily. Because higher plasma fluoxetine concentrations occur in lower weight children, the manufacturer states that both the initial and target dosage in lower weight children may be 10 mg daily. An increase in dosage to 20 mg daily may be considered after several weeks in lower weight children if insufficient clinical improvement is observed. Because a rare but serious drug interaction may occur in depressed children and adolescents with comorbid attention-deficit hyperactivity disorder (ADHD) who receive stimulants and selective serotonin-reuptake inhibitors concomitantly, some experts recommend a maximum fluoxetine dosage of 20 mg daily in such patients. (See Tramadol and Other Serotonergic Drugs under Drug Interactions: Serotonergic Drugs.)

Duration of Therapy. The optimum duration of fluoxetine therapy required to prevent recurrence of depressive symptoms has not been established to date. However, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. Systematic evaluation of fluoxetine has shown that its antidepressant efficacy is maintained for periods of up to approximately 9 months following 3 months of open-label acute treatment (12 months total) in adults receiving 20 mg daily as conventional fluoxetine capsules or for periods of up to approximately 6 months with once-weekly dosing of the 90 mg delayed-release fluoxetine capsules following 3 months of open-label treatment with 20 mg once daily as conventional fluoxetine capsules. However, the therapeutic equivalence of once-weekly administration of the 90-mg delayed-release capsules with that of once-daily administration of the 20-mg conventional preparations for delaying time to relapse has not been established. In addition, it has not been determined to date whether the dosage of the antidepressant necessary to treat acute symptoms of depression is the same as the dosage necessary to prevent recurrence of such symptoms. If therapy with the drug is prolonged, the lowest possible dosage should be employed and the need for continued therapy reassessed periodically.

Switching To or From Other Antidepressants. Because concurrent use of fluoxetine and a tricyclic antidepressant may result in greater than two- to 10-fold elevations in plasma tricyclic antidepressant concentrations, dosage of the tricyclic antidepressant may need to be reduced and plasma tricyclic concentrations may need to be monitored temporarily when fluoxetine is administered concurrently or has been recently discontinued. (See Drug Interactions: Tricyclic and Other Antidepressants.)

Because of the potential risk of serotonin syndrome, the manufacturer recommends that an interval of at least 2 weeks elapse when switching a patient from a monoamine oxidase (MAO) inhibitor to fluoxetine. Because both fluoxetine and its principal metabolite have relatively long half-lives, the manufacturers and some clinicians recommend that at least 5 weeks elapse between discontinuance of fluoxetine therapy and initiation of MAO inhibitor therapy. (See Drug Interactions: Serotonergic Drugs.)

Obsessive-Compulsive Disorder **Adult Dosage.** For the management of obsessive-compulsive disorder, the recommended initial dosage of fluoxetine in adults is 20 mg once daily. Because a possible dose-response relationship for effectiveness was suggested in one clinical study, an increase in dosage may be considered following several weeks of therapy if insufficient clinical improvement is observed. The manufacturer recommends fluoxetine dosages of 20–60 mg daily for the treatment of obsessive-compulsive disorder; dosages up to 80 mg daily have been well tolerated in clinical studies evaluating the drug in adults with obsessive-compulsive disorder. The manufacturer states that fluoxetine dosage should not exceed 80 mg daily. Like fluoxetine's antidepressant effect, the full therapeutic effect of the drug in patients with obsessive-compulsive disorder may be delayed until 5 weeks of fluoxetine therapy or longer.

Pediatric Dosage. For the management of obsessive-compulsive disorder, the recommended initial dosage of fluoxetine in children and adolescents 7–17 years of age is 10 mg once daily. In adolescents and higher weight children, the dosage should be increased to 20 mg daily after 2 weeks; additional dosage increases may be considered after several more weeks if insufficient clinical improvement is observed. In lower weight children, dosage increases may be considered after several weeks if insufficient clinical improvement is observed. The manufacturer recommends fluoxetine dosages of 20–60 mg daily for adolescents and higher weight children and fluoxetine dosages of 20–30 mg daily for lower weight children for the treatment of obsessive-compulsive disorder. In lower weight children, the manufacturer states that clinical experience with fluoxetine dosages exceeding 20 mg daily is minimal and that there is no experience with dosages exceeding 60 mg daily in such patients.

Duration of Therapy. Although the efficacy of fluoxetine for long-term use (i.e., longer than 13 weeks) has not been demonstrated in controlled studies, patients have been continued on the drug under double-blind conditions for up to an additional 6 months without loss of benefit. The manufacturer and many experts state that obsessive-compulsive disorder is chronic and requires several months or longer of sustained therapy. Therefore, it is reasonable to continue therapy in responding patients. If fluoxetine is used for extended periods, dosage should be adjusted so that the patient is maintained on the lowest effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Premenstrual Dysphoric Disorder For the management of premenstrual dysphoric disorder (previously late luteal phase dysphoric disorder), the recommended dosage of fluoxetine is 20 mg once daily given continuously throughout the menstrual cycle or intermittently (i.e., only during the luteal phase, starting 14 days prior to the anticipated onset of menstruation and continuing through the first full day of menses). The intermittent dosing regimen is then repeated with each new menstrual cycle. Decisions regarding which dosing regimen to use should be individualized. In a clinical study evaluating continuous dosing of fluoxetine dosages of 20 or 60 mg once daily for the treatment of premenstrual dysphoric disorder (PMDD), both dosages were effective but there was no evidence that the higher dosage provided any additional benefit. The manufacturer states that dosages exceeding 60 mg daily have not been systematically studied in patients with PMDD and that 80 mg daily is the maximum dosage of fluoxetine for the management of PMDD.

Clinical studies using fluoxetine dosages of 20 mg daily given intermittently or continuously have shown that the efficacy of the drug in the treatment of PMDD is maintained for up to 3 or 6 months, respectively. Patients should be periodically reassessed to determine the need for continued treatment. Discontinuance of the drug (even after more than 1 year of therapy) has resulted in relapse of PMDD within approximately 2 menstrual cycles.

Eating Disorders **Bulimia Nervosa.** For the management of bulimia nervosa in adults, the recommended dosage of fluoxetine is 60 mg daily, administered as a single dose in the morning. The manufacturer states that in some patients, oral dosage of the drug may be carefully titrated up to the recommended initial dosage over a period of several days. However, since 60-mg doses of fluoxetine were found to be well tolerated, the APA states that many clinicians initiate treatment for bulimia nervosa at the higher dosage, titrating downward as necessary to minimize adverse effects. Fluoxetine dosages exceeding 60 mg daily have not been evaluated in patients with bulimia.

Systematic evaluation of fluoxetine has demonstrated that its efficacy in the treatment of bulimia nervosa is maintained for periods of up to 12 months following 2 months of acute treatment in patients receiving 60 mg daily as conventional fluoxetine capsules. Pending further accumulation of data, most clinicians recommend that antidepressant therapy, including fluoxetine, be continued for at least 6–12 months in patients with bulimia nervosa before attempting to discontinue therapy. If fluoxetine is used for extended periods, the manufacturer states that the need for continued therapy should be reassessed periodically.

Anorexia Nervosa. Although safety and efficacy of fluoxetine for the management of anorexia nervosa† and optimal dosage of the drug for this disorder have not been established, fluoxetine has been given in a dosage of 40 mg daily in weight-restored patients with anorexia nervosa.

Panic Disorder For the management of panic disorder, the recommended initial dosage of fluoxetine in adults is 10 mg daily. After 1 week, the dosage should be increased to 20 mg once daily. If no clinical improvement is apparent after several weeks of fluoxetine therapy at 20 mg daily, an increase in dosage may be considered. Efficacy of the drug was demonstrated in clinical trials employing 10–60 mg daily. However, the most frequently administered dosage in flexible-dose clinical studies was 20 mg daily. As with the use of fluoxetine for other indications, lower dosages or less frequent dosing regimens should be considered for geriatric patients and patients with concurrent disease or those receiving multiple concomitant drug therapies. The manufacturer states that fluoxetine dosages exceeding 60 mg daily have not been systematically evaluated in patients with panic disorder.

The optimum duration of fluoxetine therapy required to prevent recurrence of panic disorder has not been established to date. The manufacturer states that the efficacy of fluoxetine beyond 12 weeks of therapy has not been demonstrated in controlled studies. However, the manufacturer and some clinicians state that panic disorder is chronic and requires several months or longer of sustained therapy. Therefore, it is reasonable to continue therapy in responding patients. The manufacturer recommends, however, that patients be reassessed periodically to determine the need for continued therapy.

Bipolar Disorder **Monotherapy.** For the short-term treatment of acute depressive episodes in patients with bipolar disorder†, fluoxetine has been given in a dosage of 20–60 mg daily. Because of the risk of developing manic episodes associated with antidepressant therapy in patients with bipolar disorder, many clinicians recommend using the lowest effective dosage of fluoxetine for the shortest time necessary using the antidepressant in conjunction with a mood-stabilizing agent (e.g., lithium).

Combination Therapy. When used in fixed combination with olanzapine for acute depressive episodes in patients with bipolar disorder, fluoxetine is administered once daily in the evening, usually initiating therapy with a dose of 6 mg of olanzapine and 25 mg of fluoxetine (Symbyax® 6/25). This dosage generally should be used as initial and maintenance therapy in patients with a predisposition to hypotensive reactions, patients with hepatic impairment, or those with factors that may slow metabolism of the drugs(s) (e.g., female gender, geriatric age, nonsmoking status); when indicated, dosage should be escalated with caution. In other patients, dosage can be increased according to patient response and tolerance as indicated. In clinical trials, antidepressive efficacy was demonstrated at olanzapine dosages ranging from 6–12 mg daily and fluoxetine dosages ranging from 25–50 mg daily. Dosages exceeding 18 mg of olanzapine and 75 mg of fluoxetine have not been evaluated in clinical studies.

Cataplexy For the management of cataplexy†, fluoxetine has been given in a dosage of 20 mg once or twice daily in conjunction with CNS stimulant therapy (e.g., methylphenidate, dextroamphetamine).

Alcohol Dependence For the management of alcohol dependence†, fluoxetine has been given in a dosage of 60 mg daily. Studies have shown that reductions in alcohol intake occur only with dosages of selective serotonin-reuptake inhibitors that are higher than the average therapeutic dosages used in depression. Alcohol intake in patients receiving lower dosages of fluoxetine (40 mg daily) was comparable to that of patients receiving placebo.

■ **Dosage in Renal and Hepatic Impairment** The need for modification of fluoxetine dosage in patients with renal impairment has not been fully determined to date, and the drug should be used with caution in such patients. Although the elimination of fluoxetine and norfluoxetine following single-dose administration does not appear to be altered substantially in patients with renal impairment, multiple-dose studies are needed to determine whether accumulation of the parent drug and/or its metabolites occurs during long-term fluoxetine therapy in patients with severe renal impairment. (See Pharmacokinetics.) The manufacturer and some clinicians state that a reduction in dose and/or frequency of administration of fluoxetine should be considered in patients with renal impairment, particularly those with severe renal impairment. Supplemental doses of fluoxetine during hemodialysis do not appear to be necessary since the drug and its active metabolite norfluoxetine are not removed substantially by hemodialysis.

Since fluoxetine is extensively metabolized in the liver, elimination may be prolonged in patients with hepatic impairment. Therefore, the manufacturer and some clinicians recommend a reduction in dose and/or frequency of administration of fluoxetine in patients with hepatic impairment. Some clinicians recommend a 50% reduction in initial fluoxetine dosage for patients with well-compensated cirrhosis; however, patients with more substantial hepatic impairment, particularly those with severe disease, will require careful individualization of dosage. Subsequent dosage adjustment based on the tolerance and therapeutic response of the patient has been recommended in patients with hepatic impairment.

■ **Treatment of Pregnant Women during the Third Trimester** Because some neonates exposed to fluoxetine and other SSRIs or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed severe complications, consideration may be given to cautiously tapering fluoxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Pregnancy under Cautions: Pregnancy, Fertility, and Lactation.)

Cautions

The adverse effect profile of fluoxetine is similar to that of other selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluvoxamine, paroxetine, sertraline). Because fluoxetine is a highly selective serotonin-reuptake inhibitor with little or no effect on other neurotransmitters, the incidence of some adverse effects commonly associated with tricyclic antidepressants, such as anticholinergic effects (dry mouth, dizziness, constipation), adverse cardiovascular effects, drowsiness, and weight gain, is lower in patients receiving fluoxetine. However, certain adverse GI (e.g., nausea) and nervous system (e.g., anxiety, nervousness, insomnia) effects appear to occur more frequently during fluoxetine therapy than during therapy with tricyclic antidepressants.

In controlled studies, the most common adverse reactions occurring more frequently in adults receiving fluoxetine than in those receiving placebo included nervous system effects such as anxiety, nervousness, insomnia, drowsiness, fatigue or asthenia, tremor, and dizziness or lightheadedness; GI effects such as anorexia, nausea, and diarrhea; vasodilation; dry mouth; abnormal vision; decreased libido; abnormal ejaculation; rash; and sweating. Discontinuance of fluoxetine therapy was required in about 15% of adults, principally because of adverse psychiatric (e.g., nervousness, anxiety, insomnia), other nervous system (e.g., dizziness, asthenia, headache), GI (e.g., nausea), and dermatologic (e.g., rash, pruritus) effects. Because of the relatively long elimination half-lives of fluoxetine and its principal metabolite norfluoxetine, the possibility that some adverse effects may resolve slowly following discontinuance of the drug should be considered.

In controlled clinical trials, adverse effects reported in adults with weekly administration of fluoxetine delayed-release capsules were similar to those reported with daily administration of conventional capsules. Diarrhea and cognitive problems occurred more frequently with the delayed-release formulation compared with the conventional capsules.

Common adverse effects associated with fluoxetine therapy for major depressive disorder or obsessive-compulsive disorder in children and adolescents 7 years of age and older are generally similar to those observed in adults and include nausea, tiredness, nervousness, dizziness, and difficulty concentrating. However, manic reactions, including mania and hypomania, were the most common adverse events associated with discontinuance of the drug in 3 pivotal, pediatric, placebo-controlled studies. These reactions occurred in 2.6% of pediatric patients receiving fluoxetine compared with 0% of those receiving placebo and resulted in the discontinuance of fluoxetine in 1.8% of the patients during the acute phases of the studies combined. Consequently, regular monitoring for the occurrence of mania and hypomania is recommended by the manufacturer.

The usual cautions and precautions of olanzapine should be observed when fluoxetine is used in fixed combination with the antipsychotic.

■ **Nervous System Effects** Headache has occurred in approximately 20% of patients receiving fluoxetine and has required discontinuance of therapy in less than 1.5% of patients. Nervousness and anxiety have occurred in about 15 and 9% of patients, respectively, and insomnia has occurred in about 14% of patients receiving the drug; such effects appear to be dose-related and have required discontinuance of therapy in approximately 5% of fluoxetine-treated patients. However, because insomnia is a symptom also associated with depression, relief of insomnia and improvement in sleep patterns may occur when clinical improvement in depression becomes apparent during antidepressant therapy. The manufacturer and some clinicians state that a sedative (e.g., a short-acting benzodiazepine, chloral hydrate) may be administered to patients who experience insomnia or nervousness early in therapy; however, the possibility that fluoxetine may interact with some benzodiazepines (e.g., diazepam) should be considered. (See Drug Interactions: Benzodiazepines.)

Drowsiness and fatigue or asthenia reportedly occur in about 12 and 4%, respectively, of patients receiving fluoxetine therapy. Tremor and dizziness have occurred in about 8 and 6% of patients, respectively; the incidence of dizziness may be dose-related. Adverse nervous system effects reportedly occurring in approximately 1–2% of patients include sedation, sensation disturbance, lightheadedness, confusion, myoclonus, agitation, amnesia, and decreased concentration. Abnormal dreams and agitation have been reported in more than 1% of patients receiving fluoxetine therapy.

Hypomania, mania, and manic reaction have been reported in 1% or less of patients receiving fluoxetine, including those with depression or obsessive-compulsive disorder. In addition, mania reportedly occurred following administration of a higher than recommended dosage (140 mg daily) in a patient with major depression refractory to conventional antidepressant therapy; this patient subsequently responded to a fluoxetine dosage of 60 mg daily without apparent adverse effects. Such reactions have occurred in patients receiving other antidepressant agents and may be caused by antidepressant-induced functional increases in catecholamine activity within the CNS, resulting in a "switch" from depressive to manic behavior. There is some evidence that patients with bipolar disorder may be more likely to experience antidepressant-induced hypomanic or manic reactions than patients without evidence of this disorder. In addition, limited evidence suggests that such reactions may occur more frequently in bipolar depressed patients receiving tricyclics and tetracyclics (e.g., maprotiline, mianserin [not commercially available in the US]) than in those receiving SSRIs (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline). However, further studies are needed to confirm these findings.

Extrapyramidal reactions, including acute dystonic reactions, torticollis, buccolingual syndrome, and akathisia, have occurred rarely in patients receiving fluoxetine. An extrapyramidal reaction consisting of torticollis, jaw rigidity, cogwheel rigidity, and loss of fluid motion in gait reportedly occurred in one patient several days after initiation of fluoxetine therapy, but responded rapidly to an anticholinergic antiparkinsonian agent (i.e., trihexyphenidyl) and did not recur despite continued fluoxetine therapy. Serum prolactin concentrations were increased and CSF 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid, HVA) concentrations were decreased in this patient, suggesting that a decrease in dopaminergic activity (possibly as a result of enhanced serotonergic neurotransmission) may have contributed to the reaction.

Although a causal relationship to the drug has not been established, serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions also have been reported rarely in patients receiving fluoxetine, other SSRIs, and selective serotonin- and norepinephrine-reuptake inhibitors. (See Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.)

The incidence of seizures during fluoxetine therapy appears to be similar to that observed during therapy with most other currently available antidepressants. Seizures or events that were described as possible seizures have been reported in approximately 0.2% of patients receiving fluoxetine therapy to date. (See Cautions: Precautions and Contraindications.) In addition, seizures have occurred following acute overdosage of the drug (see Acute Toxicity) and in at least one patient undergoing electroconvulsive therapy (ECT) concomitantly.

Adverse nervous system effects occurring in less than 1% of fluoxetine-treated patients include ataxia, abnormal gait, incoordination, hyperkinesia, hypoesthesia, neuropathy, neuralgia, and hydrocephalus; however, a causal relationship to the drug has not been established. Migraine, acute brain syndrome, amnesia, CNS stimulation, vertigo, emotional lability, hostility, depersonalization, apathy, malaise, hangover effect, and euphoria also have been reported in less than 1% of patients receiving the drug. Psychosis, paranoid reaction, delusions, and hallucinations have been reported in less than 1% of patients, although these adverse effects have not been definitely attributed to fluoxetine. Rarely reported adverse nervous system effects for which a causal relationship has not been established include antisocial reaction, violent behavior, chronic brain syndrome, confusion, circumoral paresthesia, precipitation or worsening of depression, stupor, coma, EEG abnormalities, dysarthria, hypertonia, hysteria, myoclonus, dyskinesia, nystagmus, paralysis, exacerbation of multiple sclerosis, and decreased reflexes. Interference with facial nerve conduction, manifesting as ocular tics and impaired hearing, also has been reported. In some patients developing movement disorders with fluoxetine, there were underlying risk factors such as predisposing drug therapy and/or the disorder was an exacerbation of a preexisting disorder.

Suicidality The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. Suicidal ideation, which can manifest as persistent, obsessive, and violent suicidal thoughts,

has emerged occasionally in adults receiving fluoxetine. In a report of several fluoxetine-associated cases, severe suicidal ideation developed within 2–7 weeks after initiation of fluoxetine therapy and resolved within several days to months after discontinuance of the drug; however, the patients were unresponsive to fluoxetine and had received monoamine oxidase inhibitor therapy previously, and most had a history of suicidal ideation, were receiving relatively high dosages (60–80 mg daily) of fluoxetine, and were receiving other psychotropic therapy concomitantly. Suicidal ideation also has been reported in patients who reportedly had no history of such ideation, but the drug also has been used without recurrence of suicidal ideation in a few patients in whom such ideation emerged during tricyclic antidepressant therapy. Because of the possibility of suicidality, patients should be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of fluoxetine therapy (i.e., the first few months) and during periods of dosage adjustments. (See Cautions: Precautions and Contraindications and see Cautions: Pediatric Precautions and see Acute Toxicity.)

■ **GI Effects** The most frequent adverse effect associated with fluoxetine therapy is nausea, which occurs in about 21% of patients. Nausea generally is mild, occurs early in therapy, and usually subsides after a few weeks of continued therapy with the drug. Limited evidence suggests that the incidence of nausea may be dose-related, but additional experience with the drug is necessary to confirm this finding. Adverse GI effects, principally nausea, have required discontinuance of fluoxetine therapy in about 3% of patients receiving the drug. Although the incidence of vomiting appears to be similar in patients receiving fluoxetine or tricyclic antidepressants (e.g., imipramine), the incidence of nausea appears to be higher with fluoxetine. While the mechanism(s) of fluoxetine-induced GI effects has not been fully elucidated, serotonin has been shown to have complex effects on the GI tract (e.g., stimulation of small intestine motility, inhibition of gastric and large intestine motility).

Diarrhea occurs in about 12%, anorexia in about 9%, and dyspepsia in about 6% of patients receiving the drug; limited evidence suggests that the incidence of anorexia may be dose-related. Other adverse GI effects associated with fluoxetine therapy include abdominal pain and change in taste perception, which occur in approximately 3 and 2% of patients, respectively; taste loss has been reported rarely. Vomiting, melena, and flatulence reportedly occur in about 2% and gastroenteritis in about 1% of patients receiving the drug.

Increased appetite has been reported in more than 1% of patients receiving fluoxetine, but has not been definitely attributed to the drug. Other adverse GI effects, including aphthous stomatitis, dysphagia, eructation, esophagitis, gastritis, gingivitis, glossitis, melena, stomatitis, and thirst, have been reported in less than 1% of fluoxetine-treated patients; however, a causal relationship to the drug has not been established. Bloody diarrhea, GI hemorrhage, colitis, duodenal or gastric ulcer, enteritis, pancreatitis, fecal incontinence, hematemesis, hyperchlorhydria, increased salivation, mouth ulceration, salivary gland enlargement, tongue discoloration, and tongue edema have occurred rarely, but have not been definitely attributed to fluoxetine.

Epidemiologic case-control and cohort design studies have suggested that selective serotonin-reuptake inhibitors may increase the risk of upper GI bleeding. Although the precise mechanism for this increased risk remains to be clearly established, serotonin release by platelets is known to play an important role in hemostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets thereby decreasing the amount of serotonin in platelets. In addition, concurrent use of aspirin or other nonsteroidal anti-inflammatory agents was found to substantially increase the risk of GI bleeding in patients receiving selective serotonin-reuptake inhibitors in 2 of these studies. Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated. Further clinical studies are needed to determine the clinical importance of these findings. (See Cautions: Hematologic Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

■ **Dermatologic and Sensitivity Reactions** Rash (including maculopapular, purpuric, pustular, and vesiculobullous rash; erythema multiforme) and/or urticaria occurs in about 4% and pruritus occurs in about 2% of patients receiving fluoxetine. Adverse dermatologic effects, principally rash and pruritus, generally occur during the first few weeks of therapy and have required discontinuance of the drug in approximately 1% of patients.

Fluoxetine-induced rash and/or urticaria have been associated with systemic signs or symptoms such as fever, leukocytosis, arthralgia, edema, carpal tunnel syndrome, respiratory distress, lymphadenopathy, proteinuria, and mild elevation in serum aminotransferase (transaminase) concentrations in some patients. Serious systemic illnesses have developed rarely in patients with fluoxetine-induced dermatologic reactions to date. Although the diagnosis was equivocal in at least 2 of these patients, one patient was diagnosed as having a leukocytoclastic vasculitis and the other patient exhibited a severe desquamating syndrome that was variably diagnosed as either vasculitis or erythema multiforme. In addition, serum sickness reactions have developed in several other patients who experienced adverse dermatologic effects in association with fluoxetine therapy. Additional cases of systemic reactions possibly related to vasculitis have been reported in patients with rash. Although systemic reactions appear to occur rarely in patients receiving fluoxetine, such reactions may be serious and potentially may involve the lung, kidney, or liver; death reportedly has occurred in association with such reactions. Anaphylactoid reactions (including bronchospasm, angioedema, and/or urticaria) have been reported, and adverse pulmonary effects (including inflammatory processes of varying histopathology and/or fibrosis), which usually occurred with dyspnea as the only preceding symptom, have been reported rarely. It has not been established whether the systemic reactions and associated skin rash in fluoxetine-treated patients share a common underlying cause and represent a true syndrome induced by the drug or whether the temporal association between the rash and other systemic signs and symptoms occurred only by chance; in addition, a specific, underlying immunologic basis for these effects has not been identified. However, such systemic reactions are of potential concern since zimeldine (another selective serotonin-reuptake inhibitor that previously was commercially available outside the US) reportedly was associated with the development of Guillain-Barré syndrome following flu-like, hypersensitivity reactions to the drug; because of such reactions, zimeldine no longer is commercially available. Most patients with fluoxetine-induced rash and/or urticaria improve soon after discontinuance of therapy and/or administration of an antihistamine or corticosteroid, and most patients with such reactions to date have recovered completely without serious adverse sequelae. In addition, several patients who developed hypersensitivity reactions while receiving zimeldine subsequently received fluoxetine with no recurrence of a similar reaction. However, because of associated severe adverse systemic effects with fluoxetine and pharmacologically similar antidepressants (e.g., zimeldine), it is recommended that fluoxetine be discontinued if rash, urticaria, and/or other manifestations of hypersensitivity (e.g., fever, flu-like symptoms), for which alternative etiologies cannot be identified, occur during therapy with the drug.

Excessive sweating occurs in about 8% of patients receiving fluoxetine. Acne and allergic reactions have occurred in approximately 2 and 1% of patients, respectively. Adverse dermatologic and hypersensitivity reactions occurring in less than 1% of patients receiving fluoxetine include acne, cyst formation, dry skin, contact dermatitis, facial edema, alopecia, and herpes simplex; however, these effects have not been definitely attributed to the drug. Although a causal relationship has not been established, eczema, erythema nodosum, epidermal necrolysis, exfoliative dermatitis, Stevens-Johnson syndrome, seborrhea, psoriasis, fungal dermatitis, cellulitis, hirsutism, herpes zoster, skin discoloration, skin hypertrophy, subcutaneous nodules, and ecchymoses have been reported rarely.

■ **Metabolic Effects** Unlike tricyclic antidepressants, which commonly cause weight gain, weight gain occurs in less than 1% of patients receiving fluoxetine. Weight loss, however, frequently occurs during therapy with the drug. Normal-weight and overweight (i.e., body mass index exceeding 25 kg/m^2) depressed patients lost an average of 0.9–1.8 kg and 1.8 kg, respectively, following 6 weeks of therapy with the drug. In addition, weight loss exceeding 5% of body weight has been reported in approximately 13% of fluoxetine-treated patients. Weight loss associated with fluoxetine therapy appears to be reversible, with a gradual increase in body weight occurring following discontinuance of therapy with the drug. Such weight loss appears to result from decreased food consumption rather than adverse GI effects associated with the drug; there is some evidence that fluoxetine-induced weight loss may be dose-related. (See Pharmacology: Effects on Appetite and Body Weight.) In addition, weight loss appears to occur independent of the antidepressant effect of the drug. Although weight loss is commonly associated with fluoxetine therapy, less than 1% of patients discontinue the drug because of this effect. In some cases, however, substantial weight loss may be an undesirable effect of therapy with the drug, particularly in underweight depressed patients.

Fluoxetine potentially may alter blood glucose concentrations. Hypoglycemia has occurred in less than 1% of patients receiving fluoxetine and hypoglycemic reaction has occurred rarely. In addition, hyperglycemia has developed following discontinuance of the drug. Therefore, the possibility that insulin and/or oral sulfonylurea antidiabetic agent dosage adjustments may be necessary when fluoxetine therapy is initiated or discontinued in patients with diabetes mellitus should be considered.

Hypercholesterolemia, hyperlipidemia, and hypokalemia have been reported rarely in fluoxetine-treated patients; these adverse effects have not been definitely attributed to the drug.

■ **Ocular Effects** Visual disturbances, including blurred vision, occur in approximately 3% of patients receiving fluoxetine. Adverse ocular effects reported in less than 1% of fluoxetine-treated patients include amblyopia, conjunctivitis, eye pain, mydriasis, and photophobia. Blepharitis, cataract formation, corneal lesion, diplopia, ocular hemorrhage, glaucoma, iritis, ptosis, and strabismus have been reported rarely.

■ **Cardiovascular Effects** Current evidence suggests that fluoxetine is less cardiotoxic than most antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). Unlike tricyclic antidepressants, which may cause characteristic ECG changes such as prolongation of PR, QRS, and QT intervals and ST-segment and T-wave abnormalities, clinically important ECG changes (such as conduction abnormalities) have not been reported during controlled studies in fluoxetine-treated patients without preexisting cardiac disease. In addition, while tricyclic antidepressants commonly cause an increase in heart rate, heart rate reportedly is reduced by an average of approximately 3 beats/minute in patients receiving fluoxetine. (See Pharmacology: Cardiovascular Effects.)

Palpitations and hot flushes have been reported in approximately 1 and 2% of patients receiving fluoxetine, respectively. Chest pain occurs in about 1% of patients. Unlike tricyclic antidepressants, fluoxetine has been associated with hypotension (including orthostatic hypotension) relatively infrequently; in con-

trolled studies, orthostatic hypotension was reported in less than 1% of patients receiving the drug. Angina pectoris, cardiac arrhythmia, tachycardia, hemorrhage, hypertension, and syncope have occurred infrequently in fluoxetine-treated patients, although a causal relationship to the drug has not been established. First-degree AV block, bundle-branch block, bradycardia, ventricular arrhythmia, ventricular tachycardia (including torsades de pointes-type arrhythmias), myocardial infarction, thrombophlebitis, cerebral ischemia, vascular headache, and cerebrovascular accident have occurred rarely, but these adverse effects have not been definitely attributed to fluoxetine.

■ **Musculoskeletal Effects** Back, joint, muscle, and limb pain reportedly occur in approximately 1–2% of patients receiving fluoxetine. Arthritis, bursitis, tenosynovitis, muscle twitching, jaw pain, and neck pain or rigidity have occurred in less than 1% of fluoxetine-treated patients, but these adverse effects have not been directly attributed to the drug. Bone necrosis, osteoporosis, pathological fracture, chondrodystrophy, myositis, muscle hemorrhage, and rheumatoid arthritis have been reported rarely, although a causal relationship to fluoxetine has not been established.

■ **Hematologic Effects** Lymphadenopathy or anemia has been reported in 2% or less than 1% of patients receiving fluoxetine, respectively. Blood dyscrasia, leukopenia, thrombocythemia, pancytopenia, aplastic anemia, immune-related hemolytic anemia, lymphocytosis, increased sedimentation rate, increased bleeding time, petechiae, purpura, and iron deficiency anemia have occurred rarely, although a causal relationship to the drug has not been established. Thrombocytopenia also has been reported.

Abnormal bleeding has been reported in several patients receiving selective serotonin-reuptake inhibitors. Bleeding complications (e.g., ecchymosis, purpura, menorrhagia, rectal bleeding) have been reported infrequently in patients receiving selective serotonin-reuptake inhibitors. Although the precise mechanism for these reactions has not been established, it has been suggested that impaired platelet aggregation and prolonged bleeding time may be due at least in part to inhibition of serotonin reuptake into platelets and/or that increased capillary fragility and vascular tone may contribute to these cases. (See Cautions: GI Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

■ **Respiratory Effects** Upper respiratory infection has been reported in approximately 8% of fluoxetine-treated patients. Flu-like syndrome (see Cautions: Dermatologic and Sensitivity Reactions), pharyngitis, nasal congestion, sinusitis, sinus headache, cough, and dyspnea have occurred in approximately 1–3% of patients receiving the drug. Adverse respiratory effects reportedly occurring in at least 1% of patients but not directly attributable to fluoxetine therapy include bronchitis, rhinitis, and yawning, and those occurring in less than 1% of patients but not attributed to the drug include asthma, hyperventilation, pneumonia, and hiccups. Apnea, hypoxia, pulmonary edema, laryngeal edema, pulmonary fibrosis/alveolitis, eosinophilic pneumonia, pleural effusion, and hemoptysis have occurred rarely in patients receiving fluoxetine; however, these adverse effects have not been definitely attributed to the drug.

■ **Renal, Electrolyte, and Genitourinary Effects** ***Sexual Dysfunction*** Like other selective serotonin-reuptake inhibitors, adverse effects on sexual function have been reported in both men and women receiving fluoxetine. Although changes in sexual desire, sexual performance, and sexual satisfaction often occur as manifestations of a psychiatric disorder, they also may occur as the result of pharmacologic therapy. It is difficult to determine the true incidence and severity of adverse effects on sexual function during fluoxetine therapy, in part because patients and clinicians may be reluctant to discuss these effects. Therefore, incidence data reported in product labeling and earlier studies are most likely underestimates of the true incidence of adverse sexual effects. Recent reports indicate that up to 50% of patients receiving selective serotonin-reuptake inhibitors describe some form of sexual dysfunction during treatment and the actual incidence may be even higher.

Ejaculatory disturbances (principally ejaculatory delay) are the most common adverse urogenital effects associated with fluoxetine in men, occurring in about 7% of men receiving the drug compared with less than 1% of those receiving placebo in controlled clinical studies for the treatment of obsessive-compulsive disorder or bulimia. In some cases, the adverse effect of ejaculatory delay has been used for therapeutic benefit in the treatment of premature ejaculation. (See Uses: Premature Ejaculation.) Other genital disorders reported in patients receiving the drug include impotence, penile (of the glans) anesthesia, and anorgasmy (in both males and females). Decreased or increased libido also reportedly occurs in up to 2% of patients. In addition, clitoral engorgement, sexual arousal, and orgasm reportedly occurred in at least one female patient receiving fluoxetine.

Management of sexual dysfunction caused by selective serotonin-reuptake inhibitor therapy includes waiting for tolerance to develop; using a lower dosage of the drug; using drug holidays; delaying administration of the drug until after coitus; or changing to another antidepressant. Although further study is needed, there is some evidence that adverse sexual effects of the selective serotonin-reuptake inhibitors may be reversed by concomitant use of certain drugs, including buspirone, 5-hydroxytryptamine-2 (5-HT_2) receptor antagonists (e.g., nefazodone), 5-HT_3 receptor inhibitors (e.g., granisetron), or α_2-adrenergic receptor antagonists (e.g., yohimbine), selective phosphodiesterase (PDE) inhibitors (e.g., sildenafil), or dopamine receptor agonists (e.g., amantadine, dextroamphetamine, pemoline [no longer commercially available in the US], methylphenidate). In most patients, sexual dysfunction is fully reversed 1–3 days after discontinuance of the antidepressant. Ejaculatory dysfunction associated with fluoxetine therapy also has responded to concomitant cyproheptadine therapy in a few patients.

Other Renal, Electrolyte, and Genitourinary Effects Treatment with SSRIs, including fluoxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when fluoxetine was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Discontinuance of fluoxetine should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. Because geriatric patients may be at increased risk for hyponatremia associated with these drugs, clinicians prescribing fluoxetine in such patients should be aware of the possibility that such reactions may occur. In addition, periodic monitoring of serum sodium concentrations (particularly during the first several months) in geriatric patients receiving SSRIs has been recommended by some clinicians.

Painful menstruation, sexual dysfunction, frequent micturition, and urinary tract infection have occurred in approximately 1–2% of patients receiving fluoxetine. Decreased or increased libido reportedly occur in 1–2% or less than 1% of patients, respectively. Abnormal ejaculation, impotence, penile (of the glans) anesthesia, amenorrhea, leukorrhea, menorrhagia, ovarian disorder, vaginitis, pelvic pain, menopause, urinary incontinence, urinary urgency, impaired urination, cystitis, and dysuria have been reported in less than 1% of fluoxetine-treated patients, although these adverse effects have not been definitely attributed to the drug. Dyspareunia, abortion, hypomenorrhea, metrorrhagia, uterine spasm, uterine hemorrhage, salpingitis, vaginal hemorrhage, and vaginal bleeding (which occurred following discontinuance of therapy) have occurred rarely, although a causal relationship to the drug has not been established. Albuminuria, hematuria, polyuria, pyuria, urinary tract disorder, pyelonephritis, urethritis, epididymitis, orchitis, urethral pain, and urolithiasis (including renal calculus formation) also have been reported rarely in patients receiving fluoxetine therapy, although such effects have not been directly attributed to the drug.

■ **Endocrine Effects** Hypothyroidism has been reported in less than 1% of patients receiving fluoxetine, and goiter and hyperthyroidism have occurred rarely; however, a causal relationship to the drug has not been established.

■ **Anticholinergic Effects** Although bothersome anticholinergic effects occur commonly in patients receiving tricyclic antidepressant agents, such effects occur less frequently with fluoxetine. Dry mouth, dizziness, and constipation have been reported in about 10, 6, and 5% of patients receiving the drug. Urinary retention has occurred in less that 1% of fluoxetine-treated patients; blurred vision also has been reported.

■ **Other Adverse Effects** Viral infection and influenza have been reported in approximately 3 and 1% of patients receiving fluoxetine, respectively. Fever or chills alone have occurred in more than 1% of patients receiving fluoxetine; however, fever with accompanying chills has been reported in less than 1% of patients. (See Cautions: Dermatologic and Sensitivity Reactions.) Hypothermia has occurred rarely; however, a causal relationship to the drug has not been definitely established.

Abnormal liver function test results, lymphadenopathy, and epistaxis have been reported in less than 1% of fluoxetine-treated patients, although such effects have not been definitely attributed to the drug. Adverse effects occurring rarely in patients receiving fluoxetine include hepatitis, hepatomegaly, liver tenderness, jaundice, cholecystitis, cholelithiasis, acute abdominal syndrome, moniliasis, serum sickness, and lupus erythematosus syndrome.

Ear pain and tinnitus have occurred in less than 1% of patients, and deafness has been reported rarely. Although not directly attributed to the drug, generalized and peripheral edema have been reported in less than 1% of fluoxetine-treated patients; dehydration and gout have occurred rarely.

Breast pain and fibrocystic breast disease have occurred in less than 1% of patients, and breast enlargement and female lactation have been reported rarely. Hyperprolactinemia also has occurred in patients receiving the drug. Although a causal relationship to fluoxetine has not been established for these effects, serotonin has been implicated as a possible physiologic factor in the release of prolactin. (See Pharmacology: Neuroendocrine Effects.)

■ **Precautions and Contraindications** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Cautions: Pediatric Precautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24

years of age, and a reduced risk was observed in adults 65 years of age or older. It currently is unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior, as well as the emergence of suicidality, and to report such symptoms immediately to a health care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Potentially life-threatening serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions have been reported with SSRIs, including fluoxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) alone, but particularly with concurrent administration of other serotonergic drugs (including serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"]), drugs that impair the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), or antipsychotic agents or other dopamine antagonists. Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. Patients receiving fluoxetine should be monitored for the development of serotonin syndrome or NMS-like signs and symptoms.

Fluoxetine is contraindicated in patients who currently are receiving or recently (i.e., within 2 weeks) have received therapy with MAO inhibitors used for treatment of depression. If concurrent therapy with fluoxetine and a 5-HT_1 receptor agonist (triptan) is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated. Concomitant use of fluoxetine and serotonin precursors (e.g., tryptophan) is not recommended. If signs and symptoms of serotonin syndrome or NMS develop during therapy, treatment with fluoxetine and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated. (See Drug Interactions: Serotonergic Drugs.)

Because clinical experience with fluoxetine in patients with concurrent systemic disease, including cardiovascular disease, hepatic impairment, and renal impairment, is limited, caution should be exercised when fluoxetine is administered to patients with any systemic disease or condition that may alter metabolism of the drug or adversely affect hemodynamic function. (See Dosage and Administration: Dosage.) Fluoxetine should be used with caution in patients with hepatic impairment, since prolonged elimination of the drug and its principal metabolite has been reported to occur in patients with liver cirrhosis. Because the safety of long-term fluoxetine therapy in patients with severe renal impairment has not been adequately evaluated to date, fluoxetine also should be used with caution in patients with severe renal impairment. (See Dosage and Administration: Dosage in Renal and Hepatic Impairment.) Although current evidence suggests that fluoxetine is less cardiotoxic than most older antidepressant agents (see Cautions: Cardiovascular Effects), the safety of fluoxetine in patients with a recent history of myocardial infarction or unstable cardiovascular disease has not been adequately evaluated to date.

Patients receiving fluoxetine should be advised to notify their clinician if they are taking or plan to take nonprescription (over-the-counter) or prescription medications or alcohol-containing beverages or products. (See Drug Interactions.)

Patients receiving fluoxetine should be cautioned about the concurrent use of nonsteroidal anti-inflammatory agents (including aspirin) or other drugs that affect coagulation since combined use of selective serotonin-reuptake inhibitors and these drugs has been associated with an increased risk of bleeding. (See Cautions: GI Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

Fluoxetine generally is less sedating than many other currently available antidepressants and does not appear to produce substantial impairment of cognitive or psychomotor function. However, patients should be cautioned that fluoxetine may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle) and to avoid such activities until they experience how the drug affects them.

Patients receiving fluoxetine should be advised to notify their clinician if they develop rash or hives during therapy with the drug. Pending further accumulation of data, monitoring for such effects is particularly important since these effects have been associated with the development of potentially serious systemic reactions in patients receiving fluoxetine or pharmacologically similar antidepressants (e.g., zimeldine). (See Cautions: Dermatologic and Sensitivity Reactions.)

Seizures have been reported in patients receiving therapeutic dosages and following acute overdosage of fluoxetine. Because of limited experience with fluoxetine in patients with a history of seizures, therapy with the drug should be initiated with caution in such patients.

Because fluoxetine may alter blood glucose concentrations in patients with diabetes mellitus (see Cautions: Metabolic Effects), the possibility that insulin and/or oral sulfonylurea antidiabetic agent dosage adjustments may be necessary when fluoxetine therapy is initiated or discontinued should be considered.

Because fluoxetine therapy has been commonly associated with anorexia and weight loss, the drug should be used with caution in patients who may be adversely affected by these effects (e.g., underweight patients).

Treatment with SSRIs, including fluoxetine, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when fluoxetine was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Signs and symptoms of hyponatremia include headache, difficulty concentrating, memory impairment, confusion, weakness, and unsteadiness, which may lead to falls; more severe and/or acute cases have been associated with hallucinations, syncope, seizures, coma, respiratory arrest, and death. Discontinuance of fluoxetine should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. (See Cautions: Renal, Electrolyte, and Genitourinary Effects and see also Cautions: Geriatric Precautions.)

Fluoxetine therapy is contraindicated in patients currently receiving, or having recently received, thioridazine therapy. In addition, concurrent use of fluoxetine in patients receiving pimozide is contraindicated. (See Thioridazine and also see Pimozide under Drug Interactions: Antipsychotic Agents.)

Fluoxetine is contraindicated in patients with known hypersensitivity to the drug.

■ **Pediatric Precautions** Safety and efficacy of fluoxetine in pediatric patients have not been established in children younger than 8 years of age for the management of major depressive disorder (see Pediatric Considerations under Uses: Major Depressive Disorder) or in children younger than 7 years of age for the management of obsessive-compulsive disorder.

FDA warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. The risk of suicidality for these drugs was identified in a pooled analysis of data from a total of 24 short-term (4–16 weeks), placebo-controlled studies of 9 antidepressants (i.e., fluoxetine, bupropion, citalopram, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, venlafaxine) in over 4400 children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders. The analysis revealed a greater risk of adverse events representing suicidal behavior or thinking (suicidality) during the first few months of treatment in pediatric patients receiving antidepressants than in those receiving placebo. However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

The risk of suicidality in FDA's pooled analysis differed across the different psychiatric indications, with the highest incidence observed in the major depressive disorder studies. In addition, although there was considerable variation in risk among the antidepressants, a tendency toward an increase in suicidality risk in younger patients was found for almost all drugs studied. It is currently unknown whether the suicidality risk in pediatric patients extends to longer-term use (i.e., beyond several months).

As a result of this analysis and public discussion of the issue, FDA has directed manufacturers of all antidepressants to add a boxed warning to the labeling of their products to alert clinicians of this suicidality risk in children and adolescents and to recommend appropriate monitoring and close observation of patients receiving these agents. (See Cautions: Precautions and Contraindications.) The drugs that are the focus of the revised labeling are all drugs

included in the general class of antidepressants, including those that have not been studied in controlled clinical trials in pediatric patients, since the available data are not adequate to exclude any single antidepressant from an increased risk. In addition to the boxed warning and other information in professional labeling on antidepressants, FDA currently recommends that a patient medication guide explaining the risks associated with the drugs be provided to the patient each time the drugs are dispensed. Caregivers of pediatric patients whose depression is persistently worse or who are experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality during antidepressant therapy should consult their clinician regarding the best course of action (e.g., whether the therapeutic regimen should be changed or the drug discontinued). *Patients should not discontinue use of selective serotonin-reuptake inhibitors without first consulting their clinician; it is very important that the drugs not be abruptly discontinued, as withdrawal effects may occur.* (See Dosage and Administration: Dosage.)

Anyone considering the use of fluoxetine in a child or adolescent for any clinical use must balance the potential risks of therapy with the clinical need.

Important toxicity, including myotoxicity, long-term neurobehavioral and reproductive toxicity, and impaired bone development, has been observed following exposure of juvenile animals to fluoxetine; some of these effects occurred at clinically relevant exposures to the drug. In a study in which fluoxetine (3, 10, or 30 mg/kg) was orally administered to young rats from weaning (postnatal day 21) through adulthood (day 90), male and female sexual development was delayed at all dosages, and growth (body weight gain, femur length) was decreased during the dosing period in animals receiving the highest dosage. At the end of the treatment period, serum levels of creatine kinase (a marker of muscle damage) were increased in animals receiving the intermediate and highest dosage, and abnormal muscle and reproductive organ histopathology (skeletal muscle degeneration and necrosis, testicular degeneration and necrosis, epididymal vacuolation and hypospermia) was observed at the highest dosage. When animals were evaluated after a recovery period (up to 11 weeks after drug cessation), neurobehavioral abnormalities (decreased reactivity at all dosages and learning deficit at the highest dosage) and reproductive functional impairment (decreased mating at all dosages and impaired fertility at the highest dosage) were noted; testicular and epididymal microscopic lesions and decreased sperm concentrations were observed in the high-dosage group indicating that the reproductive organ effects seen at the end of treatment were irreversible. Reversibility of fluoxetine-induced muscle damage was not assessed in this study. Adverse effects similar to those observed in rats treated with fluoxetine during the juvenile period have not been reported after administration of fluoxetine to adult animals. Plasma exposures (AUC) to fluoxetine in juvenile rats receiving the low, intermediate, and high dosages in this study were approximately 0.1–0.2, 1–2, and 5–10 times, respectively, the average exposure in pediatric patients receiving the maximum recommended dosage of 20 mg daily. Exposures to norfluoxetine, the principal active metabolite of fluoxetine, in rats were approximately 0.3–0.8, 1–8, and 3–20 times the pediatric exposure at the maximum recommended dosage, respectively.

A specific effect of fluoxetine on bone development has been reported in mice treated with fluoxetine during the juvenile period. In mice treated with fluoxetine (5 or 20 mg/kg given intraperitoneally) for 4 weeks beginning at 4 weeks of age, bone formation was reduced resulting in decreased bone mineral content and density. These dosages did not affect overall growth (e.g., body weight gain or femoral length). The dosages given to juvenile mice in this study were approximately 0.5 and 2 times the maximum recommended dose for pediatric patients on a mg/m^2 basis.

In a study conducted in mice, fluoxetine administration (10 mg/kg intraperitoneally) during early postnatal development (postnatal days 4 to 21) produced abnormal emotional behaviors (decreased exploratory behavior in elevated plus-maze, increased shock avoidance latency) in adulthood (12 weeks of age). The dosage used in this study was approximately equal to the pediatric maximum recommended dosage on a mg/m^2 basis. Because of the early dosing period in this study, the clinical importance of these findings for the labeled pediatric use in humans is unknown.

As with other SSRIs, decreased weight gain has been observed in association with the use of fluoxetine in children and adolescents. In one clinical trial in pediatric patients 8–17 years of age, height gain averaged about 1.1 cm less and weight gain averaged about 1 kg less after 19 weeks of fluoxetine therapy relative to placebo-treated patients. In addition, fluoxetine therapy was associated with a decrease in plasma alkaline phosphatase concentrations. Because the safety of fluoxetine in pediatric patients has not been systematically assessed for chronic therapy longer than several months in duration and studies that directly evaluate the long-term effects of fluoxetine on the growth, development, and maturation of children and adolescents are lacking, height and weight should be monitored periodically in pediatric patients receiving fluoxetine. The clinical importance of these findings on long-term growth currently is not known, but the manufacturer will conduct a phase IV study to evaluate any potential impact of fluoxetine therapy on long-term pediatric growth. For further information on adverse effects associated with the use of fluoxetine in pediatric patients, see the opening discussion in Cautions.

■ **Geriatric Precautions** The efficacy of fluoxetine has been established in clinical studies in geriatric patients. Although no overall differences in efficacy or safety were observed between geriatric and younger patients, the possibility that some older patients particularly those with systemic disease or those who are receiving other drugs concomitantly (see Pharmacokinetics: Elimination and also see Uses: Major Depressive Disorder) may exhibit increased sensitivity to the drug cannot be ruled out.

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Cautions: Precautions and Contraindications.)

Limited evidence suggests that geriatric patients may be more likely than younger patients to develop fluoxetine-induced hyponatremia and transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Therefore, clinicians prescribing fluoxetine in geriatric patients should be aware of the possibility that such reactions may occur. In addition, periodic monitoring (especially during the first several months) of serum sodium concentrations in geriatric patients receiving the drug has been recommended by some clinicians.

As with other psychotropic drugs, geriatric patients receiving antidepressants appear to have an increased risk of hip fracture. Despite the fewer cardiovascular and anticholinergic effects associated with SSRIs, these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered at increased risk of falls, and appropriate measures should be taken.

■ **Mutagenicity and Carcinogenicity** Fluoxetine and norfluoxetine did not exhibit mutagenic activity in vitro in mammalian cell (e.g., mouse lymphoma, rat hepatocyte DNA repair) or microbial (the *Salmonella* microbial mutagen [Ames]) test systems, or with the in vivo sister chromatid-exchange assay in Chinese hamster bone marrow cells. No evidence of carcinogenesis was seen in rats or mice receiving oral fluoxetine dosages of about 7.5 or 9 times the maximum recommended human dosage of the drug, respectively, for 24 months.

■ **Pregnancy, Fertility, and Lactation** ***Pregnancy*** Some neonates exposed to fluoxetine and other selective serotonin-reuptake inhibitors (SSRIs) or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed complications that have sometimes been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special care nurseries. Such complications can arise immediately upon delivery and usually last several days or up to 2–4 weeks. Clinical findings reported to date in the neonates have included respiratory distress, cyanosis, apnea, seizures, temperature instability or fever, feeding difficulty, dehydration, excessive weight loss, vomiting, hypoglycemia, hypotonia, hypertonia, hyperreflexia, tremor, jitteriness, irritability, lethargy, reduced or lack of reaction to pain stimuli, and constant crying. These clinical features appear to be consistent with either a direct toxic effect of the SSRI or SNRI or, possibly, a drug withdrawal syndrome. It should be noted that, in some cases, the clinical picture was consistent with serotonin syndrome (see Drug Interactions: Serotonergic Drugs). When treating a pregnant woman with fluoxetine during the third trimester of pregnancy, the clinician should carefully consider the potential risks and benefits of such therapy. Consideration may be given to cautiously tapering fluoxetine therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Dosage and Administration: Treatment of Pregnant Women during the Third Trimester.)

FDA states that decisions about management of depression in pregnant women are challenging and that the patient and her clinician must carefully consider and discuss the potential benefits and risks of SSRI therapy during pregnancy for the individual woman. Two recent studies provide important information on risks associated with discontinuing or continuing antidepressant therapy during pregnancy.

The first study, which was prospective, naturalistic, and longitudinal in design, evaluated the potential risk of relapsed depression in pregnant women with a history of major depressive disorder who discontinued or attempted to discontinue antidepressant (SSRIs, tricyclic antidepressants, or others) therapy during pregnancy compared with that in women who continued antidepressant therapy throughout their pregnancy; all women were euthymic while receiving antidepressant therapy at the beginning of pregnancy. In this study, women who discontinued antidepressant therapy were found to be 5 times more likely to have a relapse of depression during their pregnancy than were women who continued to receive their antidepressant while pregnant, suggesting that pregnancy does not protect against a relapse of depression.

The second study suggests that infants exposed to SSRIs in late pregnancy may have an increased risk of persistent pulmonary hypertension of the newborn (PPHN), which is associated with substantial neonatal morbidity and mortality. PPHN occurs at a rate of 1–2 neonates per 1000 live births in the general population in the US. In this retrospective case-control study of 377 women whose infants were born with PPHN and 836 women whose infants were born healthy, the risk for developing PPHN was approximately sixfold higher for infants exposed to SSRIs after the twentieth week of gestation compared with infants who had not been exposed to SSRIs during this period. The study was too small to compare the risk of PPHN associated with individual SSRIs, and the findings have not been confirmed. Although the risk of PPHN identified in this study still is low (6–12 cases per 1000) and further study is needed, the findings add to concerns from previous reports that infants exposed to SSRIs late in pregnancy may experience adverse serotonergic effects.

Fluoxetine and its principal metabolite norfluoxetine have been shown to cross the placenta in animals. There are no adequate and controlled studies to

date using fluoxetine in pregnant women, and the drug should be used during pregnancy only when clearly needed. Women should be advised to notify their clinician if they are or plan to become pregnant. FDA states that women who are pregnant or thinking about becoming pregnant should not discontinue any antidepressant, including fluoxetine, without first consulting their clinician. The decision whether or not to continue antidepressant therapy should be made only after careful consideration of the potential benefits and risks of antidepressant therapy for each individual pregnant patient. If a decision is made to discontinue treatment with fluoxetine or other SSRIs before or during pregnancy, discontinuance of therapy should be done in consultation with the clinician in accordance with the prescribing information for the antidepressant, and the patient should be closely monitored for possible relapse of depression. In addition, the prolonged elimination of the drug and its active metabolite from the body after discontinuance of therapy should be considered when a woman of childbearing potential receiving fluoxetine plans to become pregnant.

Most epidemiologic studies of pregnancy outcome following first trimester exposure to SSRIs, including fluoxetine, conducted to date have not revealed evidence of an increased risk of major congenital malformations. In a prospective, controlled, multicenter study, maternal use of several SSRIs (sertraline, fluvoxamine, paroxetine) in a limited number of pregnant women did not appear to increase the risk of congenital malformation, miscarriage, stillbirth, or premature delivery when used during pregnancy at recommended dosages. Birth weight and gestational age in neonates exposed to the drugs were similar to those in the control group. In another small study based on medical records review, the incidence of congenital anomalies reported in infants born to women who were treated with fluoxetine and other SSRIs during pregnancy was comparable to that observed in the general population. However, the results of epidemiologic studies indicate that exposure to paroxetine during the first trimester of pregnancy may increase the risk for congenital malformations, particularly cardiovascular malformations. (See Pregnancy, under Cautions: Pregnancy, Fertility, and Lactation, in Paroxetine 28:16.04.20.) Additional epidemiologic studies are needed to more thoroughly evaluate the relative safety of fluoxetine and other SSRIs during pregnancy, including their potential teratogenic risks and possible effects on neurobehavioral development.

The effect of fluoxetine on labor and delivery is not known.

Fertility Reproduction studies in rats using fluoxetine dosages 5–9 times the maximum recommended human daily dosage have not revealed evidence of impaired fertility. However, a slight decrease in neonatal survival that probably was related to reduced maternal food consumption and suppressed weight gain was reported in the offspring. Like some other SSRIs, pretreatment with fluoxetine inhibits methoxydimethyltryptamine-induced ejaculation in rats; this effect is blocked by metergoline, a serotonin antagonist. Alterations in sexual function also have been reported in patients receiving the drug. (See Sexual Dysfunction under Cautions: Renal, Electrolyte, and Genitourinary Effects and see also Cautions: Pediatric Precautions.)

Lactation Fluoxetine and its metabolites distribute into human milk. Limited data indicate that fluoxetine and norfluoxetine concentrations are 20–30% of concurrent maternal plasma drug concentrations. Crying, sleep disturbance, vomiting, and watery stools developed in an infant who nursed from a woman receiving fluoxetine; plasma fluoxetine and norfluoxetine concentrations in the infant on the second day of feeding were 340 and 208 ng/mL, respectively. Therefore, fluoxetine should not be used in nursing women, and women should be advised to notify their physician if they plan to breast-feed. In addition, the slow elimination of fluoxetine and norfluoxetine from the body after discontinuance of the drug should be considered.

Drug Interactions

As with other drugs, the possibility that fluoxetine may interact with any concomitantly administered drug by a variety of mechanisms, including pharmacodynamic and pharmacokinetic interactions, should be considered. The potential for interactions exists not only with concomitantly administered drugs but also with drugs administered for several weeks after discontinuance of fluoxetine therapy due to the prolonged elimination of fluoxetine and its principal metabolite, norfluoxetine. (See Pharmacokinetics: Elimination.)

■ **Serotonergic Drugs** Use of selective serotonin-reuptake inhibitors (SSRIs) such as fluoxetine concurrently or in close succession with other drugs that affect serotonergic neurotransmission may result in serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions. Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). Although the syndrome appears to be relatively uncommon and usually mild in severity, serious and potentially life-threatening complications, including seizures, disseminated intravascular coagulation, respiratory failure, and severe hyperthermia, as well as death occasionally have been reported. In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. The precise mechanism of these reactions is not fully understood; however, they appear to result from excessive serotonergic activity in the CNS, probably mediated by activation of serotonin 5-HT_{1A} receptors. The possible involvement of dopamine and 5-HT_2 receptors also has been suggested, although their roles remain unclear.

Serotonin syndrome most commonly occurs when 2 or more drugs that affect serotonergic neurotransmission are administered either concurrently or in close succession. Serotonergic agents include those that increase serotonin synthesis (e.g., the serotonin precursor tryptophan), stimulate synaptic serotonin release (e.g., some amphetamines, dexfenfluramine [no longer commercially available in the US], fenfluramine [no longer commercially available in the US]), inhibit the reuptake of serotonin after release (e.g., SSRIs, selective serotonin- and norepinephrine-reuptake inhibitors [SNRIs], tricyclic antidepressants, trazodone, dextromethorphan, meperidine, tramadol), decrease the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), have direct serotonin postsynaptic receptor activity (e.g., buspirone), or nonspecifically induce increases in serotonergic neuronal activity (e.g., lithium salts). Selective agonists of serotonin (5-hydroxytryptamine; 5-HT) type 1 receptors ("triptans") and dihydroergotamine, agents with serotonergic activity used in the management of migraine headache, and St. John's wort (*Hypericum perforatum*) also have been implicated in serotonin syndrome.

The combination of SSRIs and MAO inhibitors may result in serotonin syndrome or NMS-like reactions. Such reactions have also been reported when SSRIs have been used concurrently with tryptophan, lithium, dextromethorphan, sumatriptan, dihydroergotamine, or antipsychotics or other dopamine antagonists. In rare cases, the serotonin syndrome reportedly has occurred in patients receiving the recommended dosage of a single serotonergic agent (e.g., clomipramine) or during accidental overdosage (e.g., sertraline intoxication in a child). Some other drugs that have been implicated in precipitating symptoms suggestive of serotonin syndrome or NMS-like reactions include buspirone, bromocriptine, dextropropoxyphene, linezolid, methylenedioxymethamphetamine (MDMA; "ecstasy"), selegiline (a selective MAO-B inhibitor), and sibutramine (an SNRI used for the management of obesity). Other drugs that have been associated with the syndrome but for which less convincing data are available include carbamazepine, fentanyl, and pentazocine.

Clinicians should be aware of the potential for serious, possibly fatal reactions associated with serotonin syndrome or NMS-like reactions in patients receiving 2 or more drugs that affect serotonergic neurotransmission, even if no such interactions with the specific drugs have been reported to date in the medical literature. Pending further accumulation of data, serotonergic drugs should be used cautiously in combination and such combinations avoided whenever clinically possible. Serotonin syndrome may be more likely to occur when initiating therapy with a serotonergic agent, increasing the dosage, or following the addition of another serotonergic drug. Some clinicians state that patients who have experienced serotonin syndrome may be at higher risk for recurrence of the syndrome upon reinitiation of serotonergic drugs. Pending further experience in such cases, some clinicians recommend that therapy with serotonergic agents be limited following recovery. In cases in which the potential benefit of the drug is thought to outweigh the risk of serotonin syndrome, lower potency agents and reduced dosages should be used, combination serotonergic therapy should be avoided, and patients should be monitored carefully for manifestations of serotonin syndrome. If signs and symptoms of serotonin syndrome or NMS develop during therapy, treatment with fluoxetine and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated.

Serotonin Syndrome **Manifestations.** Serotonin syndrome is characterized by mental status and behavioral changes, altered muscle tone or neuromuscular activity, autonomic instability with rapid fluctuations of vital signs, hyperthermia, and diarrhea. Some clinicians have stated that the diagnosis of serotonin syndrome can be made based on the presence of at least 3 of the following manifestations: mental status changes (e.g., confusion, hypomania), agitation, myoclonus, hyperreflexia, fever, shivering, tremor, diaphoresis, ataxia, and diarrhea in the setting of a recent addition or an increase in dosage of a serotonergic agent; the absence of other obvious causes of mental status changes and fever (e.g., infection, metabolic disorders, substance abuse or withdrawal); and no recent initiation or increase in dosage of an antipsychotic agent prior to the onset of the signs and symptoms (in order to rule out NMS). In some cases, features of the serotonin syndrome have resembled those associated with NMS, which may occur in patients receiving phenothiazines or other antipsychotic agents. (See Extrapyramidal Reactions in Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.)

Other signs and symptoms associated with serotonin syndrome have included restlessness, irritability, insomnia, aggressive behavior, headache, drowsiness, dizziness, disorientation, loss of coordination, anxiety, euphoria, hallucinations, dilated pupils, nystagmus, paresthesias, rigidity, clonus, seizures, and coma. Nausea, vomiting, abdominal cramping, flushing, hypertension, hypotension, tachycardia, tachypnea, and hyperventilation also have occurred.

The onset of the serotonin syndrome can range from minutes after initiating therapy with a second serotonergic agent to several weeks after receiving a stable dosage. Preliminary evidence to date suggests that neither the occurrence nor the severity of serotonin syndrome is related to the dose or duration of serotonergic drug therapy.

The incidence of serotonin syndrome is unknown, but it is likely that the syndrome is underreported because it is not recognized or appears in various degrees of severity (mild, moderate, or severe). In addition, serotonin syndrome may be confused with or resemble NMS in some cases.

Treatment. Mild cases of serotonin syndrome generally respond within 12–24 hours to the immediate discontinuance of serotonergic agents and general supportive therapy. Symptoms rarely last more than 72–96 hours in the

absence of complications. Supportive therapy in such cases may include hospitalization, adequate hydration, control of myoclonus and hyperreflexia with benzodiazepines such as clonazepam (and possibly propranolol), and control of fever with acetaminophen and external cooling, if necessary. Other possible causes of altered mental status and fever also should be considered and treated accordingly.

Patients with severe hyperthermia (i.e., a temperature of more than 40.5°C) are considered to have more severe cases of serotonin syndrome which are associated with more serious complications and mortality. Muscular rigidity often accompanies hyperthermia and may respond to benzodiazepine therapy. Such patients should be managed with aggressive cooling measures, including external cooling, the institution of muscular paralysis (to decrease body temperature, help prevent rhabdomyolysis and disseminated intravascular coagulation from muscular rigidity refractory to benzodiazepines, and facilitate intubation), and maintenance of a patent airway with endotracheal intubation. Seizures may be treated with benzodiazepines and, if necessary, other anticonvulsants (e.g., barbiturates). Patients who develop hypertension, cardiac arrhythmias, and other serious complications such as disseminated intravascular coagulation or rhabdomyolysis associated with serotonin syndrome should receive appropriate therapy for these conditions.

Although there is no specific therapy for serotonin syndrome, nonspecific serotonin (5-HT_1 and 5-HT_2) receptor antagonists such as cyproheptadine and methysergide and drugs with 5-HT_{1A} receptor affinity such as propranolol have been used with some success in a limited number of patients whose symptoms persisted or were unusually severe. Dantrolene, bromocriptine, and chlorpromazine (for sedation, to help reduce fever, and because of its 5-HT-receptor blocking activity) also have been used in a limited number of patients with serotonin syndrome but with inconsistent results; the possibility that chlorpromazine may lower the seizure threshold in this setting should be considered.

Monoamine Oxidase Inhibitors Potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions have been reported in patients receiving serotonin-reuptake inhibitors in combination with an MAO inhibitor. Such reactions also have been reported in patients who recently have discontinued a selective serotonin-reuptake inhibitor and have been started on an MAO inhibitor.

Probably because of its extensive clinical use and the prolonged elimination half-life of both fluoxetine and norfluoxetine, fluoxetine has been the selective serotonin-reuptake inhibitor most commonly implicated in serotonin syndrome. In at least 2 cases, serotonin syndrome developed when MAO inhibitor therapy was initiated after the discontinuance of fluoxetine therapy. Shivering, diplopia, nausea, confusion, and anxiety reportedly occurred in one patient 6 days after discontinuance of fluoxetine therapy and 4 days after initiation of tranylcypromine therapy; signs and symptoms resolved without apparent sequelae within 24 hours following discontinuance of the MAO inhibitor in this patient. In another case, the initiation of tranylcypromine therapy more than 5 weeks after discontinuance of fluoxetine reportedly resulted in serotonin syndrome.

Concurrent administration of fluoxetine and MAO inhibitors is contraindicated. Because both fluoxetine and its principal metabolite have relatively long half-lives, at least 5 weeks should elapse between discontinuance of fluoxetine therapy and initiation of MAO inhibitor therapy, since administration of an MAO inhibitor prior to elapse of this time may increase the risk of serious adverse effects. Based on clinical experience with concurrent administration of tricyclic antidepressants and MAO inhibitors, at least 2 weeks should elapse following discontinuance of an MAO inhibitor prior to initiation of fluoxetine therapy.

Linezolid. Linezolid, an anti-infective agent that is a nonselective and reversible MAO inhibitor, has been associated with drug interactions resulting in serotonin syndrome, including some associated with SSRIs, and potentially may also cause NMS-like reactions. Therefore, at least one manufacturer of fluoxetine states that linezolid should be used with caution in patients receiving fluoxetine. The manufacturer of linezolid states that, unless patients are carefully observed for signs and/or symptoms of serotonin syndrome, the drug should not be used in patients receiving SSRIs. Some clinicians suggest that linezolid only be used with caution and close monitoring in patients concurrently receiving SSRIs, and some suggest that SSRI therapy should be discontinued before linezolid is initiated and not reinitiated until 2 weeks after linezolid therapy is completed.

Moclobemide. Moclobemide, a selective and reversible MAO-A inhibitor (not commercially available in the US), also has been associated with serotonin syndrome and such reactions have been fatal in several cases in which the drug was given in combination with the selective serotonin-reuptake inhibitor citalopram or with clomipramine. Pending further experience with such combinations, some clinicians recommend that concurrent therapy with moclobemide and selective serotonin-reuptake inhibitors be used only with extreme caution and serotonin-reuptake inhibitors should have been discontinued for some time (depending on the elimination half-lives of the drug and its active metabolites) before initiating moclobemide therapy.

Selegiline. Selegiline, a selective MAO-B inhibitor used in the management of parkinsonian syndrome, also has been reported to cause serotonin syndrome when given concurrently with selective serotonin-reuptake inhibitors (fluoxetine, paroxetine, sertraline). Although selegiline is a selective MAO-B inhibitor at therapeutic dosages, the drug appears to lose its selectivity for the MAO-B enzyme at higher dosages (e.g., those exceeding 10 mg/kg), thereby increasing the risk of serotonin syndrome in patients receiving higher dosages of the drug either alone or in combination with other serotonergic agents. The manufacturer of selegiline recommends avoiding concurrent selegiline and selective serotonin-reuptake inhibitor therapy. In addition, the manufacturer of selegiline recommends that a drug-free interval of at least 2 weeks elapse between discontinuance of selegiline and initiation of selective serotonin-reuptake inhibitor therapy. Because of the long half-lives of fluoxetine and its principal metabolite, at least 5 weeks should elapse or even longer (particularly if fluoxetine has been prescribed chronically and/or at higher dosages) between discontinuance of fluoxetine and initiation of selegiline therapy.

Isoniazid. Isoniazid, an antituberculosis agent, appears to have some MAO-inhibiting activity. In addition, iproniazid (not commercially available in the US), another antituberculosis agent structurally related to isoniazid that also possesses MAO-inhibiting activity, reportedly has resulted in serotonin syndrome in at least 2 patients when given in combination with meperidine. Pending further experience, clinicians should be aware of the potential for serotonin syndrome when isoniazid is given in combination with selective serotonin-reuptake inhibitor therapy or other serotonergic agents.

Tryptophan and Other Serotonin Precursors Adverse nervous system effects (e.g., agitation, restlessness, aggressive behavior, insomnia, poor concentration, headache, paresthesia, incoordination, worsening of symptoms of obsessive-compulsive disorder), adverse GI effects (e.g., nausea, abdominal cramps, diarrhea), palpitation, and/or chills reportedly have occurred in a limited number of patients receiving fluoxetine concurrently with tryptophan, a serotonin precursor. Such symptoms generally resolved within several weeks following discontinuance of tryptophan despite continued fluoxetine therapy. Although the mechanism for this interaction has not been fully elucidated, it has been suggested that these adverse effects resemble the serotonin syndrome observed in animals and therefore may result from a marked increase in serotonin availability when tryptophan and potent serotonin-reuptake inhibitors such as fluoxetine are administered concurrently. Because of the potential risk of serotonin syndrome or NMS-like reactions, concurrent use of tryptophan or other serotonin precursors should be avoided in patients receiving fluoxetine.

Sibutramine Because of the possibility of developing potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions, sibutramine should be used with caution in patients receiving fluoxetine.

5-HT_1 Receptor Agonists ("Triptans") Weakness, hyperreflexia, and incoordination have been reported rarely during postmarketing surveillance in patients receiving sumatriptan concomitantly with an SSRI (e.g., fluoxetine, citalopram, escitalopram, fluvoxamine, paroxetine, sertraline). Oral or subcutaneous sumatriptan and SSRIs were used concomitantly in some clinical studies without unusual adverse effects. However, an increase in the frequency of migraine attacks and a decrease in the effectiveness of sumatriptan in relieving migraine headache have been reported in a patient receiving subcutaneous injections of sumatriptan intermittently while undergoing fluoxetine therapy.

Clinicians prescribing 5-HT_1 receptor agonists, SSRIs, and SNRIs should consider that triptans often are used intermittently and that either the 5-HT_1 receptor agonist, SSRI, or SNRI may be prescribed by a different clinician. Clinicians also should weigh the potential risk of serotonin syndrome or NMS-like reactions with the expected benefit of using a triptan concurrently with SSRI or SNRI therapy. If concomitant treatment with fluoxetine and a triptan is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, dosage increases, and following the addition of other serotonergic agents. Patients receiving concomitant triptan and fluoxetine therapy should be informed of the possibility of serotonin syndrome or NMS-like reactions and advised to immediately seek medical attention if they experience symptoms of these syndromes.

Other Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors Concomitant administration of fluoxetine with other SSRIs or SNRIs potentially may result in serotonin syndrome or NMS-like reactions and is therefore not recommended.

Antipsychotic Agents and Other Dopamine Antagonists Concomitant use of antipsychotic agents and other dopamine antagonists with fluoxetine potentially may result in serotonin syndrome or NMS-like reactions. If signs and symptoms of serotonin syndrome or NMS occur, treatment with fluoxetine and any concurrently administered antidopaminergic or serotonergic agents should be immediately discontinued and supportive and symptomatic treatment initiated. (See Drug Interactions: Antipsychotic Agents.)

Tramadol and Other Serotonergic Drugs Because of the potential risk of serotonin syndrome or NMS-like reactions, caution is advised whenever SSRIs, including fluoxetine, and SNRIs are concurrently administered with other drugs that may affect serotonergic neurotransmitter systems, including tramadol and St. John's wort (*Hypericum perforatum*).

Pentazocine, an opiate partial agonist analgesic, has been reported to cause transient symptoms of diaphoresis, ataxia, flushing, and tremor suggestive of the serotonin syndrome when used concurrently with fluoxetine.

Serotonin syndrome rarely may occur following concomitant use of fluoxetine and stimulants because stimulants can release serotonin, and amphetamine is metabolized by the cytochrome P-450 (CYP) 2D6 isoenzyme, which is inhibited by some SSRIs (e.g., fluoxetine, paroxetine).

■ **Drugs Undergoing Metabolism by Hepatic Microsomal Enzymes** ***Drugs Metabolized by Cytochrome P-450 (CYP) 2D6*** Fluoxetine, like many other antidepressants (e.g., other selective serotonin-

reuptake inhibitors, many tricyclic antidepressants), is metabolized by the drug-metabolizing cytochrome P-450 (CYP) 2D6 isoenzyme (debrisoquine hydroxylase). In addition, like many other drugs metabolized by CYP2D6, fluoxetine inhibits the activity of CYP2D6 and potentially may increase plasma concentrations of concomitantly administered drugs that also are metabolized by this enzyme. Fluoxetine may make normal CYP2D6 metabolizers resemble "poor metabolizers". Although similar interactions are possible with other selective serotonin-reuptake inhibitors, there is considerable variability among the drugs in the extent to which they inhibit CYP2D6; fluoxetine and paroxetine appear to be more potent in this regard than sertraline.

Concomitant use of fluoxetine with other drugs metabolized by CYP2D6 has not been systematically studied. The extent to which this potential interaction may become clinically important depends on the extent of inhibition of CYP2D6 by the antidepressant and the therapeutic index of the concomitantly administered drug. The drugs for which this potential interaction is of greatest concern are those that are metabolized principally by CYP2D6 and have a narrow therapeutic index, such as tricyclic antidepressants, class IC antiarrhythmics (e.g., propafenone, flecainide, encainide), vinblastine, and some phenothiazines (e.g., thioridazine).

Caution should be exercised whenever concurrent therapy with fluoxetine and other drugs metabolized by CYP2D6 is considered. If fluoxetine therapy is initiated in a patient already receiving a drug metabolized by CYP2D6, the need for decreased dosage of that drug should be considered. In addition, a low initial dosage should be used whenever a drug that is predominantly metabolized by CYP2D6 and has a relatively narrow therapeutic margin (e.g., tricyclic antidepressants, class IC antiarrhythmics) is initiated in a patients who is receiving or has received fluoxetine during the previous 5 weeks. Because of the risk of serious ventricular arrhythmias and sudden death potentially associated with increased plasma concentrations of thioridazine, thioridazine is contraindicated in any patient who is receiving or has received fluoxetine during the previous 5 weeks. (See Thioridazine under Drug Interactions: Antipsychotic Agents.)

Drugs Metabolized by Cytochrome P-450 (CYP) 3A4 Although fluoxetine can inhibit the cytochrome P-450 (CYP) 3A4 isoenzyme, results of in vitro and in vivo studies indicate that the drug is a much less potent inhibitor of this enzyme than many other drugs. In one in vivo drug interaction study, concomitant administration of single doses of the CYP3A4 substrate terfenadine (no longer commercially available in the US) and fluoxetine did not increase plasma concentrations of terfenadine. In addition, in vitro studies have shown that ketoconazole, a potent inhibitor of CYP3A4 activity, is at least 100 times more potent than fluoxetine or norfluoxetine as an inhibitor of several substrates of this enzyme (e.g., astemizole [no longer commercially available in the US], cisapride, midazolam). Some clinicians state that concomitant use of fluoxetine with astemizole or terfenadine is not recommended since substantially increased plasma concentrations of unchanged astemizole or terfenidine could occur, resulting in an increased risk of serious adverse cardiac effects. However, the manufacturer of fluoxetine states that the extent of fluoxetine's inhibition of CYP3A4 activity is unlikely to be of clinical importance.

■ **Tricyclic and Other Antidepressants** Concurrent administration of fluoxetine and a tricyclic antidepressant (e.g., nortriptyline, desipramine, imipramine) reportedly has resulted in adverse effects associated with tricyclic toxicity (including sedation, decreased energy, lightheadedness, psychomotor retardation, dry mouth, constipation, memory impairment). In patients receiving imipramine or desipramine, initiation of fluoxetine therapy reportedly resulted in plasma concentrations of these tricyclic antidepressants that were at least 2–10 times higher; this effect persisted for 3 weeks or longer after fluoxetine was discontinued. Elevated plasma trazodone concentrations and adverse effects possibly associated with trazodone toxicity (e.g., sedation, unstable gait) also have been reported during concomitant fluoxetine and trazodone therapy. Although the mechanism for this possible interaction has not been established, it has been suggested that fluoxetine may inhibit the hepatic metabolism of tricyclic antidepressants. (See Drugs Metabolized by Cytochrome P-450 (CYP) 2D6 under Drug Interactions: Drugs Undergoing Metabolism by Hepatic Microsomal Enzymes.) Further study of this potential interaction is needed, but current evidence suggests that patients receiving fluoxetine and a tricyclic antidepressant or trazodone concomitantly should be closely observed for adverse effects; monitoring of plasma tricyclic or trazodone concentrations also should be considered and their dosage reduced as necessary. Because fluoxetine may increase plasma concentrations and prolong the elimination half-life of tricyclic antidepressants, the need for more prolonged monitoring following combined tricyclic and fluoxetine overdose should be considered. In addition, because of the prolonged elimination of fluoxetine and norfluoxetine, the possibility that the drug may interact with tricyclic antidepressants after recent discontinuance of fluoxetine also should be considered.

■ **Antipsychotic Agents** Concomitant use of antipsychotic agents with fluoxetine potentially may result in serotonin syndrome or NMS-like reactions. If signs and symptoms of serotonin syndrome or NMS occur, treatment with fluoxetine and any concurrently administered antipsychotic agent should be immediately discontinued and supportive and symptomatic treatment initiated. (See Drug Interactions: Serotonergic Drugs.)

Some clinical data suggest a possible pharmacodynamic and/or pharmacokinetic interaction between SSRIs, including fluoxetine, and some antipsychotic agents.

Clozapine Concomitant use of fluoxetine and clozapine can increase plasma concentrations of clozapine and enhance clozapine's pharmacologic effects secondary to suspected inhibition of clozapine metabolism by fluoxetine. Increased plasma clozapine concentrations also have been reported in patients receiving other SSRIs (e.g., fluvoxamine, paroxetine). There has been at least one fatality related to clozapine toxicity following ingestion of clozapine, fluoxetine, and alcohol. The manufacturer of clozapine states that caution should be used and patients closely monitored if clozapine is used in patients receiving SSRIs, and a reduction in clozapine dosage should be considered.

Haloperidol Elevated plasma concentrations of haloperidol have been observed in patients receiving concomitant fluoxetine therapy. Severe extrapyramidal symptoms (e.g., tongue stiffness, parkinsonian symptoms, akathisia), which required hospitalization and were refractory to conventional therapy (including anticholinergic antiparkinsonian agents, diphenhydramine, and diazepam), reportedly occurred in a patient receiving fluoxetine and haloperidol concurrently; this patient previously had experienced only mild adverse extrapyramidal effects with haloperidol therapy alone. The extrapyramidal symptoms gradually abated following discontinuance of both drugs, and the patient subsequently tolerated haloperidol therapy with evidence of only a slight parkinsonian gait. The clinical importance of this possible interaction has not been established, and additional study is required to determine the safety of combined fluoxetine and antipsychotic therapy.

Olanzapine Concomitant administration of fluoxetine (60 mg as a single dose or 60 mg daily for 8 days) with a single 5-mg dose of oral olanzapine caused a small increase in peak plasma olanzapine concentrations (averaging 16%) and a small decrease (averaging 16%) in olanzapine clearance; the elimination half-life was not substantially affected. Fluoxetine is an inhibitor of CYP2D6, and thereby may affect a minor metabolic pathway for olanzapine. Although the changes in pharmacokinetics are statistically significant when olanzapine and fluoxetine are given concurrently, the changes are unlikely to be clinically important in comparison to the overall variability observed between individuals; therefore, routine dosage adjustment is not recommended.

When fluoxetine is used in fixed combination with olanzapine (Symbyax®), the drug interactions associated with olanzapine should also be considered. (See Drug Interactions in Olanzapine 28:16.08.04.)

Pimozide Clinical studies evaluating pimozide in combination with other antidepressants have demonstrated an increase in adverse drug interactions or QT_c prolongation during combined therapy. In addition, rare case reports have suggested possible additive cardiovascular effects of fluoxetine and pimozide, resulting in bradycardia. Marked changes in mental status (e.g., stupor, inability to think clearly) and hypersalivation also were reported in one woman who received both drugs concurrently. Although a specific study evaluating concurrent fluoxetine and pimozide therapy has not been performed to date, concurrent use of these drugs is contraindicated because of the potential for adverse drug interactions or QT_c prolongation.

Risperidone Extrapyramidal symptoms followed by persistent tardive dyskinesia (dyskinetic tongue movements) have occurred in one 18-year-old who received risperidone concomitantly with fluoxetine; however, a causal relationship has not been established. The AUC of risperidone increased during concomitant fluoxetine therapy in one study in psychotic patients, and the AUC of active drug (risperidone plus 9-hydroxyrisperidone) increased in poor and extensive metabolizers (determined by CYP2D6 genotyping); there was no evidence of increased severity or incidence of extrapyramidal symptoms in this 30-day study.

Thioridazine Although specific drug interaction studies evaluating concomitant use of fluoxetine and thioridazine are not available, concomitant use of other SSRIs (e.g., fluvoxamine) has resulted in increased plasma concentrations of the antipsychotic agent. Because of the risk of serious ventricular arrhythmia and sudden death associated with elevated plasma concentrations of thioridazine, thioridazine is contraindicated in any patient who is receiving or has received fluoxetine during the previous 5 weeks. (See Drugs Metabolized by Cytochrome P-450 (CYP) 2D6 under Drug Interactions: Drugs Undergoing Metabolism by Hepatic Microsomal Enzymes.)

■ **Benzodiazepines** Fluoxetine appears to inhibit the metabolism of diazepam, as evidenced by increases in the elimination half-life and plasma concentration of diazepam and decreases in diazepam clearance and the rate of formation of desmethyldiazepam (an active metabolite of diazepam) during concomitant use of the drugs. Although clinically important increase in psychomotor impairment has not been noted when fluoxetine and diazepam were administered concomitantly as compared with administration of diazepam alone, concomitant administration of alprazolam and fluoxetine has resulted in increased plasma concentrations of alprazolam and further psychomotor performance impairments. Pending further accumulation of data, the possibility that a clinically important interaction could occur in geriatric or other susceptible patients should be considered.

■ **Buspirone** Buspirone has serotonergic activity and may have been partially responsible for a case of serotonin syndrome that resulted in the death of a patient receiving fluoxetine, buspirone, and an MAO inhibitor (tranylcypromine) concomitantly. (See Drug Interactions: Serotonergic Drugs.)

In a patient with depression, generalized anxiety disorder, and panic attacks who was receiving concomitant buspirone and trazodone therapy, an increase in anxiety symptoms to a level comparable to that observed prior to buspirone

therapy occurred when fluoxetine was added to the regimen. Although the mechanism of this possible interaction has not been established, it was suggested that fluoxetine may have either directly antagonized the therapeutic activity of buspirone or may have precipitated the anxiety symptoms through a separate mechanism. However, combined use of the drugs also has been reported to potentiate therapeutic efficacy in patients with obsessive-compulsive disorder.

■ **Lithium** Fluoxetine and lithium have been used concurrently in a limited number of patients without apparent adverse effects. However, both increased and decreased serum lithium concentrations and adverse neuromuscular effects possibly associated with lithium toxicity and/or serotonin syndrome (e.g., ataxia, dizziness, dysarthria, stiffness of the extremities) have been reported during combined therapy with the drugs. Lithium appears to have some serotonergic activity, and serotonin syndrome has been reported following the initiation of lithium therapy in at least one patient receiving fluoxetine. (See Drug Interactions: Serotonergic Drugs.) The clinical importance of this potential interaction remains to be determined and further substantiation is required; however, caution should be exercised when fluoxetine and lithium are administered concurrently. It is recommended that serum lithium concentrations be monitored closely during concomitant fluoxetine therapy.

■ **Anticonvulsants** ***Carbamazepine*** Fluoxetine can increase plasma carbamazepine and carbamazepine 10,11-epoxide (CBZ-E, an active metabolite) concentrations, and carbamazepine toxicity (e.g., ocular changes, vertigo, tremor) has been reported in some patients maintained on carbamazepine following initiation of fluoxetine. It has been suggested that fluoxetine-induced inhibition of hepatic metabolism (e.g., inhibition of epoxide hydrolase) of carbamazepine and/or CBZ-E may be principally responsible for such increases; alteration in protein binding does not appear to be principally responsible for this interaction. The patient and plasma concentrations of carbamazepine and its metabolite should be monitored closely whenever fluoxetine therapy is initiated or discontinued; carbamazepine dosage should be adjusted accordingly.

Phenytoin Initiation of fluoxetine in patients stabilized on phenytoin has resulted in increased plasma phenytoin concentrations and clinical manifestations of phenytoin toxicity.

■ **β-Adrenergic Blocking Agents** Concomitant use of fluoxetine and a β-adrenergic blocking agent has resulted in increased plasma concentrations that have enhanced the β-adrenergic blocking effects of the drug, possibly resulting in cardiac toxicity. Metoprolol is metabolized by the CYP2D6 isoenzyme and fluoxetine is known to potently inhibit this enzyme. Although specific data are lacking, β-adrenergic blocking agents that are renally eliminated (e.g., atenolol) may be a safer choice. Patients who were previously stabilized on propranolol or metoprolol should be monitored for toxicity (e.g., bradycardia, conduction defects, hypotension, heart failure, central nervous system disturbances) following initiation of fluoxetine therapy.

■ **Protein-bound Drugs** Because fluoxetine is highly protein bound, the drug theoretically could be displaced from binding sites by, or it could displace from binding sites, other protein-bound drugs such as oral anticoagulants and digitoxin (no longer commercially available in the US). Pending further accumulation of data, patients receiving fluoxetine with any highly protein-bound drug should be observed for potential adverse effects associated with such therapy. (See Drug Interactions: Drugs Affecting Hemostasis.)

■ **Drugs Affecting Hemostasis** ***Warfarin*** Concomitant use of fluoxetine and warfarin has resulted in altered anticoagulant effects, including increased bleeding. Therefore, patients receiving warfarin should be carefully monitored whenever fluoxetine is initiated or discontinued.

Other Drugs that Interfere with Hemostasis Epidemiologic case-control and cohort design studies that have demonstrated an association between selective serotonin-reuptake inhibitor therapy and an increased risk of upper GI bleeding also have shown that concurrent use of aspirin or other nonsteroidal anti-inflammatory agents substantially increases the risk of GI bleeding. Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated. The precise mechanism for this increased risk remains to be clearly established; however, serotonin release by platelets is known to play an important role in homostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets, thereby decreasing the amount of serotonin in platelets. Patients receiving fluoxetine should be cautioned about the concomitant use of drugs that interfere with hemostasis, including aspirin and other nonsteroidal anti-inflammatory agents.

■ **Alcohol** Concurrent administration of single or multiple doses of fluoxetine and alcohol does not appear to alter blood or Breathalyzer® alcohol, plasma fluoxetine, or plasma norfluoxetine concentrations in healthy individuals, suggesting that there is no pharmacokinetic interaction between fluoxetine and alcohol. In addition, fluoxetine does not appear to potentiate the psychomotor and cognitive impairment or cardiovascular effects induced by alcohol. However, the drug's ability to reduce alcohol consumption in animals and humans suggests that there may be a serotonergically mediated, pharmacodynamic interaction between fluoxetine and alcohol within the CNS. (See Pharmacology: Effects on Alcohol Intake, and also see Uses: Alcohol Dependence.)

■ **Electroconvulsive Therapy** The effects of fluoxetine in conjunction with electroconvulsive therapy (ECT) for the management of depression have not been evaluated to date in clinical studies. Prolonged seizures reportedly have occurred rarely during concurrent use of fluoxetine and ECT.

■ **Antidiabetic Agents** Fluoxetine potentially may alter blood glucose concentrations in patients with diabetes mellitus. (See Cautions: Metabolic Effects.) Therefore, dosage adjustments of insulin and/or sulfonylurea antidiabetic agents may be necessary when fluoxetine therapy is initiated or discontinued in such patients.

Acute Toxicity

Limited information is available on the acute toxicity of fluoxetine.

■ **Pathogenesis** The acute lethal dose of fluoxetine in humans is not known. The median oral LD_{50} of fluoxetine has been reported to be approximately 452 and 248 mg/kg in rats and mice, respectively. In animals, oral administration of single large doses of the drug has resulted in hyperirritability and seizures. Tonic-clonic seizures occurred in 5 of 6 dogs given a toxic dose of fluoxetine orally; the seizures ceased immediately after IV administration of diazepam. In these dogs, the lowest plasma fluoxetine concentration at which seizures occurred reportedly was only twice the maximum plasma concentration reported in humans receiving 80 mg of the antidepressant daily during long-term therapy. Single large oral doses of fluoxetine reportedly do not cause QT- or PR-interval prolongation or widening of the QRS complex in dogs, although tachycardia and an increase in blood pressure have occurred.

The risk of fluoxetine overdosage may be increased in patients with a genetic deficiency in the cytochrome P-450 (CYP) isoenzyme 2D6.

■ **Manifestations** In general, overdosage of fluoxetine may be expected to produce effects that are extensions of the drug's pharmacologic and adverse effects. Animal studies and case reports in humans indicate that possible effects of overdosage include agitation, restlessness, hypomania, vertigo, insomnia, tremor, and other signs of CNS excitation; nausea and vomiting; and tachycardia and/or increased blood pressure. Seizures have been reported in at least one patient after overdosage of fluoxetine. Acute overdosage of fluoxetine alone reportedly has resulted in nystagmus, drowsiness, coma, urticaria, spontaneous emesis, and ST-segment depression. Nausea and vomiting appear to occur commonly following acute ingestion of relatively large single doses of the drug.

Several fatalities following fluoxetine overdosage have been reported to date. One of the deaths occurred in a patient who reportedly ingested 1.8 g of fluoxetine and an unknown quantity of maprotiline; plasma fluoxetine and maprotiline concentrations in this patient were approximately 4570 and 4180 ng/mL, respectively. Another patient died after concomitantly ingesting fluoxetine, codeine, and temazepam; plasma fluoxetine, norfluoxetine, codeine, and temazepam concentrations in this patient reportedly were 1930, 1110, 1800, and 3800 ng/mL, respectively. A fatal overdose also has been reported in a patient ingesting fluoxetine and alcohol concomitantly. There also are a few reported cases of overdose in which fatality was attributed to fluoxetine alone. In one such case, death was associated with extracted blood fluoxetine and norfluoxetine concentrations of 6000 and 5000 ng/mL, respectively, and biliary concentrations of 13,000 ng/mL each for the drug and metabolite. A patient enrolled in a clinical study of fluoxetine reportedly died following intentional ingestion of an unknown quantity of amitriptyline, clobazam, and pentazocine; however, it is not known whether this patient also ingested fluoxetine with the other drugs.

A patient with a history of seizures who reportedly ingested 3 g of fluoxetine and an unknown quantity of aspirin experienced 2 tonic-clonic seizures, tachycardia, dizziness, blurred vision, unsustained clonus, and ECG changes. The seizures occurred about 9 hours post-ingestion, lasted approximately 2–3 minutes, and remitted spontaneously without anticonvulsant therapy. Although the actual amount of fluoxetine absorbed by this patient may have been less than expected because of vomiting and gastric lavage, the plasma fluoxetine concentration reportedly was 2461 ng/mL when seizures occurred; the patient recovered with no apparent sequelae. Another patient reported that he experienced sleepiness and nausea that lasted for several days following the intentional ingestion of 840 mg of fluoxetine with alcohol; this patient did not seek medical treatment. Drowsiness, lethargy, and nausea occurred in a patient who reportedly ingested 1.4 g of fluoxetine and 15 mg of clonazepam. No ECG abnormalities were reported in 2 patients who intentionally ingested 200 mg and 1 g of fluoxetine.

A child with a genetic deficiency in the CYP2D6 isoenzyme died following prolonged therapy with fluoxetine, methylphenidate, and clonidine. Autopsy findings revealed blood, brain, and other tissue concentrations of fluoxetine and norfluoxetine that were several-fold higher than expected. Poor metabolism of fluoxetine via CYP2D6 was the likely cause of fluoxetine intoxication in this child.

■ **Treatment** Because fatalities and severe toxicity have been reported following overdosage of selective serotonin-reuptake inhibitors, particularly in large overdosage and when taken with other drugs or alcohol, some clinicians recommend that any overdosage involving these drugs be managed aggressively. Because suicidal ingestion often involves more than one drug, clinicians treating fluoxetine overdosage should be alert to possible toxic manifestations caused by drugs other than fluoxetine.

Clinicians also should consider the possibility of serotonin syndrome or NMS-like reactions in patients presenting with similar clinical features and a recent history of fluoxetine ingestion and/or ingestion of other serotonergic and/

or antipsychotic agents or other dopamine antagonists. (See Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.)

Management of fluoxetine overdosage generally involves symptomatic and supportive care. A patent airway should be established and maintained, and adequate oxygenation and ventilation should be assured. ECG and vital sign monitoring is recommended following acute overdosage with the drug, although the value of ECG monitoring in predicting the severity of fluoxetine-induced cardiotoxicity is not known. (See Acute Toxicity: Manifestations, in the Tricyclic Antidepressants General Statement.) There is no specific antidote for fluoxetine intoxication.

Following recent (i.e., within 4 hours) ingestion of a potentially toxic amount of fluoxetine and in the absence of signs and symptoms of cardiac toxicity, the stomach should be emptied immediately by inducing emesis or by gastric lavage. If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of gastric contents. Since administration of activated charcoal (which may be used in conjunction with sorbitol or a saline cathartic) may be as effective or more effective than induction of emesis or gastric lavage, its use has been recommended either in the initial management of fluoxetine overdosage or following induction of emesis or gastric lavage in patients who have ingested a potentially toxic quantity of the drug.

Based on data from animal studies, IV diazepam should be considered for the management of fluoxetine-induced seizures that do not remit spontaneously. If seizures are not controlled or recur following administration of diazepam, administration of phenytoin or phenobarbital has been recommended by some clinicians.

Fluoxetine and norfluoxetine are not substantially removed by hemodialysis. Because of the large volume of distribution and extensive protein binding of the drug and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion probably are also ineffective in removing substantial amounts of fluoxetine and norfluoxetine from the body. Clinicians should consider consulting a poison control center for additional information on the management of fluoxetine overdosage.

Chronic Toxicity

Fluoxetine has not been studied systematically in animals or humans to determine whether therapy with the drug is associated with tolerance or psychologic and/or physical dependence. One patient receiving the drug for the management of obesity reportedly experienced nervousness 2 days following discontinuance of fluoxetine therapy. However, it is unclear whether this adverse effect represented a withdrawal reaction since both the parent drug and its principal metabolite have relatively long half-lives, and withdrawal reactions following discontinuance of fluoxetine therapy may therefore be more delayed. Although clinical experience to date has not revealed substantial evidence of drug-seeking behavior or a withdrawal syndrome associated with discontinuance of fluoxetine therapy, it is difficult to predict from the limited data currently available the extent to which a CNS-active drug like fluoxetine may be misused, diverted, and/or abused.

Despite the lack of substantial evidence for abuse potential or dependence liability, clinicians should carefully evaluate patients for a history of substance abuse prior to initiating fluoxetine therapy. If fluoxetine therapy is initiated in patients with a history of substance abuse, such patients should be monitored closely for signs of misuse or abuse of the drug (e.g., development of tolerance, use of increasing doses, drug-seeking behavior).

The potential for misuse of fluoxetine by depressed patients with concurrent eating disorders and/or those who may seek the drug for its appetite-suppressant effects also should be considered. One patient with an undisclosed history of anorexia nervosa and laxative abuse who was given fluoxetine for depression ingested larger-than-prescribed doses (e.g., 90–120 mg/day) and lost 9.1 kg within 2 months; this patient falsely claimed mood improvement in order to continue receiving the drug for its anorectic and weight-reducing effects.

Fluoxetine has produced phospholipidosis following long-term administration in animals; however, no evidence of phospholipidosis has been reported in humans receiving the drug to date. Additional study is needed to determine the clinical importance of these findings in patients receiving long-term fluoxetine therapy. (See Pharmacology: Effects on Phospholipids.)

Pharmacology

The pharmacology of fluoxetine is complex and in many ways resembles that of other antidepressant agents, particularly those agents (e.g., citalopram, clomipramine, escitalopram, fluvoxamine, paroxetine, sertraline, trazodone) that predominantly potentiate the pharmacologic effects of serotonin (5-HT). Like other selective serotonin-reuptake inhibitors (SSRIs), fluoxetine is a potent and highly selective reuptake inhibitor of serotonin and has little or no effect on other neurotransmitters.

■ **Nervous System Effects** The precise mechanism of antidepressant action of fluoxetine is unclear, but the drug has been shown to selectively inhibit the reuptake of serotonin at the presynaptic neuronal membrane. Fluoxetine-induced inhibition of serotonin reuptake causes increased synaptic concentrations of serotonin in the CNS, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission. Like other selective serotonin-reuptake inhibitors (fluvoxamine, paroxetine, sertraline), fluoxetine appears to have minimal or no effect on the reuptake of norepinephrine or dopamine and does not exhibit clinically important anticholinergic, antihistaminic, or α_1-adrenergic blocking activity at usual therapeutic dosages.

Although the mechanism of antidepressant action of antidepressant agents may involve inhibition of the reuptake of various neurotransmitters (i.e., norepinephrine, serotonin) at the presynaptic neuronal membrane, it has been suggested that postsynaptic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of antidepressant agents. During long-term therapy with most antidepressants (e.g., tricyclic antidepressants, monoamine oxidase [MAO] inhibitors), these adaptive changes generally consist of subsensitivity of the noradrenergic adenylate cyclase system in association with a decrease in the number of β-adrenergic receptors; such effects on noradrenergic receptor function commonly are referred to as "down-regulation." In addition, some antidepressants reportedly decrease the number of 5-HT binding sites following chronic administration. Fluoxetine may exert its antidepressant activity by somewhat different mechanisms than those usually associated with tricyclic and some other antidepressants. Although some evidence indicates that long-term administration of fluoxetine does not substantially decrease the number of β-adrenergic binding sites or reduce the sensitivity of β-adrenergic receptors, a decrease in the number of β-adrenergic binding sites in the brain has been reported in at least one study in animals. Data regarding the effects of fluoxetine on the number of serotonin (5-HT_1 and/or 5-HT_2) binding sites have been conflicting, with either no change or a reduction in the number of binding sites being reported during chronic administration of the drug. Increased postsynaptic receptor binding of GABA B also has been reported following prolonged administration of many antidepressants, including fluoxetine. The clinical importance of these findings for fluoxetine has not been fully elucidated to date, and further study is needed to determine the role, if any, of binding site alteration in the antidepressant action of fluoxetine and other antidepressants.

The precise mechanism of action responsible for the efficacy of fluoxetine in the treatment of obsessive-compulsive disorder is unclear. However, based on the efficacy of other selective serotonin-reuptake inhibitors (e.g., fluvoxamine, paroxetine, sertraline) and clomipramine in the treatment of obsessive-compulsive disorder and the potency of these drugs in inhibiting serotonin reuptake, a serotonergic hypothesis has been developed to explain the pathogenesis of the condition. The hypothesis postulates that a dysregulation of serotonin is responsible for obsessive-compulsive disorder and that fluoxetine and these other agents are effective because they correct this imbalance. Although the available evidence supports the serotonergic hypothesis of obsessive-compulsive disorder, additional studies are necessary to confirm this hypothesis.

Serotonergic Effects Fluoxetine is a highly selective inhibitor of serotonin reuptake at the presynaptic neuronal membrane. In addition, the potency and selectivity of serotonin-reuptake inhibition exhibited by fluoxetine's principal metabolite, norfluoxetine, appear to be similar to those of the parent drug. Fluoxetine- and norfluoxetine-induced inhibition of serotonin reuptake causes increased synaptic concentrations of serotonin, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission.

Data from in vitro studies suggest that fluoxetine is approximately equivalent to or less potent than clomipramine as a serotonin-reuptake inhibitor; however, in vivo studies indicate that the serotonin-reuptake inhibiting effect of fluoxetine may be more potent than that of clomipramine on a weight as well as an equimolar basis. This apparent discrepancy may be explained at least in part by the relatively long elimination half-lives of fluoxetine and norfluoxetine. In addition, metabolism via *N*-demethylation decreases the potency and specificity of serotonin-reuptake inhibition of clomipramine but not fluoxetine. Data from both in vivo and in vitro studies indicate that fluoxetine also is a more potent serotonin-reuptake inhibitor than other currently available antidepressant agents, including imipramine and trazodone. Fluoxetine appears to have practically no affinity for serotonin (e.g., 5-HT_1 and 5-HT_2) receptors in vitro, although limited in vivo data suggest that the drug may bind to low-affinity sites on 5-HT receptors.

Fluoxetine appears to decrease the turnover of serotonin in the CNS, probably as a result of a decrease in the rate of serotonin synthesis. The drug reportedly decreases brain concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of serotonin; reduces the uptake of radiolabeled tryptophan by synaptosomes; and reduces the rate of conversion of tryptophan to serotonin. Fluoxetine also inhibits spontaneous firing of serotonergic neurons in the dorsal raphe nucleus.

Like other serotonin-reuptake inhibitors, administration of fluoxetine alone does not produce the serotonin behavioral syndrome (a characteristic behavioral pattern caused by central stimulation of serotonin activity) in animals. However, the drug potentiates the serotonin behavioral syndrome induced by oxitriptan (l-5-hydroxytryptophan, l-5HTP), MAO inhibitors, and MAO inhibitors combined with tryptophan.

Effects on Other Neurotransmitters Like other selective serotonin-reuptake inhibitors, fluoxetine appears to have little or no effect on the reuptake of other neurotransmitters such as norepinephrine or dopamine. In addition, the drug appears to have a substantially higher selectivity ratio of serotonin-to-norepinephrine reuptake inhibiting activity than tricyclic antidepressant agents, including clomipramine.

Unlike tricyclic and some other antidepressants, fluoxetine does not exhibit clinically important anticholinergic, α_1-adrenergic blocking, or antihistaminic activity at usual therapeutic dosages. As a result, the incidence of adverse effects commonly associated with blockade of muscarinic cholinergic receptors

(e.g., dry mouth, blurred vision, urinary retention, constipation, confusion), α_1-adrenergic receptors (e.g., orthostatic hypotension), and histamine H_1- and H_2-receptors (e.g., sedation) is lower in fluoxetine-treated patients. In vitro studies have demonstrated that the drug possesses only weak affinity for α_1- and α_2-adrenergic, β-adrenergic, H_1 and H_2, muscarinic, opiate, GABA-benzodiazepine, and dopamine receptors.

Effects on Sleep Like tricyclic and most other antidepressants, fluoxetine suppresses rapid eye movement (REM) sleep. Although not clearly established, there is some evidence that the REM-suppressing effects of antidepressant agents may contribute to the antidepressant activity of these drugs. In animal studies, fluoxetine produces a dose-related suppression of REM sleep; the drug generally appears to reduce the amount of REM sleep by increasing REM latency (the time to onset of REM sleep) and by decreasing the number rather than the duration of REM episodes. Limited data in animals suggest that REM rebound does not occur following discontinuance of fluoxetine. The precise mechanism has not been fully elucidated, but results of animal studies indicate that fluoxetine's effects on REM sleep are serotonergically mediated. Like other specific serotonin-reuptake inhibitors (e.g., zimeldine [previously zimelidine]), the effects of fluoxetine on non-REM sleep reported to date have been variable and do not appear to be as clearly defined as those of tricyclic antidepressants, which usually increase slow-wave sleep.

Effects on EEG Limited data currently are available regarding the effects of fluoxetine on the EEG. Substantial EEG changes did not occur following oral administration of single 30-mg doses of the drug in healthy individuals. An increase in alpha activity and a decrease in fast beta activity and slow activity were noted following single oral 60-mg doses in this study; such changes are characteristic of desipramine-type antidepressants and appear to indicate increased vigilance. Single 75-mg doses of fluoxetine produced an increase in slow and fast activity and a decrease in alpha activity; such EEG changes are similar to those observed with amitriptyline and imipramine and suggest possible sedative activity.

Effects on Psychomotor Function Fluoxetine does not appear to cause clinically important sedation and does not interfere with psychomotor performance. Controlled studies in healthy young adults 21–45 of years and in adults with major depression did not demonstrate any adverse effects on psychomotor performance in those receiving the drug. No adverse effects on psychomotor performance or cognitive function were observed in men with depression older than 60 years of age who received 20-mg doses of fluoxetine in a controlled study. Results of this study showed that overall cognition, as assessed by the critical flicker fusion thresholds test, generally was better in patients receiving fluoxetine than in those receiving amitriptyline (a tricyclic antidepressant); however, less sedating tricyclic antidepressants (e.g., desipramine) were not included in the study and it is possible that fluoxetine may not have such an advantage over these other agents. In a controlled study evaluating the effects of fluoxetine (20 mg daily for 22 days) on psychomotor performance and car driving in healthy adults, the drug did not affect the highway driving or the car following tests but slightly impaired performance in correctly detecting changes in visual signals was evident in the sustained attention test.

Analgesic Effects Like other serotonin-reuptake inhibitors (e.g., zimeldine), fluoxetine exhibits analgesic activity in some analgesic test systems when administered alone in animals, but the lack of such effects observed in other test systems suggests that demonstration of analgesic activity may be test-dependent. Fluoxetine has potentiated opiate agonist-induced analgesia in most but not all studies, possibly as a result of the drug's ability to enhance serotonergic neurotransmission. The clinical importance of these effects in the management of acute and chronic pain remains to be determined.

Effects on Respiration Usual therapeutic dosages of fluoxetine do not appear to affect respiration substantially in humans; however, the effect of higher dosages of the drug on respiratory function remains to be established. In animals, administration of single 20-mg/kg doses of fluoxetine reportedly increased blood Po_2 concentrations but did not alter blood Pco_2 concentrations. The drug also has been shown to attenuate morphine-induced respiratory depression, although the precise mechanism for this effect has not been established.

Effects on Thermoregulation Data are conflicting regarding the effect of fluoxetine on thermoregulation. In animals, fluoxetine has produced dose-dependent hypothermia in some studies, suggesting that serotonin may play a role in thermoregulation, but the drug has produced only slight or minimal hypothermia in other studies.

The drug has been used safely in at least one patient with established susceptibility to malignant hyperthermia; however, additional experience with the drug is needed to confirm the safety of fluoxetine in patients known to be susceptible to this condition.

■ **Cardiovascular Effects** The cardiovascular effects of fluoxetine have been studied in animals and to a limited extent in humans. Unlike some other antidepressant agents (e.g., tricyclic antidepressants, MAO inhibitors), fluoxetine has been associated with only minimal cardiovascular effects. The absence of substantial anticholinergic activity, α_1-adrenergic blocking activity, catecholamine-potentiating effects, and quinidine-like cardiotoxic effects appears to be the principal reason for the general lack of cardiovascular effects associated with fluoxetine.

Fluoxetine does not exhibit clinically important α_1-adrenergic blocking activity and does not inhibit catecholamine reuptake. Unlike tricyclic antidepressants, fluoxetine does not block the neuronal reuptake of norepinephrine and therefore does not potentiate the pressor response associated with administration of norepinephrine. In addition, the drug does not inhibit the reuptake of and has no effect on the pressor response to tyramine.

Fluoxetine does not appear to have substantial arrhythmogenic activity; however, safety of the drug in patients with a recent history of myocardial infarction or unstable cardiovascular disease has not been adequately evaluated to date. Fluoxetine generally does not appear to affect cardiac conduction, and clinically important ECG changes have not been reported in patients without preexisting heart disease receiving therapeutic dosages of the drug. Unlike tricyclic antidepressants, which commonly cause an increase in heart rate, fluoxetine reportedly reduces heart rate by an average of about 3 beats/minute in patients receiving usual therapeutic dosages of the antidepressant. (See Cautions: Cardiovascular Effects.) Unlike tricyclics, the drug does not appear to exhibit direct quinidine-like cardiotoxic activity, although the cardiovascular effects associated with fluoxetine overdosage have not been fully established to date. (See Acute Toxicity.)

■ **Effects on Appetite and Body Weight** Like some other serotonergic agents (e.g., fenfluramine [no longer commercially available in the US], zimeldine), fluoxetine possesses anorectic activity. Although the precise mechanism has not been clearly established, results of animal studies indicate that the drug's appetite-inhibiting action may result from serotonin-reuptake blockade and the resultant increase in serotonin availability at the neuronal synapse. Following administration of single and multiple doses of fluoxetine in both meal-fed and free-feeding animals, a reduction in food intake usually occurs, particularly at relatively high doses of the drug (i.e., 10 mg/kg). The anorectic effect of fluoxetine appears to be potentiated by oxitriptan. Tolerance to the anorectic effect of fluoxetine has not developed following short-term administration in humans and animals; however, long-term studies in humans are necessary to fully determine whether tolerance develops during chronic therapy with the drug.

In animal studies, fluoxetine has been shown to suppress palatability-induced food consumption (as determined by the volume of sweetened versus plain water ingested). Like fenfluramine, fluoxetine also appears to selectively suppress carbohydrate and overall food intake while maintaining protein intake. Such carbohydrate intake-suppressing and protein-sparing effects may be of potential clinical importance in the management of obesity; however, additional study is necessary. (See Uses: Obesity.) Fluoxetine therapy also has resulted in decreases in body weight in normal-weight and obese animals as well as in depressed, nondepressed, and obese individuals receiving the drug. (See Uses: Obesity and also see Cautions: Metabolic Effects.)

■ **Effects on Alcohol Intake** Like some other serotonergic agents, fluoxetine produces a dose-dependent decrease in voluntary alcohol intake in normal and alcohol-preferring animals. Like some other serotonin-reuptake inhibitors (e.g., citalopram, zimeldine), fluoxetine has been shown to reduce alcohol consumption in a limited number of heavy drinkers receiving 60 mg of the drug daily. Because serotonin appears to be involved in the regulation of alcohol intake, it has been suggested that fluoxetine may attenuate alcohol consumption via enhanced serotonergic neurotransmission. In addition, there is some evidence that such effects may be at least partially mediated by the renin-angiotensin-aldosterone system. (See Uses: Alcohol Dependence and see Drug Interactions: Alcohol.)

■ **Neuroendocrine Effects** Fluoxetine affects the endocrine system. Like other selective inhibitors of serotonin reuptake, the drug has produced a dose-related increase in serum corticosterone concentrations in animals. Fluoxetine also reportedly potentiates oxitriptan-induced elevation in serum corticosterone concentrations. Such effects appear to be serotonergically mediated. Following parenteral administration of fluoxetine in animals, the elevation in serum corticosterone concentration generally lasts only a few hours, although fluoxetine-induced inhibition of serotonin reuptake is known to persist for longer than 24 hours. Therefore, it has been suggested that other compensatory mechanisms, possibly including decreased firing of serotonergic neurons, may contribute to the restoration of normal hypothalamic-pituitary-adrenal (HPA) axis function despite prolonged blockade of serotonin reuptake by the drug. Fluoxetine also has increased corticotropin (ACTH) and vasopressin (antidiuretic hormone, ADH) concentrations in peripheral plasma and has increased corticotropin and corticotropin-releasing factor (CRF, corticoliberin) concentrations in hypophysial portal blood. These effects may represent the initial step in fluoxetine-induced elevation of plasma corticosterone concentrations.

The effects of fluoxetine on serum prolactin concentrations have not been clearly established. In some animal studies, fluoxetine potentiated tryptophan-induced increases in serum prolactin concentrations, although administration of the drug alone in animals and humans usually does not substantially alter prolactin concentrations. However, administration of fluoxetine alone reportedly increased serum prolactin concentrations in young but not old male rats in one study. Fluoxetine-induced effects on prolactin secretion appear to be serotonergically mediated.

■ **Effects on Phospholipids** Like many other cationic, amphiphilic drugs (e.g., amiodarone, fenfluramine, imipramine, ranitidine), fluoxetine reportedly increases tissue phospholipid concentrations following chronic ad-

ministration in animal studies; however, such effects have not been demonstrated in humans receiving fluoxetine to date. Histologic examination following long-term (i.e., 1–12 months) fluoxetine administration in animals has revealed the presence of characteristic concentric, lamellar inclusion bodies associated with phospholipidosis in alveolar macrophages of the lung, Kupffer cells of the liver, and adrenal cortical cells; an increase in phospholipid content of the lung also has been reported. Fluoxetine-induced phospholipid accumulation in these animals was reversible within 1–2 months following discontinuance of the drug.

Studies in humans receiving fluoxetine have not revealed biochemical or clinical evidence of drug-induced phospholipidosis to date. There was no evidence of increased phospholipid content or changes in lamellar inclusion bodies in peripheral blood lymphocytes of either healthy individuals receiving 1 month of fluoxetine therapy or depressed patients receiving long-term (0.9–2.6 years) therapy with the drug. In addition, ophthalmologic examination and chest radiographs in patients receiving fluoxetine during clinical studies have not revealed evidence of phospholipidosis induced by the drug. Although data from clinical studies suggest that fluoxetine-induced phospholipidosis is unlikely to occur in humans receiving long-term therapy with the drug, further study is needed to fully determine whether the phospholipidosis observed in animal studies is clinically important in humans receiving therapeutic dosages of the drug.

■ **Other Effects** Fluoxetine has demonstrated some antimyoclonic activity in animals and humans when used in combination with oxitriptan. Although the mechanism of fluoxetine's antimyoclonic activity has not been fully elucidated, some forms of myoclonus appear to be related to impaired serotonergic neurotransmission. Therefore, it has been suggested that fluoxetine-induced enhancement of serotonergic neurotransmission via serotonin-reuptake blockade potentially may contribute to oxitriptan-induced increases in CNS serotonin concentrations in the management of this condition. (See Uses: Myoclonus.)

Fluoxetine also has reduced cataplexy in both humans and animals. (See Uses: Cataplexy.)

Fluoxetine reportedly has produced a dose-related elevation in plasma β-endorphin and β-lipotropin concentrations in healthy individuals receiving single oral doses of the drug.

Pharmacokinetics

In all human studies described in the Pharmacokinetics section, fluoxetine was administered as the hydrochloride salt.

■ **Absorption** Fluoxetine hydrochloride appears to be well absorbed from the GI tract following oral administration. The oral bioavailability of fluoxetine in humans has not been fully elucidated to date, but at least 60–80% of an oral dose appears to be absorbed. However, the relative proportion of an oral dose reaching systemic circulation unchanged currently is not known. The oral conventional capsules and tablets, delayed-release capsules, and solution of fluoxetine hydrochloride reportedly are bioequivalent. However, onset of absorption of fluoxetine hydrochloride delayed-release capsules (Prozac® Weekly®) is delayed 1–2 hours relative to the onset of absorption when the drug is administered as a conventional preparation. Limited data from animals suggest that the drug may undergo first-pass metabolism and extraction in the liver and/or lung following oral administration. In these animals (beagles), approximately 72% of an oral dose reached systemic circulation unchanged. Food appears to cause a slight decrease in the rate, but not the extent, of absorption of fluoxetine in humans.

Peak plasma fluoxetine concentrations usually occur within 4–8 hours (range: 1.5–12 hours) after oral administration of conventional preparations. Following oral administration of a single 40-mg dose of the drug in healthy fasting adults, peak plasma concentrations of approximately 15–55 ng/mL are attained. Peak plasma fluoxetine concentrations following administration of single oral doses of 20–80 mg are approximately proportional and are linearly related to dose, although there appears to be considerable interindividual variation in plasma concentrations attained with a given dose. The manufacturer states that the peak plasma concentrations achieved following weekly administration of fluoxetine 90-mg delayed-release capsules are in the range of the average concentrations achieved following daily administration of 20-mg conventional preparations; however, average trough concentrations are reported to be lower following weekly administration of the delayed-release preparation. Peak-to-trough fluctuations in plasma concentrations of fluoxetine and norfluoxetine (the principal metabolite) reportedly are greater following weekly administration of the delayed-release capsules (164 and 43%, respectively) compared with daily administration of conventional preparations (24 and 17%, respectively).

Preliminary data suggest that fluoxetine may exhibit nonlinear accumulation following multiple dosing. (See Pharmacokinetics: Elimination.) The relatively slow elimination of fluoxetine and its active metabolite, norfluoxetine, leads to clinically important accumulation of these active species in chronic use and delayed attainment of steady state, even when a fixed dose is used. In healthy adults receiving 40 mg of fluoxetine daily for 30 days, plasma concentrations of 91–302 and 72–258 ng/mL of fluoxetine and norfluoxetine, respectively, were attained. These plasma concentrations of fluoxetine were higher than those predicted by single-dose studies because fluoxetine's metabolism is not proportional to dose. In addition, prolonged administration of the drug and/or patient's disease states did not appear to affect steady-state concentrations. In one study, steady-state plasma fluoxetine and norfluoxetine concentrations did not differ substantially among healthy individuals receiving 4 weeks of fluoxetine therapy, depressed patients receiving 5 weeks of fluoxetine therapy, or depressed patients receiving more than a year of fluoxetine therapy.

Average steady-state fluoxetine and norfluoxetine concentrations, however, were affected by patient age. In pediatric patients with major depressive disorder or obsessive-compulsive disorder (OCD) who received fluoxetine 20 mg daily for up to 62 days, average steady-state concentrations of fluoxetine and norfluoxetine in children 6–12 years of age were 2- and 1.5-fold higher, respectively, than in adolescents 13–17 years of age who received the same fluoxetine regimen. These results are consistent with those observed in another study in 94 pediatric patients 8–17 years of age diagnosed with major depressive disorder, and can be almost entirely explained by differences in children's weight. Higher average steady-state fluoxetine and norfluoxetine concentrations also were observed in children relative to adults; however, these concentrations were within the range of concentrations observed in the adult population. As in adults, fluoxetine and norfluoxetine accumulated extensively following multiple oral dosing. Following daily oral administration of the drug, steady-state plasma fluoxetine and norfluoxetine concentrations generally are achieved within about 2–4 weeks.

The manufacturer states that average steady-state plasma fluoxetine concentrations are approximately 50% lower with weekly administration of the 90-mg delayed-release capsules compared with daily administration of a 20-mg conventional preparation. In patients being switched from daily therapy with fluoxetine 20-mg conventional preparations to weekly therapy with fluoxetine 90-mg delayed-release capsules, peak plasma fluoxetine concentrations reportedly were 1.7 times higher with the weekly regimen than with the established daily regimen when there was no transition period (i.e., therapy with delayed-release fluoxetine was initiated the day after the last daily dose of fluoxetine 20 mg). When weekly therapy was initiated one week after the last daily dose of fluoxetine 20 mg, peak plasma fluoxetine concentrations for the 2 regimens were similar. (See Dosage and Administration: Dosage.)

The onset of antidepressant activity following oral administration of fluoxetine hydrochloride usually occurs within the first 1–3 weeks of therapy, but optimum therapeutic effect usually requires 4 weeks or more of therapy with the drug. Maximal EEG changes and behavioral changes on psychometric tests reportedly occur about 8–10 hours after single oral doses of the drug; the delay in maximal CNS effects compared with achievement of peak plasma fluoxetine concentrations may relate to formation of an active metabolite or to delayed distribution of the parent drug and its principal metabolite into the CNS.

The relationship between plasma fluoxetine and norfluoxetine concentrations and the therapeutic and/or toxic effects of the drug has not been clearly established. In a group of patients receiving fluoxetine for the management of major depressive disorder, there was no correlation between plasma fluoxetine, norfluoxetine, or total fluoxetine plus norfluoxetine concentrations and either the antidepressant response or the weight-reducing effect of the drug.

■ **Distribution** Distribution of fluoxetine and its metabolites into human body tissues and fluids has not been fully characterized. Limited pharmacokinetic data obtained during long-term administration of fluoxetine to animals suggest that the drug and some of its metabolites, including norfluoxetine, are widely distributed in body tissues, with highest concentrations occurring in the lungs and liver. The drug crosses the blood-brain barrier in humans and animals. In animals, fluoxetine:norfluoxetine ratios reportedly were similar in the cerebral cortex, corpus striatum, hippocampus, hypothalamus, brain stem, and cerebellum 1 hour after administration of a single dose of the drug.

The apparent volumes of distribution of fluoxetine and norfluoxetine in healthy adults each reportedly average 20–45 L/kg. Limited data suggest that the volume of distribution of fluoxetine is not altered substantially following multiple dosing. The apparent volume of distribution of norfluoxetine reportedly is higher in patients with cirrhosis than in healthy individuals, although this difference may reflect decreases in the rates of formation and elimination of the metabolite rather than changes in volume of distribution. The volumes of distribution of fluoxetine and norfluoxetine do not appear to be altered substantially in patients with renal impairment.

At in vitro plasma concentrations of 200–1000 ng/mL, fluoxetine is approximately 94.5% bound to plasma proteins, including albumin and α_1-acid glycoprotein (α_1-AGP); the extent of protein binding appears to be independent of plasma concentration. The extent of fluoxetine protein binding does not appear to be altered substantially in patients with hepatic cirrhosis or renal impairment, including those undergoing hemodialysis.

It is not known whether fluoxetine or its metabolites cross the placenta in humans, but fluoxetine and norfluoxetine reportedly cross the placenta in rats following oral administration. Fluoxetine and norfluoxetine are distributed into milk. Limited data indicate that concentrations of the drug and this metabolite in milk are about 20–30% of concurrent plasma concentrations.

■ **Elimination** Fluoxetine and norfluoxetine, the principal metabolite, are eliminated slowly. Following a single oral dose of fluoxetine in healthy adults, the elimination half-life of fluoxetine reportedly averages approximately 2–3 days (range: 1–9 days) and that of norfluoxetine averages about 7–9 days (range: 3–15 days). The plasma half-life of fluoxetine exhibits considerable interindividual variation, which may be related to genetic differences in the

rate of *N*-demethylation of the drug in the liver. The absence of either a bimodal or trimodal distribution of clearance values suggests that the rate of such metabolism may be under polygenic control. The half-life of fluoxetine reportedly is prolonged (to approximately 4–5 days) after administration of multiple versus single doses, suggesting a nonlinear pattern of drug accumulation during long-term administration. Norfluoxetine appears to exhibit dose-proportional pharmacokinetics following multiple dosing, although limited data indicate that the rate of formation of the metabolite is decreased slightly once steady-state plasma concentrations have been achieved.

Following oral administration of single doses of fluoxetine in healthy individuals, total apparent plasma clearances of fluoxetine and norfluoxetine average approximately 346 mL/minute (range: 94–703 mL/minute) and 145 mL/minute (range: 61–284 mL/minute), respectively. Limited data suggest that plasma clearance of fluoxetine decreases by approximately 75% following multiple oral doses of the drug once steady-state plasma fluoxetine concentrations have been achieved. Plasma clearances of fluoxetine and norfluoxetine also reportedly are decreased in patients with chronic liver disease (e.g., cirrhosis). Evidence from single-dose studies indicates that clearances of the drug and its principal metabolite are not altered substantially in patients with renal impairment.

The exact metabolic fate of fluoxetine has not been fully elucidated. The drug appears to be metabolized extensively, probably in the liver, to norfluoxetine and several other metabolites. Norfluoxetine (desmethylfluoxetine), the principal metabolite, is formed by *N*-demethylation of fluoxetine, which may be under polygenic control. The potency and selectivity of norfluoxetine's serotonin-reuptake inhibiting activity appear to be similar to those of the parent drug. Both fluoxetine and norfluoxetine undergo conjugation with glucuronic acid in the liver, and limited evidence from animals suggests that both the parent drug and its principal metabolite also undergo *O*-dealkylation to form *p*-trifluoromethylphenol, which subsequently appears to be metabolized to hippuric acid.

Following oral administration, fluoxetine and its metabolites are excreted principally in urine. In healthy individuals, approximately 60% of an orally administered, radiolabeled dose of fluoxetine is excreted in urine within 35 days, with approximately 72.8% of excreted drug as unidentified metabolites, 10% as norfluoxetine, 9.5% as norfluoxetine glucuronide, 5.2% as fluoxetine glucuronide, and 2.5% as unchanged drug. Approximately 12% of the dose was eliminated in feces within 28 days following oral administration, but the relative proportion of unabsorbed versus absorbed drug that is excreted in feces (e.g., via biliary elimination) is not known.

The effect of age on the elimination of fluoxetine has not been fully elucidated. Single-dose studies suggest that the pharmacokinetics of fluoxetine in healthy geriatric individuals do not differ substantially from those in younger adults. However, because the drug has a relatively long half-life and nonlinear disposition following multiple-dose administration, single-dose studies are not sufficient to exclude the possibility of altered pharmacokinetics in geriatric individuals, particularly those with systemic disease and/or in those receiving multiple medications concomitantly. The elimination half-lives of fluoxetine and norfluoxetine may be prolonged in patients with hepatic impairment. Following a single oral dose of the drug in patients with hepatic cirrhosis, the elimination half-lives of fluoxetine and norfluoxetine reportedly average approximately 7 and 12 days, respectively.

The elimination half-lives of fluoxetine and norfluoxetine do not appear to be altered substantially in patients with renal impairment following oral administration of single doses of the drug, although multiple-dose studies are needed to determine whether accumulation of the parent drug and/or its metabolites occurs during long-term therapy in such patients.

Fluoxetine and norfluoxetine are not removed substantially by hemodialysis. Because of the large volume of distribution and extensive protein binding of the drug and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion also are likely to be ineffective in removing substantial amounts of fluoxetine and norfluoxetine from the body.

Chemistry and Stability

■ **Chemistry** Fluoxetine, a selective serotonin-reuptake inhibitor (SSRI) antidepressant, is a phenylpropylamine-derivative. The drug differs structurally from other selective serotonin-reuptake inhibitor antidepressants (e.g., citalopram, paroxetine, sertraline) and also differs structurally and pharmacologically from other currently available antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors).

Fluoxetine contains a *p*-trifluoromethyl substituent that appears to contribute to the drug's high selectivity and potency for inhibiting serotonin reuptake, possibly as a result of its electron-withdrawing effect and lipophilicity. The commercially available drug is a racemic mixture of 2 optical isomers. Limited in vivo and in vitro data suggest that the pharmacologic activities of the optical isomers do not differ substantially, although the dextrorotatory isomer appears to have slightly greater serotonin-reuptake inhibiting activity and a longer duration of action than the levorotatory isomer.

Fluoxetine is commercially available as the hydrochloride salt, which occurs as a white to off-white crystalline solid and has a solubility of 14 mg/mL in water.

■ **Stability** Fluoxetine hydrochloride capsules and the oral solution should be stored in tight, light-resistant containers, both at 15–30°C. Fluoxetine tablets and delayed-release capsules should be stored at 15–30°C.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Paroxetine

■ Paroxetine hydrochloride and paroxetine mesylate, selective serotonin-reuptake inhibitors (SSRIs), are antidepressant agents.

Uses

Paroxetine is commercially available in the US as paroxetine hydrochloride (e.g., Paxil®, Paxil CR®) and as paroxetine mesylate (i.e., Pexeva®). The US Food and Drug Administration (FDA) considers paroxetine mesylate (Pexeva®) conventional tablets to be a pharmaceutical *alternative* (as described in section 505[b][2] of the Federal Food, Drug, and Cosmetic Act) and not a pharmaceutical (generic) equivalent to paroxetine hydrochloride conventional tablets (e.g., Paxil®), since both contain the same active moiety (paroxetine) but have different salts. The clinical studies that established efficacy of paroxetine in various conditions have been conducted with paroxetine hydrochloride. Because paroxetine hydrochloride and paroxetine mesylate contain the same active moiety (paroxetine), clinical efficacy is expected to be similar between the 2 different salts.

Paroxetine hydrochloride conventional tablets and oral suspension are used in the treatment of major depressive disorder, obsessive-compulsive disorder, panic disorder with or without agoraphobia, social phobia (social anxiety disorder), generalized anxiety disorder, and posttraumatic stress disorder. Paroxetine hydrochloride extended-release tablets are used in the treatment of major depressive disorder, panic disorder with or without agoraphobia, social phobia, and premenstrual dysphoric disorder (PMDD). Paroxetine mesylate conventional tablets are used in the treatment of major depressive disorder, obsessive-compulsive disorder, and panic disorder with or without agoraphobia. In addition, paroxetine has been used in the treatment of premature ejaculation†,

of therapy or during periods of dosage adjustment. FDA recommends providing written patient information (medication guide) explaining risks of suicidality each time the drug is dispensed.

Risk of orthostatic hypotension, especially during initial dosage titration and at times of reinitiation of therapy or increases in dosage.

Risk of somnolence and impairment of judgment, thinking, or motor skills; avoid driving, operating machinery, or performing hazardous tasks until effects on the individual are known.

Importance of avoiding alcohol during quetiapine therapy.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., diabetes mellitus).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of avoiding overheating or dehydration.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview (see Users Guide). **For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labelling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.**

Risperidone

■ Risperidone has been described as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Risperidone is used for the symptomatic management of psychotic disorders. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia and Other Psychotic Disorders Efficacy of oral risperidone for the management of psychotic disorders has been established by controlled studies of 4–8 weeks' duration principally in patients with schizophrenic disorders in hospital settings. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention. For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

In clinical studies principally in patients with schizophrenia, oral risperidone was more effective than placebo and at least as effective as typical (e.g., haloperidol, perphenazine) and certain atypical (e.g., olanzapine) antipsychotics in the treatment of schizophrenia. Data from limited clinical studies indicate that risperidone improves both positive and negative manifestations of schizophrenia, but that such improvements may not be substantially greater than those achieved by haloperidol, a typical antipsychotic. Risperidone was more effective than haloperidol in preventing relapse in adult outpatients with clinically stable schizophrenia or schizoaffective disorders who were assigned to receive either drug for a minimum of 1 year. In this study, approximately 25% of patients who received usual dosages of risperidone had relapsed by the end of the study compared with approximately 40% of those receiving usual dosages of haloperidol. In these studies, improvement in manifestations of schizophrenia was based on the results of various psychiatric rating scales, including the Brief Psychiatric Rating Scale (BPRS) that assesses factors such as anergy, thought disturbances, activation, hostility/suspiciousness, and anxiety/depression; the BPRS psychosis cluster that assesses factors such as conceptual disorganization, hallucinatory behavior, suspiciousness, and unusual thought content in actively psychotic schizophrenic patients; the Scale for the Assessment of Negative Symptoms (SANS); the Positive and Negative Syndrome Scale (PANSS); and the Clinical Global Impression (CGI) scale.

Because of their safety and efficacy, some authorities consider conventional antipsychotic agents or risperidone to be reasonable first-line drugs for the management of the acute phase of schizophrenia. Risperidone may be particularly useful in patients who experience extrapyramidal reactions with typical antipsychotic agents since the drug appears to cause fewer extrapyramidal reactions at clinically effective dosages. Some authorities state that risperidone or newer atypical antipsychotic agents (such as olanzapine) also may be advantageous in patients who have not responded adequately to therapy with a conventional antipsychotic agent. However, the efficacy of atypical antipsychotics, other than clozapine, in treatment-resistant schizophrenia has yet to be established, and the possible clinical benefits of risperidone therapy should be weighed against the potential drawbacks, including its higher cost compared with standard agents and the lack of a parenteral preparation of the drug.

Geriatric Considerations. Although risperidone has been studied for use in the management of psychosis and aggression in institutionalized geriatric patients with moderate to severe dementia of the Alzheimer's† type (Alzheimer's disease, presenile or senile dementia), vascular dementia†, or a combination of the 2 types of dementia (i.e., mixed dementia†), there is evidence that use of the drug in geriatric patients with dementia may be associated with an increased risk of adverse cerebrovascular events. In randomized, placebo-controlled studies in nursing home residents with dementia, oral risperidone at a dosage of approximately 1 mg daily was more effective than placebo in decreasing psychotic and behavioral symptoms (e.g., aggression, agitation) of dementia, as assessed by the Behavioral Pathology in Alzheimer's Disease scale (BEHAVE-AD) and the Cohen-Mansfield Agitation Inventory (CMAI). However, evidence from these studies showed a significantly higher incidence of adverse cerebrovascular events such as stroke and transient ischemic attacks (TIAs) associated with risperidone therapy relative to placebo. In addition, geriatric patients with dementia-related psychosis treated with atypical antipsychotic agents appear to be at an increased risk of death compared with that among patients receiving placebo. (See Cautions: Geriatric Precautions.) Risperidone is not approved for the treatment with dementia-related psychosis.

■ **Bipolar Disorder** Risperidone is used alone or in conjunction with lithium or valproate for the management of manic and mixed episodes associated with bipolar I disorder. Efficacy of risperidone monotherapy in the treatment of acute manic and mixed episodes has been demonstrated in 2 placebo-controlled trials of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder with acute manic or mixed episodes with or without psychotic features. The principal rating instrument used for assessing manic symptoms in these trials was the Young Mania Rating Scale (Y-MRS), an 11-item clinician-rated scale traditionally used to assess the degree of manic symptomatology in a range from 0 (no manic features) to 60 (maximum score). In the first 3-week, placebo-controlled trial, which was limited to patients with manic episodes, risperidone monotherapy was given at an initial dosage of 3 mg daily and subsequently in a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 4.1 mg daily. In the second 3-week, placebo-controlled trial, patients also were given an initial dosage of risperidone 3 mg daily and subsequently a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 5.6 mg daily. Risperidone was found to be superior to placebo in the reduction of the Y-MRS total score in both studies.

Efficacy of risperidone when used in conjunction with lithium or valproate in the treatment of acute manic or mixed episodes has been demonstrated in one placebo-controlled trial of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder (with or without a rapid cycling course) and who met diagnostic criteria for an acute manic or mixed episode (with or without psychotic features). In this study, inpatients and outpatients with bipolar disorder experiencing manic or mixed episodes who had not adequately responded to lithium or valproate monotherapy were randomized to receive risperidone, haloperidol, or placebo in conjunction with their original therapy. Risperidone therapy was given in an initial dosage of 2 mg daily and subsequently given in a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 3.8 mg daily. Lithium and valproate were given in conjunction with risperidone and plasma drug concentrations were maintained within ther-

apeutic ranges of 0.6–1.4 mEq/L for lithium and 50–120 mcg/mL for valproate. Addition of risperidone to lithium or valproate was shown to be superior to continued monotherapy with lithium or valproate as assessed by reduction of Y-MRS total score.

In a second 3-week, placebo-controlled trial, inpatients and outpatients with bipolar mania receiving lithium, valproate (as divalproex), or carbamazepine therapy with inadequately controlled manic or mixed symptoms were randomized to receive risperidone or placebo in conjunction with their original therapy. Risperidone was given in a flexible dosage range of 1–6 mg daily, with an initial dosage of 2 mg daily; the mean modal dosage was 3.7 mg daily. Addition of risperidone to lithium, valproate, or carbamazepine therapy (with plasma drug concentrations maintained within therapeutic ranges of 0.6–1.4 mEq/L, 50–120 mcg/mL, or 4–12 mcg/mL, respectively) was not found to be superior to lithium, valproate, or carbamazepine given alone as assessed by reduction of the Y-MRS total score. A possible explanation for the failure of this trial was enzymatic induction of clearance of risperidone and its principal active metabolite, 9-hydroxyrisperidone, by carbamazepine in the subgroup of patients receiving combined therapy with these drugs, resulting in subtherapeutic plasma concentrations of risperidone and 9-hydroxyrisperidone.

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current American Psychiatric Association (APA) recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic such as olanzapine may be adequate. For more severe manic or mixed episodes, combined therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

The manufacturer states that efficacy of risperidone has not been systematically evaluated for long-term use (i.e., exceeding 3 weeks) in the treatment of acute manic episodes or for prophylactic use in patients with bipolar disorder.

■ **Autistic Disorder** Risperidone is used for the management of irritability associated with autistic disorder in children and adolescents, including symptoms of aggression towards others, deliberate self-injuriousness, temper tantrums, and quickly changing moods.

Short-term efficacy of risperidone in children and adolescents with autistic disorder has been demonstrated in 2 placebo-controlled trials of 8 weeks' duration in children and adolescents (aged 5–16 years) who met the DSM-IV criteria for autistic disorder. Over 90% of the patients in these 2 trials were under 12 years of age and the majority weighed over 20 kg (weight range: 16–104.3 kg). The principal rating instruments used for assessing efficacy in these trials were the Aberrant Behavior Checklist (ABC) and the Clinical Global Impression-Change (CGI-C) scale. The primary outcome measure in both trials was the change from baseline to endpoint in the Irritability subscale of the ABC (ABC-I), which measures the emotional and behavioral symptoms of autism, including aggression toward others, deliberate self-injuriousness, temper tantrums, and rapidly changing moods. The CGI-C rating at endpoint was a co-primary outcome measure in one of the studies.

In the first 8-week, placebo-controlled trial, children and adolescents with autistic disorder aged from 5 to 16 years received twice daily placebo or risperidone 0.5–3.5 mg daily on a weight-adjusted basis, starting at 0.25 mg daily or 0.5 mg daily if baseline weight was less than 20 kg or 20 kg or greater, respectively; dosage was then titrated according to clinical response. Risperidone (mean modal dosage of 1.9 mg/day; equivalent to 0.06 mg/kg daily) was found to substantially improve scores on the ABC-I subscale and the CGI-C scale compared with placebo in this study.

In the second 8-week, placebo-controlled trial, children and adolescents with autistic disorder aged from 5–12 years were given an initial risperidone dosage of 0.01 mg/kg daily, which was then titrated up to 0.02–0.06 mg/kg daily based on clinical response. Risperidone (mean modal dosage of 0.05 mg/kg daily; equivalent to 1.4 mg daily) improved scores on the ABC-I subscale compared with placebo.

The efficacy of risperidone for long-term use (i.e., longer than 8 weeks) in children and adolescents with autistic disorder has been demonstrated in an open-label extension of the first 8-week, placebo-controlled trial in which patients received risperidone for 4 or 6 months (depending on whether they received risperidone or placebo in the double-blind study). During the open-label treatment period, patients were maintained on a mean modal risperidone dosage of 1.8–2.1 mg daily (equivalent to 0.05–0.07 mg/kg daily).

Children and adolescents who maintained their positive response to risperidone (defined as at least a 25% improvement on the ABC-I subscale and a CGI-C rating of much improved or very much improved) during the 4–6 month open-label treatment period (average duration of therapy was 140 days) were randomized to receive either risperidone or placebo during an 8-week, double-blind withdrawal trial. A substantially lower relapse rate was observed in the risperidone group compared with the placebo group during the pre-planned interim analysis of data from this trial. Based on the interim analysis results, the study was terminated since a statistically significant effect on relapse prevention was demonstrated. Relapse was defined as at least a 25% worsening on the most recent assessment of the ABC-I subscale (in relation to baseline for the randomized withdrawal phase). The manufacturer states that clinicians who elect to use risperidone in children and adolescents with autistic disorder for extended periods should periodically re-evaluate the long-term risks and benefits of the drug for the individual patient.

Although not curative, pharmacologic agents, such as risperidone, generally are used in children and adolescents with autistic disorder to reduce behavioral disturbances associated with autism and to help facilitate the child's or adolescent's adjustment and engagement in intensive, targeted educational interventions. In clinical studies, risperidone was not found to improve certain core symptoms of autism (e.g., language deficits, impaired social relatedness). However, the drug was more effective than placebo for improving scores on subscales for sensory motor behaviors, affectual reactions, and sensory responses in a controlled study. The possible risks, including clinically important weight gain, tardive dyskinesia, withdrawal dyskinesia, and other extrapyramidal reactions associated with the drug, should be considered.

Risperidone also has been used for the treatment in a limited number of adults† with autistic disorder and other pervasive developmental disorders.

Dosage and Administration

■ **Administration** Risperidone is administered orally or by IM injection.

Oral Administration Risperidone is administered orally, either in a once-daily dose or in 2 equally divided doses daily. Because risperidone can cause orthostatic hypotension, twice-daily oral administration may be preferable during initiation of therapy and in patients who may be more susceptible to orthostatic hypotension, such as geriatric or debilitated patients. If once-daily dosing is being considered in geriatric or debilitated patients, it is recommended that the patient be titrated on a twice-daily regimen for 2–3 days at the target dose. Subsequent switching to the once-daily dosing regimen can be done thereafter. Some experts state that once-daily administration of risperidone may be sufficient in most patients receiving maintenance therapy because of the extended half-life of the drug's principal active metabolite (9-hydroxyrisperidone).

In children and adolescents receiving risperidone for the management of irritability associated with autistic disorder who experience persistent somnolence, administering the drug once daily at bedtime, twice-daily administration, or a reduction in dosage may be helpful.

Since food reportedly does not affect the rate or extent of GI absorption of risperidone, the drug can be administered without regard to meals. Compatibility tests show that risperidone oral solution is compatible in the following beverages: water, coffee, orange juice, and low-fat milk; such testing also indicates that risperidone oral solution is *not* compatible in cola or tea.

Patients receiving risperidone orally disintegrating tablets should be instructed not to remove a tablet from the blister until just prior to dosing. The tablet should not be pushed through the foil. With dry hands, the blister backing should be peeled completely off the blister. The tablet should then be gently removed and immediately placed on the tongue, where it rapidly disintegrates in saliva, and then subsequently swallowed with or without liquid. Risperidone orally disintegrating tablets should not be divided or chewed.

IM Administration The commercially available risperidone powder for injection containing the drug in extended-release microspheres must be reconstituted prior to administration using the components of the dose pack supplied by the manufacturer. The dose pack should be allowed to reach room temperature before reconstituting the injection. Risperidone extended-release microspheres should be reconstituted using only the diluent in the prefilled syringe supplied by the manufacturer. The entire contents of the prefilled syringe should be injected into the vial, and the vial should be shaken vigorously while the plunger rod is held down with the thumb for at least 10 seconds to ensure a homogeneous suspension; the reconstituted suspension should appear uniform, thick, and milky. The manufacturer's prescribing information should be consulted for additional details on use of the components of the dose pack to reconstitute and administer risperidone injection. The manufacturer states that different dosage strengths of IM risperidone should not be combined in a single administration.

Following reconstitution, immediate use is recommended because the suspension will settle over time. If more than 2 minutes pass before administration, the vial should again be vigorously shaken to resuspend the drug. The contents of the vial must be used within 6 hours of reconstitution and should not be exposed to temperatures exceeding 25°C.

The entire contents of the vial should be administered by deep IM injection into the upper outer quadrant of the gluteal area every 2 weeks, alternating buttocks. The injection should *not* be administered IV.

■ **Dosage** ***Schizophrenia*** Oral Dosage. Risperidone has a bell-shaped dose-response curve, with therapeutic efficacy of oral dosages of 12–16 mg daily lower than that of dosages of 4–8 mg daily in adults. Because dosage information contained in the manufacturer's labeling principally is derived from early clinical studies of the drug in patients not typical of the general population of patients treated in the community (i.e., in hospitalized, chronically-ill schizophrenic patients accustomed to high-dose antipsychotic therapies), dosage of risperidone should be individualized according to the patient's response and tolerance. Clinicians also may consider consulting published protocols for specific dosage information, particularly in geriatric or younger patients, and in those experiencing their first psychotic episode.

The manufacturer's labeling states that the initial oral dosage of risperidone in adults generally is 1 mg twice daily, with dosage increase in increments of 1 mg twice daily on the second and third day, as tolerated, to a target dosage of 6–8 mg daily (administered once daily or in 2 equally divided doses). However, more recent evidence from open labeled studies and clinical experience with the drug indicates that an initial dosage of 1–2 mg daily, with dosage

increases in increments of 0.5–1 mg daily titrated over 6–7 days, as tolerated, to a target dose of 4 mg daily may be more appropriate for the management of schizophrenia in most otherwise healthy adult patients. Because steady-state plasma concentrations of 9-hydroxyrisperidone (an active metabolite of risperidone) may not be attained for 7 days at a given dosage, subsequent dosage adjustments generally should be made at intervals of at least 7 days. Lower initial dosages (e.g., 1 mg daily) and slower dosage titrations to an initial target dosage of 2 mg daily may be appropriate for younger patients and in those being treated for their first psychotic episode; dosage may then be titrated up to 4 mg daily depending on clinical response at the lower dosage and adverse neurologic effects. Such patients appear to benefit optimally from risperidone dosage of 1–3 mg daily. A substantial number of patients being treated for their first psychotic episode start to develop extrapyramidal symptoms once dosages are increased above 2 mg daily. Dosage reductions should be considered in any patient who develops extrapyramidal symptoms.

While antipsychotic efficacy has been established in clinical trials at oral dosages ranging from 4–16 mg daily, maximum efficacy of the drug was observed in most patients at risperidone dosages of 4–8 mg daily. In addition, the manufacturer and some clinicians state that dosages exceeding 6 mg daily, when given in 2 divided doses, did not result in further improvement but were associated with increases in some adverse effects, including extrapyramidal manifestations. Therefore, the manufacturer states that dosages exceeding 6 mg (in 2 divided doses) daily generally are not recommended and those exceeding 16 mg daily have not been evaluated for safety. In a single study of once-daily dosing, efficacy results generally were stronger for 8 mg than for 4 mg.

The manufacturer states that there are no systematically collected data that specifically address switching from other antipsychotic agents to risperidone or concomitant administration with other antipsychotic agents. While immediate discontinuance of the previous antipsychotic treatment may be acceptable for some patients with schizophrenia, gradual discontinuance of the drug may be appropriate for most patients. In all cases, the period of overlapping antipsychotic administration should be minimized. The first risperidone dose should be administered in place of the next scheduled parenteral antipsychotic dose in schizophrenic patients being switched from long-acting (depot) parenteral antipsychotic therapy to oral risperidone therapy.

The optimum duration of oral risperidone therapy currently is not known, but maintenance therapy with risperidone 2–8 mg daily has been shown to be effective for up to 2 years. Patients should be reassessed periodically to determine the need for continued therapy with the drug. If risperidone therapy is reinitiated after a drug-free period, the manufacturer recommends that the appropriate recommended schedule of careful dosage titration be employed.

IM Dosage. For the management of schizophrenia, the recommended initial adult IM dosage of risperidone injection extended-release microspheres is 25 mg administered by deep IM injection in the gluteal area every 2 weeks. The manufacturer recommends that patients first receive oral risperidone to establish tolerability of the drug before the extended-release risperidone injection is used. To ensure that adequate plasma antipsychotic concentrations are maintained prior to the main release of risperidone from the injection site, therapy with oral risperidone or another oral antipsychotic agent (e.g., for patients being switched from other oral antipsychotic therapy to IM risperidone) should be given with the first IM injection of risperidone, and such oral therapy should be continued for 3 weeks, then discontinued. If risperidone injection is used in patients previously receiving other oral antipsychotic agents, the need for continuing any concomitant therapy for managing extrapyramidal manifestations should be periodically reevaluated.

Some patients not responding to the initial dosage of 25 mg every 2 weeks may benefit from increasing the IM dosage to 37.5 or 50 mg every 2 weeks. However, the dosage should not be increased more frequently than every 4 weeks, and clinical effects of the increased dosage should not be expected earlier than 3 weeks after the first injection of the higher dose. The maximum IM dosage should not exceed 50 mg every 2 weeks since higher dosages were associated with an increased incidence of adverse effects, but no additional clinical benefit was observed.

Although no controlled studies have been conducted to establish the optimum duration of IM risperidone therapy in patients with schizophrenia, oral risperidone has been shown to be effective in delaying time to relapse with longer term use. It is recommended that responding patients be continued on treatment with IM risperidone at the lowest dose needed. Patients should periodically be reassessed to determine the need for continued treatment.

If therapy with IM risperidone is reinitiated after a drug-free period, oral risperidone (or another oral antipsychotic agent) should again be administered for supplementation.

Bipolar Disorder For the management of acute manic and mixed episodes associated with bipolar disorder as monotherapy or as combined therapy in adults, an initial risperidone oral dosage of 2–3 mg given once daily was found to be effective in clinical trials. Dosage may be increased or decreased by 1 mg daily at intervals of not less than 24 hours, reflecting the procedures in the placebo-controlled trials. In these trials, the short-term (i.e., 3-week) antimanic efficacy of risperidone was demonstrated in a flexible dosage ranging from 1 to 6 mg daily. Safety of dosages exceeding 6 mg daily has not been established.

The optimum duration of risperidone therapy for bipolar disorder currently is not known. While it is generally agreed that pharmacologic treatment beyond an acute response in mania is desirable, both for maintenance of the initial response and for prevention of new manic episodes, there are no systematically obtained data to support the use of risperidone beyond 3 weeks. Therefore, the manufacturer states that clinicians who elect to use risperidone for extended periods should periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

Autistic Disorder For the management of irritability associated with autistic disorder in children 5 years of age and older and adolescents, an initial risperidone oral dosage of 0.25 mg daily is recommended for patients weighing less than 20 kg and 0.5 mg daily is recommended for patients weighing 20 kg or more. The drug may be administered either once or twice daily.

Dosage should be individualized according to clinical response and tolerability of the patient. After a minimum of 4 days following initiation of therapy, the dosage may be increased to the recommended dosage of 0.5 mg daily for patients weighing less than 20 kg and 1 mg daily for patients weighing 20 kg or more; this dosage should then be maintained for a minimum of 14 days. In patients not responding adequately, increases in dosage may be considered at intervals of 2 weeks or longer in increments of 0.25 mg daily for patients weighing less than 20 kg or 0.5 mg daily for patients weighing 20 kg or more. Exercise caution with risperidone dosages in smaller children who weigh less than 15 kg. Safety and effectiveness in pediatric patients less than 5 years of age not established.

In clinical trials, 90% of patients who responded to risperidone therapy (based on at least 25% improvement in the Irritability subscale of the Aberrant Behavior Checklist [ABC-I]) received dosages from 0.5–2.5 mg daily. The maximum daily dosage in one of the pivotal trials, when the therapeutic effect reached a plateau, was 1 mg in patients weighing less than 20 kg, 2.5 mg in patients weighing 20 kg or more, and 3 mg in patients weighing more than 45 kg. Dosage data for children weighing less than 15 kg currently are lacking.

Once adequate clinical response has been achieved, consider a gradual reduction in dosage to achieve an optimal balance of efficacy and safety. Patients experiencing excessive somnolence may benefit from a once-daily dosage administered at bedtime or administering half the daily dosage twice daily, or a reduction in dosage.

The manufacturer states that clinicians who elect to use risperidone in children and adolescents with autistic disorder for extended periods should periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

Geriatric Patients and Others at Risk of Orthostatic Hypotension Like other α-adrenergic blocking agents, risperidone can induce orthostatic hypotension (e.g., manifested as dizziness, tachycardia, and occasionally syncope), particularly during initiation of therapy with the drug. The manufacturer and some clinicians state that the risk of this effect can be minimized by limiting the initial oral dosage of risperidone to 1 mg twice daily in otherwise healthy adults and to 0.5 mg once or twice daily in geriatric or debilitated patients, in patients with renal or hepatic impairment, and in those predisposed to, or at risk from, hypotension. Dosages in such patients should then be increased gradually at increments of not more than 0.5 mg twice daily as necessary and tolerated. Increases beyond a dosage level of 1.5 mg twice daily generally should occur at intervals of at least 7 days. However, other clinicians recommend initiating risperidone therapy at a dosage of 0.25 mg daily in geriatric patients and gradually increasing the dosage as tolerated. (See Cautions: Geriatric Precautions.) Most geriatric patients should not be maintained at an oral dosage exceeding 3 mg daily.

For geriatric patients with schizophrenia, the recommended IM risperidone dosage of the extended-release injection is 25 mg every 2 weeks. Oral risperidone (or another oral antipsychotic agent) should be given with the first risperidone extended-release injection and should be continued for 3 weeks to ensure that adequate antipsychotic plasma concentrations are maintained prior to the main release phase of risperidone from the injection site.

Elderly patients and patients with a predisposition to hypotensive reactions or for whom such reactions would pose a particular risk should be instructed in nonpharmacologic interventions that help reduce the occurrence of orthostatic hypotension (e.g., sitting on the edge of the bed for several minutes before attempting to stand in the morning, slowly rising from a seated position). These patients should avoid sodium depletion or dehydration and circumstances that accentuate hypotension (e.g., alcohol intake, high ambient temperature). Monitoring of orthostatic vital signs should be considered.

Particular caution also is warranted in patients with known cardiovascular disease (e.g., history of myocardial infarction or ischemia, heart failure, conduction abnormalities), cerebrovascular disease, or conditions that would predispose to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy) and in those for whom such reactions would pose a risk, and cautious dosage titration and careful monitoring are necessary in such patients. Dosage reduction should be considered in any patient in whom hypotension develops.

■ **Dosage in Renal and Hepatic Impairment** Because elimination of risperidone may be reduced and the risk of adverse effects, particularly hypotension, increased in patients with renal impairment, oral risperidone therapy should be initiated at a reduced dosage of 0.5 mg twice daily in adults and increased as necessary and tolerated at increments of 0.5 mg twice daily; increases beyond a dosage level of 1.5 mg twice daily should be made at intervals of at least 7 days. Likewise, this reduced oral dosage should be employed in patients with hepatic impairment because of the risk of an increased free fraction of risperidone in such patients.

If IM risperidone is used for management of schizophrenia in adult patients

with renal or hepatic impairment, the patient should be treated with titrated doses of oral risperidone prior to initiating treatment with the extended-release injection. The recommended starting oral risperidone dosage is 0.5 mg twice daily during the first week, which can be increased to 1 mg twice daily or 2 mg once daily during the second week. If a dosage of at least 2 mg daily of oral risperidone is well tolerated, an IM dosage of 25 mg of the extended-release injection can be administered every 2 weeks. Oral supplementation should be continued for 3 weeks after the first injection until the main release of risperidone from the injection site has begun. In some patients, slower titration may be medically appropriate.

Cautions

Although risperidone differs chemically from the phenothiazines, the drug may be capable of producing many of the toxic manifestations of phenothiazine derivatives. Not all adverse effects of the phenothiazines have been reported with risperidone, but the possibility that they may occur should be considered. Adverse effects of risperidone and the phenothiazines are numerous and may involve nearly all organ systems. Although these effects usually are reversible when dosage is reduced or the drug is discontinued, some effects may be irreversible and, rarely, fatal. In some patients, unexpected death associated with antipsychotic therapy has been attributed to cardiac arrest or asphyxia resulting from failure of the gag reflex. (See Cautions: Cardiovascular Effects.) In other cases, the cause of death could not be determined or definitely attributed to antipsychotic drug therapy.

The most frequent adverse effects of oral risperidone reported in at least 5% of adult patients with schizophrenia who received the drug in 2 short-term (6–8 week) clinical studies and with an incidence of at least twice that of those who received placebo included nervous system (e.g., anxiety, dizziness, extrapyramidal symptoms, somnolence), GI (e.g., constipation, dyspepsia, nausea), dermatologic (e.g., rash), respiratory (e.g., rhinitis), and cardiovascular (e.g., tachycardia) effects. Approximately 9% of patients receiving risperidone in phase 2 or 3 studies discontinued treatment because of adverse effects compared with about 7% of those receiving placebo and 10% of those receiving an active control drug (haloperidol). Adverse effects commonly associated with discontinuance of therapy and considered to be possibly or probably related to risperidone include extrapyramidal symptoms, dizziness, hyperkinesia, somnolence, and nausea.

The most frequent adverse effects of oral risperidone reported in at least 5% of adult patients with bipolar mania who received the drug as monotherapy in the US placebo-controlled trial and with an incidence of at least twice that of those receiving placebo included nervous system (e.g., somnolence, dystonia, akathisia, parkinsonism, vision abnormalities) and GI (e.g., dyspepsia, nausea, increased salivation) effects. In the US placebo-controlled trial of risperidone in conjunction with mood stabilizers (lithium or valproate), the most common adverse effects associated with risperidone administration were somnolence, dizziness, parkinsonism, increased saliva, akathisia, abdominal pain, and urinary incontinence. In the US placebo-controlled trial of risperidone monotherapy, approximately 8% of patients receiving risperidone discontinued therapy because of adverse effects compared with about 6% of those receiving placebo. Adverse effects associated with discontinuance of therapy in this study and considered to be possibly, probably, or very likely related to risperidone included paroniria, somnolence, dizziness, extrapyramidal reaction, and involuntary muscle contractions; each of these occurred in 1 risperidone-treated patient (0.7%) but in none of those receiving placebo. In the US placebo-controlled trial of risperidone used in conjunction with mood stabilizers, there was no overall difference in the incidence of discontinuance because of adverse effects (4% for risperidone and 4% for placebo).

The most frequent adverse effects of oral risperidone reported in at least 5% of pediatric patients with autistic disorder who received the drug in 2 placebo-controlled trials and with an incidence of at least twice that of those receiving placebo included nervous system (e.g., somnolence, fatigue, tremor, dystonia, dizziness, parkinsonism, automatism, dyskinesia, confusion), GI (e.g., increased appetite, increased salivation, constipation, dry mouth), respiratory (e.g., upper respiratory tract infection), cardiovascular effects (e.g., tachycardia), and weight gain. Somnolence was the most frequent adverse effect in these trials, occurring in 67% of the risperidone-treated patients and in 23% of patients receiving placebo. Average weight gain over 8 weeks was 2.6 kg for the risperidone-treated patients compared with 0.9 kg for patients receiving placebo. Extrapyramidal symptoms occurred in approximately 28% of the risperidone-treated patients compared with 10% of those receiving placebo.

The most frequent adverse effects associated with use of risperidone extended-release IM injection reported in at least 5% of adult patients with schizophrenia in clinical trials and with an incidence of at least twice that of those receiving placebo included somnolence, akathisia, parkinsonism, dyspepsia, constipation, dry mouth, fatigue, and increased weight.

■ **Nervous System Effects** ***Tardive Dyskinesia*** Like other antipsychotic agents (e.g., phenothiazines), risperidone has been associated with tardive dyskinesias. Although it has been suggested that atypical antipsychotics appear to have a lower risk of tardive dyskinesia, whether antipsychotic drugs differ in their potential to cause tardive dyskinesia is as yet unknown. In one open-label study, an annual incidence of tardive dyskinesia of 0.3% was reported in patients with schizophrenia who received approximately 8–9 mg of oral risperidone daily for at least 1 year. The prevalence of this syndrome appears to be highest among geriatric patients (particularly females). The risk of developing tardive dyskinesia and the likelihood that it will become irreversible also appear to increase with the duration of therapy and cumulative dose of antipsychotic agents administered; however, the syndrome may occur, although much less frequently, after relatively short periods of treatment with low dosages. For additional information on tardive dyskinesia, see Tardive Dyskinesia under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Extrapyramidal Reactions Extrapyramidal reactions occurred in 17% of patients with schizophrenia receiving oral risperidone dosages of 10 mg daily or less and in 34% of patients receiving dosages of 16 mg daily in clinical studies. Although the incidence of extrapyramidal manifestations in patients receiving risperidone dosages of 10 mg daily or less was similar to that reported in patients receiving placebo, the incidence increased as the dosage of the drug increased, suggesting a dose-related effect. At recommended therapeutic dosages of risperidone (4–8 mg daily) for schizophrenia, the severity of extrapyramidal reactions appears to be comparable to placebo and clozapine 400 mg daily, and substantially less than that associated with haloperidol 10 or 20 mg daily. Similarly, the severity of parkinsonian symptoms, as assessed on the parkinsonism subscale of the Extrapyramidal Symptom Rating Scale (ESRS), is also linearly related to risperidone dosages of 2–16 mg daily, with the incidence of parkinsonian symptoms at risperidone dosages of 6 mg daily or less comparable to that of placebo and substantially less than that seen with haloperidol dosages of 20 mg daily.

Neuroleptic malignant syndrome (NMS), a potentially fatal symptom complex, has been reported in patients receiving antipsychotic agents. NMS requires immediate discontinuance of the drug and intensive symptomatic and supportive care. For additional information on NMS, see Neuroleptic Malignant Syndrome under Nervous System Effects: Extrapyramidal Reactions in Cautions, in the Phenothiazines General Statement 28:16.08.24.

Other Nervous System Effects Dose-related somnolence was a commonly reported adverse effect associated with risperidone treatment. Approximately 8% of adult patients with schizophrenia receiving 16 mg of oral risperidone daily and 1% of patients receiving placebo reported somnolence in studies utilizing direct questioning or a checklist to detect adverse events, respectively.

Insomnia, agitation, and anxiety have been reported in 20–26% of patients receiving risperidone. In addition, headache, dizziness, and aggressive reaction have been reported in 12–14, 4–7, and 1–3% of schizophrenia patients, respectively.

Adverse nervous system effects reported in 1% or more of patients with schizophrenia who received risperidone in clinical studies include increased sleep duration or dream activity, diminished sexual desire, fatigue, and nervousness. Impaired concentration, depression, apathy, catatonic reaction, euphoria, increased libido, amnesia, dysarthria, vertigo, stupor, paraesthesia,malaise, seizure, and confusion also have been reported in 0.1–1% of patients. In addition, aphasia, cholinergic syndrome, choreoathetosis, coma, delirium, emotional lability, hypoesthesia, hypotonia, hyperreflexia, leg cramps, migraine, nightmares, tongue paralysis, torticollis, withdrawal syndrome, and yawning have been reported in fewer than 0.1% of patients. Mania also has been reported during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Cardiovascular Effects** ***Orthostatic Hypotension*** Orthostatic hypotension associated with dizziness, tachycardia, and in some patients, syncope, especially during the initial dose-titration period has been reported in patients receiving risperidone, probably reflecting the drug's α-adrenergic antagonistic properties. The risk of orthostatic hypotension and syncope may be minimized by limiting initial doses in geriatric patients and patients with renal or hepatic impairment. (See Dosage and Administration.) Monitoring of orthostatic vital signs should be considered in patients for whom this is of concern. A dose reduction should be considered if hypotension occurs. Risperidone should be used with particular caution in patients with known cardiovascular disease (history of myocardial infarction or ischemia, heart failure, or conduction abnormalities), cerebrovascular disease, or conditions that would predispose to hypotension (e.g., dehydration, hypovolemia). Clinically important hypotension has been observed with concomitant use of risperidone and antihypertensive drug therapy.

Other Cardiovascular Effects Pooled analysis of results of placebo-controlled studies indicates that risperidone therapy is not associated with statistically significant changes in ECG parameters (e.g., PR, QT, or QT_c intervals, heart rate). In pivotal clinical studies, however, tachycardia, which may be dose dependent, occurred in 3 or 5% of patients with schizophrenia receiving daily oral dosages of risperidone of 10 mg or less or 16 mg, respectively. In addition, palpitation, hypertension, hypotension, AV block, and myocardial infarction have occurred in 1% or more of patients receiving risperidone. Ventricular tachycardia, angina pectoris, atrial premature complexes (APCs, PACs), T-wave inversions, ventricular extrasystoles, ST depression, and myocarditis have occurred in fewer than 0.1% of patients receiving the drug in clinical trials. Atrial fibrillation, pulmonary embolism, cerebrovascular disorders (including stroke and transient ischemic attack) (see Cautions: Geriatric Precautions), and rarely, sudden death and/or cardiopulmonary arrest also have been reported during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **Endocrine and Metabolic Effects** Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been

reported in patients receiving certain atypical antipsychotic agents, including risperidone. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., risperidone, clozapine, olanzapine, quetiapine).

Precise risk estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., clozapine, olanzapine) than with others (e.g., risperidone, quetiapine) in the class, available data are conflicting and insufficient to provide reliable estimates of relative risk associated with use of the various atypical antipsychotics.

Similar to other antipsychotic agents, risperidone causes elevated prolactin concentrations, which may persist during chronic use of the drug. Risperidone appears to be associated with a higher level of prolactin elevation than other currently available antipsychotic agents. The clinical importance of elevated serum prolactin concentrations is as yet unknown for most patients receiving these drugs. Gynecomastia and breast pain in men have been reported in fewer than 0.1% of patients. In addition, galactorrhea, amenorrhea, and impotence have been reported with agents that increase serum prolactin concentrations, including risperidone.

Hyponatremia, weight gain or loss, increased serum creatine kinase (CK, creatine phosphokinase, CPK) concentrations, thirst, and diabetes mellitus have been reported in 0.1–1% of schizophrenia patients receiving oral risperidone in clinical studies. In addition, decreased serum iron concentrations, cachexia, dehydration, disorders in antidiuretic hormone, hypokalemia, hypoproteinemia, hyperphosphatemia, hypertriglyceridemia, hyperuricemia, and hypoglycemia have been reported in fewer than 0.1% of patients. Precocious puberty and pituitary adenomas also have been reported during postmarketing surveillance; however, a causal relationship to the drug has not been established.

■ **GI Effects** Adverse GI effects that have been reported in 5–13% of patients with schizophrenia receiving oral risperidone in clinical studies include constipation, nausea, dyspepsia, and vomiting. Abdominal pain, increased salivation, and toothache also have been reported in 1–4% of patients receiving risperidone in clinical studies. In addition, anorexia and reduced salivation were reported in 1% or more of patients receiving risperidone in clinical trials. Flatulence, diarrhea, increased appetite, stomatitis, melena, dysphagia, hemorrhoids, and gastritis have also been reported in 0.1–1% of patients. In addition, fecal incontinence, eructation, gastroesophageal reflux, gastroenteritis, esophagitis, lingual discoloration, cholelithiasis, lingual edema, diverticulitis, gingivitis, discolored feces, GI hemorrhage, and hematemesis have been reported in fewer than 0.1% of patients receiving the drug in clinical trials. Although a causal relationship to risperidone has not been established, intestinal obstruction has been reported during postmarketing surveillance.

■ **Respiratory Effects** Rhinitis has been reported in 8–10% of patients with schizophrenia receiving oral risperidone and was the most common adverse respiratory effect reported during clinical studies. In addition, cough, sinusitis, pharyngitis, upper respiratory infections, and dyspnea have been reported in 1–3% of patients receiving risperidone in clinical studies. Hyperventilation, bronchospasm, pneumonia, and stridor also have been reported in 0.1–1% of patients receiving risperidone in clinical studies. Asthma, increased sputum, and aspiration have been rarely reported in fewer than 0.1% of patients. Although a causal relationship to the drug has not been established, apnea also has been reported during postmarketing surveillance.

■ **Dermatologic Effects and Sensitivity Reactions** Rash and dry skin have been reported in about 2–5% of patients with schizophrenia receiving oral risperidone in clinical studies. In addition, adverse dermatologic effects that have been reported in 1% or more of patients receiving risperidone include seborrhea and increased pigmentation. Increased or decreased sweating, acne, alopecia, hyperkeratosis, pruritus, and skin exfoliation were reported in 0.1–1% of patients in clinical trials. Bullous eruption, skin ulceration, aggravated psoriasis, furunculosis, verruca, dermatitis lichenoid, hypertrichosis, genital pruritus, and urticaria have been rarely reported.

Although a causal relationship has not been established, hypersensitivity reactions, including anaphylaxis, angioedema, and photosensitivity have been reported in patients receiving risperidone.

■ **Genitourinary Effects** Adverse genitourinary effects reported in 1% or more of patients with schizophrenia receiving oral risperidone include polyuria, polydipsia, menorrhagia, orgasmic dysfunction, and vaginal dryness. In addition, urinary incontinence, hematuria, dysuria, nonpuerperal lactation, amenorrhea, breast or perineal pain in females, leukorrhea, mastitis, dysmenorrhea, intermenstrual bleeding, and vaginal hemorrhage have been reported in 0.1–1% of patients receiving risperidone in clinical studies. Urinary retention, cystitis, and renal insufficiency also have been reported in fewer than 0.1% of patients.

In male patients, erectile dysfunction and ejaculation failure were reported in up to 1% of schizophrenia patients receiving oral risperidone in clinical studies. In addition, rare cases of priapism have been reported. While a causal relationship to risperidone use has not been established, other drugs with α-adrenergic blocking effects have been reported to cause priapism, and it is possible that risperidone may share this capacity. Severe priapism may require surgical intervention.

■ **Musculoskeletal Effects** Back or chest pain and arthralgia have been reported in 2–3% of patients with schizophrenia receiving oral risperidone in clinical studies. In addition, myalgia has been reported in 0.1–1% of patients. Arthrosis, synostosis, bursitis, arthritis, and skeletal pain also have occurred in fewer than 0.1% of patients.

■ **Hematologic Effects** Anemia, hypochromic anemia, epistaxis, and purpura have been reported in 0.1–1% of adult patients with schizophrenia and granulocytopenia has been reported in 0.1–1% of children and adolescents with autistic disorder receiving oral risperidone in clinical studies. Normocytic anemia, leukocytosis, lymphadenopathy, leukopenia, Pelger-Huet anomaly, hemorrhage, superficial phlebitis, thrombophlebitis, and thrombocytopenia also have been reported in fewer than 0.1% of patients. In addition, thrombotic thrombocytopenic purpura occurred in at least one patient (a 28 year-old female patient) receiving risperidone in a large, open-labeled study. This patient experienced jaundice, fever, and bruising but eventually recovered after receiving plasmapheresis. The relationship of this adverse event to risperidone therapy is unknown.

■ **Hepatic Effects** Increased SGOT and increased SGPT have been reported in 0.1–1% of patients with schizophrenia receiving oral risperidone in clinical studies. In addition, hepatic failure, cholestatic hepatitis, cholecystitis, cholelithiasis, hepatitis, and hepatocellular damage have been reported in fewer than 0.1% of patients. Although a causal relationship to the drug has not been established, jaundice also has been reported during postmarketing surveillance.

■ **Ocular and Otic Effects** Abnormal vision has been reported in 1–2% of patients with schizophrenia receiving oral risperidone in clinical studies. Abnormal accommodation and xerophthalmia also have been reported in 0.1–1% of patients receiving risperidone in clinical studies. In addition, diplopia, ocular pain, blepharitis, photopsia, photophobia, abnormal lacrimation, tinnitus, hyperacusis, and decreased hearing have been reported in fewer than 0.1% of patients.

■ **Other Adverse Effects** Chest pain and fever have been reported in 2–3% of patients with schizophrenia receiving oral risperidone in clinical studies. Although a causal relationship to the drug has not been established, pancreatitis and aggravated parkinsonian syndrome has been reported during postmarketing surveillance.

■ **Precautions and Contraindications** Risperidone shares many of the toxic potentials of other antipsychotic agents (e.g., phenothiazines), and the usual precautions associated with therapy with these agents should be observed. (See Cautions, in the Phenothiazines General Statement 28:16.08.24.)

Because severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents, including risperidone, the manufacturers of atypical antipsychotic agents state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. (See Cautions: Endocrine and Metabolic Effects.) Any patient who develops manifestations of hyperglycemia during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the antipsychotic; in other cases hyperglycemia resolved with discontinuance of the suspect drug. For further information on the management of diabetes risks in patients receiving atypical antipsychotics, see Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications, in Clozapine 28:16.08.04.

Because of the possibility of orthostatic hypotension, caution should be observed in patients with known cardiovascular disease (e.g., history of myocardial infarction or ischemia, heart failure, conduction abnormalities), cerebrovascular disease (see Cautions: Geriatric Precautions), conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia), and patients receiving antihypertensive agents. Since patients with a recent history of myocardial infarction or unstable heart disease were excluded from clinical studies, clinicians should be aware that risperidone has not been evaluated or used to any appreciable extent in such patients. Patients receiving risperidone should be advised of the risk of orthostatic hypotension, especially during the period of initial dosage titration. (See Cautions: Cardiovascular Effects.)

Patients with parkinsonian syndrome or dementia with Lewy bodies who receive antipsychotics, including risperidone, reportedly have an increased sensitivity to antipsychotic agents. Clinical manifestations of this increased sensitivity have been reported to include confusion, obtundation, postural instability with more frequent falling, extrapyramidal adverse effects, and clinical features consistent with neuroleptic malignant syndrome. (For additional information on extrapyramidal adverse effects and neuroleptic malignant syndrome, see Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.)

Plasma concentrations of risperidone and its principal active metabolite, 9-hydroxyrisperidone, are increased in patients with severe renal impairment (creatinine clearance less than 30 mL/minute per 1.73 m^2), and an increased free fraction of risperidone occurs in patients with severe hepatic impairment.

Therefore, lower initial dosages should be used in such patients. (See Dosage and Administration.)

Individuals with phenylketonuria (i.e., homozygous genetic deficiency of phenylalanine hydroxylase) and other individuals who must restrict their intake of phenylalanine should be warned that risperidone 0.5-, 1-, 2-, 3-, or 4-mg orally disintegrating tablets contain aspartame (e.g., NutraSweet®) which is metabolized in the GI tract to provide about 0.14, 0.28, or 0.42, 0.63, or 0.84 mg of phenylalanine, respectively, following oral administration.

Because seizures have occurred in 0.3% of patients receiving risperidone in clinical studies, the drug should be administered with caution to patients with a history of seizures.

Esophageal dysmotility and aspiration have been associated with the use of antipsychotic agents, including risperidone. Because aspiration pneumonia is a common cause of morbidity and mortality in patients with advanced dementia of the Alzheimer's type, risperidone and other antipsychotic drugs should be used with caution in patients at risk for aspiration pneumonia.

Because both hypothermia and hyperthermia have been associated with risperidone therapy, the drug should be administered with caution in patients who will be exposed to temperature extremes.

Because risperidone has the potential to impair judgment, thinking, or motor skills, patients should be cautioned about operating hazardous machinery, including driving automobiles, until they are reasonably certain that risperidone therapy does not adversely affect them.

Risperidone has an antiemetic effect in animals; this effect also may occur in humans, and may mask manifestations of overdosage with certain drugs or may obscure the cause of vomiting in various disorders such as intestinal obstruction, Reye's syndrome or brain tumor.

Patients should be advised to inform their clinician if they are taking, or plan to take, any prescription or nonprescription drugs, or have any concomitant illnesses (e.g., diabetes mellitus). Patients also should be advised to avoid alcohol while taking risperidone.

Risperidone is contraindicated in patients with known hypersensitivity to the drug.

■ **Pediatric Precautions** The manufacturer states that safety and effectiveness of risperidone in children with schizophrenia or acute mania associated with bipolar I disorder have not been established. However, efficacy and safety of the drug in the treatment of irritability associated with autistic disorder have been established in 2 placebo-controlled trials of 8 weeks' duration in 156 children and adolescents aged from 5–16 years. (See Uses: Autistic Disorder.) Additional safety information also was assessed from a long-term study in patients with autistic disorder and from short- and long-term studies in more than 1200 pediatric patients with other psychiatric disorders who were of similar age and weight and who received similar risperidone dosages as patients treated for irritability associated with autistic disorder. Safety and effectiveness of risperidone in pediatric patients with autistic disorder younger than 5 years of age have not been established.

In clinical trials in 1885 children and adolescents with autistic disorder or other psychiatric disorders treated with risperidone, 2 patients (0.1%) reportedly developed tardive dyskinesia, which resolved upon discontinuance of therapy. In addition, approximately 15% of children and adolescents receiving 0.5–2.5 mg daily dosages of risperidone developed withdrawal dyskinesia during the discontinuance phase of one long-term (6 month), open-label study.

In long-term, open-label trials in patients with autistic disorder or other psychiatric disorders, a mean body weight gain of 7.5 kg after 12 months of risperidone therapy was reported, which was higher than the normal expected weight gain (i.e., 3–3.5 kg per year adjusted for age, based on the Centers for Disease Control and Prevention normative data). The majority of the weight increase occurred within the first 6 months of drug exposure. Average percentiles at baseline and at 12 months were 49 and 60 for weight, 48 and 53 for height, and 50 and 62 for body mass index, respectively. When treating pediatric patients with risperidone, the manufacturer recommends that weight gain should be assessed against that expected with normal growth.

Somnolence frequently occurred in placebo-controlled trials in pediatric patients with autistic disorder. Most cases were mild to moderate in severity, occurred early during therapy (peak incidence during the first 2 weeks of therapy), and were transient (median duration of 16 days). Patients experiencing persistent somnolence may benefit from a change in dosage regimen.

Risperidone has been shown to elevate prolactin concentrations in children and adolescents as well as adults. In double-blind, placebo-controlled, 8-week trials in children and adolescents aged from 5–17 years, 49% of risperidone-treated patients had elevated prolactin concentrations compared with 2% of those receiving placebo.

In clinical trials conducted in 1885 children and adolescents with autistic disorder or other psychiatric disorders, galactorrhea and gynecomastia reportedly occurred in 0.8 and 2.3% of risperidone-treated patients, respectively.

The manufacturer states that the long-term effects of risperidone on growth and maturation have not been fully evaluated.

■ **Geriatric Precautions** Clinical studies of risperidone for the management of schizophrenia did not include sufficient numbers of patients 65 years of age and older to determine whether geriatric patients respond differently than younger patients. However, serious adverse effects, including an increased risk of death, have been reported in geriatric patients receiving risperidone or other atypical antipsychotic agents in clinical trials in patients with dementia-related psychosis. Risperidone is not approved for the treatment of dementia-related psychosis. (See Geriatric Considerations in Uses: Psychotic Disorders.)

Adverse cerebrovascular events (e.g., stroke, transient ischemic attack), some of which resulted in fatalities, have been reported in clinical studies of risperidone for the management of psychosis in geriatric patients (mean age 85 years; range 73–97) with dementia. Analysis of pooled data from 4 randomized, placebo-controlled studies indicates that adverse cerebrovascular events occurred in approximately 4% of geriatric patients with dementia of the Alzheimer's type, vascular dementia, or mixed dementia receiving risperidone compared with 2% of those receiving placebo. Although many of the patients who experienced adverse cerebrovascular events during the course of these studies had at least one risk factor for cerebrovascular events (e.g., arrhythmia, atherosclerosis, atrial fibrillation, diabetes, heart failure, hypertension, prior history of stroke or transient ischemic attack), the total number of such patients was too small to permit definitive conclusions about the relationship between known risk factors for cerebrovascular events and risperidone therapy. An increased risk of adverse cerebrovascular events has not been identified to date in clinical studies of risperidone for the management of schizophrenia.

An increased risk of death has been reported among geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs compared with that among patients receiving placebo. Analyses of 17 placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6- to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., risperidone, aripiprazole, olanzapine, quetiapine) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature.

A higher incidence of mortality also was observed in geriatric patients with dementia-related psychosis receiving risperidone and furosemide concurrently in placebo-controlled trials when compared with that in patients receiving risperidone alone or placebo and furosemide concurrently. The increase in mortality in patients receiving risperidone and furosemide concurrently was observed in 2 out of 4 clinical trials. The pathological mechanism for this finding remains to be established and no consistent pattern for the cause of death was observed. An increased incidence of mortality in geriatric patients with dementia-related psychosis was observed with risperidone regardless of concurrent furosemide administration.

Risperidone dosage generally should be titrated carefully in geriatric patients, usually initiating therapy at the low end of the dosage range. The greater frequency of decreased hepatic, renal, and/or cardiac function and of concomitant disease and drug therapy observed in the elderly also should be considered. Although geriatric patients exhibit a greater tendency to orthostatic hypotension, the manufacturer states that its risk may be minimized by limiting the initial oral dosage to 0.5 mg twice daily followed by careful titration and close monitoring of orthostatic vital signs in patients for whom this is of concern. More recent evidence however, indicates that even lower initial dosages and slower dosage titration are better tolerated in these patients. Therefore, some clinicians recommend initiating oral risperidone therapy at 0.25 mg daily, and gradually increasing dosages, as tolerated, to a dosage of 2 mg daily in these patients. Higher oral dosages (e.g., 3 or 4 mg daily) may be required in some patients, but are usually associated with greater incidence of extrapyramidal reactions. Most geriatric patients should *not* be maintained at an oral risperidone dosage exceeding 3 mg daily. (See Geriatric Patients and Others at Risk of Orthostatic Hypotension under Dosage and Administration: Dosage.)

■ **Mutagenicity and Carcinogenicity** Risperidone did not exhibit mutagenic potential in in vitro chromosomal aberration studies in human lymphocytes or Chinese hamster cells, mouse lymphoma assay, in vitro rat hepatocyte DNA-repair assay, in vivo micronucleus test in mice, the sex-linked recessive lethal test in Drosophila, or in microbial (Ames) test systems.

Statistically significant increases in pituitary gland adenomas and mammary gland adenocarcinomas were observed in female mice receiving risperidone dosages of 0.63, 2.5, and 10 mg/kg (equivalent to 2.4, 9.4, and 37.5 times the maximum recommended human dosage for schizophrenia on a mg/kg basis or 0.2, 0.75, and 3 times the maximum recommended human dosage on a mg/m^2 basis, respectively) for 18 months. In addition, statistically significant increases were observed in mammary gland adenocarcinomas in both male and female rats, and mammary gland neoplasms and endocrine pancreas adenomas in male rats receiving risperidone dosages of 0.63, 2.5, and 10 mg/kg (equivalent to 0.4, 1.5, and 6 times the maximum recommended human dosage for schizophrenia on a mg/kg basis or 0.2, 0.75, and 3 times the maximum recommended human dosage on a mg/m^2 basis, respectively) for 25 months.

Although an increase in mammary neoplasms has been found in rodents following long-term administration of prolactin-stimulating antipsychotic agents, no clinical or epidemiologic studies conducted to date have shown an association between long-term administration of prolactin-stimulating drugs and mammary tumorigenesis in humans. Current evidence is considered too limited to be conclusive, and further study is needed to determine the clinical importance in most patients of elevated serum prolactin concentrations associated with antipsychotic agents. Since in vitro tests indicate that approximately one-third of human breast cancers are prolactin-dependent, risperidone should be used with caution in patients with previously detected breast cancer.

■ **Pregnancy, Fertility, and Lactation** Reproductive studies in rats and rabbits using risperidone dosages of 0.4–6 times the maximum recom-

mended human dosage on a mg/m² basis have not revealed evidence of fetal malformation. However, risperidone has been shown to cross the placenta in rats, and an increased rate of stillborn rat pups occurred at dosages 1.5 times higher than the maximum recommended human dosage on a mg/m² basis. In 3 reproductive studies in rats, there was an increase in pup deaths during the first 4 days of lactation at dosages 0.1–3 times the human dosage on a mg/m² basis. It is not known whether these deaths resulted from a direct effect on the fetuses or pups or to effects on the dams. In a separate reproductive study in rats, an increased number of pup daths (at birth or by the day after birth) and a decrease in birth weight were observed in pups of dams treated with risperidone dosages that were 3 times the maximum recommended human dosage on a mg/m² basis. Risperidone also appeared to impair maternal behavior, as evidenced by reduced weight gain and decreased survival (from day 1–4 of lactation) in pups born to control dams but reared by risperidone-treated dams.

Although there are no adequate and controlled studies to date in humans, one case of agenesis of the corpus callosum has been reported in an infant exposed to risperidone in utero; however, a causal relationship to risperidone therapy is unknown. Reversible extrapyramidal adverse effects in the neonate also were observed following postmarketing use of risperidone during the third trimester of pregnancy. Risperidone should be used during pregnancy only when the potential benefits justify the possible risks to the fetus. The effect of risperidone on labor and delivery in humans is unknown.

Risperidone (0.16–5 mg/kg) has been shown to impair mating, but not fertility, in Wistar rats in 3 reproductive studies at dosages 0.1–3 times the maximum recommended human dosage on a mg/m² basis. The effect appeared to be in females since impaired mating behavior was not noted in the Segment I study in which males only were treated. Sperm motility and serum testosterone concentrations were decreased in beagles at dosages 0.6–10 times the human dose on a mg/m² basis. Serum testosterone and sperm parameters partially recovered but remained decreased after treatment was discontinued. A no-effect dosage was not found in these studies in either rats or dogs.

Risperidone and its principal active metabolite, 9-hydroxyrisperidone, are distributed into milk. The manufacturer states that women receiving risperidone should avoid nursing.

Description

Risperidone is a benzisoxazole-derivative antipsychotic agent and is chemically unrelated to other antipsychotic agents. While risperidone shares some of the pharmacologic actions of other antipsychotic agents, the drug has been described as an atypical or second-generation antipsychotic agent since many of its CNS effects differ from those of typical or first-generation agents (e.g., butyrophenones, phenothiazines). The exact mechanism of antipsychotic action of risperidone has not been fully elucidated but, like that of clozapine, appears to be more complex than that of most other antipsychotic agents and may involve antagonism of central type 2 serotonergic (5-HT_2) receptors and central dopamine D_2 receptors.

SumMon® (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the labeling be consulted for detailed information on the usual cautions, precautions, and contraindications concerning potential drug interactions and/or laboratory test interferences and for information on acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Ziprasidone

■ Ziprasidone has been referred to as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** *Schizophrenia* Ziprasidone is used for the symptomatic management of schizophrenia. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Because of ziprasidone's greater capacity to prolong the QT/QT_c-interval compared with that of several other antipsychotic agents, use of ziprasidone may be reserved for patients whose disease fails to respond adequately to appropriate courses of other antipsychotic agents. (See Prolongation of QT interval under Warnings/Precautions: Warnings, in Cautions.) However, it should be noted that patients with a history of resistance to antipsychotic therapy (i.e., failed to respond to adequate courses of 2 or more antipsychotic agents) usually were excluded in clinical studies of ziprasidone.

Efficacy of oral ziprasidone was evaluated in 5 placebo-controlled studies of variable duration (4 short-term [4–6 weeks] and one long-term [52 weeks]), principally in patients with schizophrenic disorders in hospital settings. Ziprasidone appears to be superior to placebo in improving both positive and negative manifestations in acute exacerbations of schizophrenia and in reducing the rate of relapse for up to 52 weeks.

Although results of a limited comparative study suggest that oral ziprasidone hydrochloride dosages of 160 mg daily may be as effective as oral haloperidol 15 mg daily in reducing positive symptoms of schizophrenia, a reliable and valid comparison of ziprasidone and oral haloperidol cannot be made at this time based solely on this study due to its relatively small sample size (90 patients), high dropout rate (51.1%), and brief duration (4 weeks). Data from one unpublished comparative study also suggest that ziprasidone hydrochloride (mean dosage of 130 mg daily) may be as effective as olanzapine (mean dosage of 11 mg daily) in the treatment of schizophrenia.

Ziprasidone is used IM for the management of acute agitation in patients with schizophrenia for whom treatment with ziprasidone is appropriate and who require an IM antipsychotic agent for rapid control of behaviors that interfere with diagnosis and care (e.g., threatening behaviors, escalating or urgently distressing behavior, self-exhausting behavior). The efficacy of IM ziprasidone for the management of acute agitation in schizophrenia was established in single-day controlled trials in hospital settings. Because there is no experience regarding the safety of administering ziprasidone IM to schizophrenic patients already receiving oral ziprasidone, concomitant use of oral and IM formulations of ziprasidone is *not* recommended.

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Ziprasidone is used for the treatment of acute manic and mixed episodes (with or without psychotic features) associated with bipolar I disorder. According to DSM-IV criteria, manic episodes are distinct periods lasting 1 week or longer (or less than 1 week if hospitalization is required) of abnormally and persistently elevated, expansive, or irritable mood accompanied by at least 3 (or 4 if the mood is only irritability) of the following 7 symptoms: grandiosity, reduced need for sleep, pressure of speech, flight of ideas, distractibility, increased goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation, and engaging in high risk behavior (e.g., unrestrained buying sprees, sexual indiscretions, foolish business investments).

Efficacy of ziprasidone in the treatment of acute manic and mixed episodes has been demonstrated in 2 short-term (3 weeks' duration), double-blind, pla-

turer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Quetiapine Fumarate

■ Quetiapine is considered an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Quetiapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia Short-term efficacy of quetiapine for the management of schizophrenia has been established by placebo-controlled studies of 6 weeks' duration principally in hospitalized patients with schizophrenia. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

In clinical studies in patients with schizophrenia, quetiapine was more effective than placebo in reducing the severity of symptoms associated with this disorder. Quetiapine appears to improve both positive and negative manifestations of schizophrenia. Results from comparative clinical studies and meta-analyses suggest that quetiapine is at least as effective as chlorpromazine or haloperidol in reducing positive and negative symptoms of schizophrenia.

The American Psychiatric Association (APA) considers certain atypical antipsychotic agents (i.e., quetiapine, aripiprazole, olanzapine, risperidone, ziprasidone) first-line drugs for the management of the acute phase of schizophrenia (including first psychotic episodes), principally because of the decreased risk of adverse extrapyramidal effects and tardive dyskinesia, with the understanding that the relative advantages, disadvantages, and cost-effectiveness of conventional and atypical antipsychotic agents remain controversial. The APA states that, with the possible exception of clozapine for the management of treatment-resistant symptoms, there currently is no definitive evidence that one atypical antipsychotic agent will have superior efficacy compared with another agent in the class, although meaningful differences in response may be observed in individual patients. Conventional antipsychotic agents may be considered first-line therapy in patients who have been treated successfully in the past with or who prefer conventional agents. The choice of an antipsychotic agent should be individualized, considering past response to therapy, adverse effect profile (including the patient's experience of subjective effects such as dysphoria), and the patient's preference for a specific drug, including route of administration.

Although the efficacy of quetiapine for long-term use has not been established in controlled studies, the manufacturer states that beneficial effects of the drug were maintained for up to 4 years in some patients during an open-label extension study in patients who achieved an initial response to treatment during double-blind clinical studies. If quetiapine is used for extended periods, the need for continued therapy should be reassessed periodically on an individualized basis. (See Dosage and Administration: Dosage.)

For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Quetiapine is used alone or in conjunction with lithium or divalproex sodium for the management of acute manic episodes associated with bipolar I disorder. Efficacy of quetiapine monotherapy in the treatment of acute manic episodes has been demonstrated in 2 placebo-controlled studies of 12 weeks' duration in patients who met the DSM-IV criteria for bipolar disorder and who met diagnostic criteria for an acute manic episode (with or without psychotic features). Patients with rapid cycling and mixed episodes were excluded from these studies. The principal rating instrument used for assessing manic symptoms in these studies was the Young Mania Rating Scale (YMRS) score, an 11-item clinician rated scale traditionally used to assess the degree of manic symptomatology in a range from 0 (no manic features) to 60 (maximum score). In these studies, quetiapine was shown to be superior to placebo in reduction of the YMRS total score after 3 and 12 weeks of treatment.

Efficacy of quetiapine when used in combination with lithium or divalproex sodium in the management of acute manic episodes has been demonstrated in a placebo-controlled study of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder with acute manic episodes (with or without psychotic features). Patients with rapid cycling and mixed episodes were excluded from enrollment and patients included in the study may or may not have received an adequate course of therapy with lithium or divalproex sodium prior to randomization. Quetiapine was shown to be superior to placebo when added to lithium or divalproex sodium alone in the reduction of YMRS total score. However, in a similarly designed study, quetiapine was associated with an improvement of YMRS scores but did not demonstrate superiority to placebo.

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current APA recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic (e.g., olanzapine) may be adequate. For more severe manic or mixed episodes, combination therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Quetiapine also is used for the treatment of depressive episodes associated with bipolar disorder. Efficacy of quetiapine in the treatment of depressive episodes has been demonstrated in 2 randomized, double-blind, placebo-controlled studies of 8 weeks' duration in patients with bipolar I or II disorder (with or without a rapid-cycling course). Patients in these studies received fixed daily quetiapine dosages of 300 or 600 mg once daily. The principal rating instrument used for assessing depressive symptoms in these studies was the Montgomery-Asberg Depression Rating Scale (MADRS), a 10-item clinician-rated scale with scores ranging from 0 to 60. In both studies, quetiapine was found to be superior to placebo in reduction of MADRS scores at week 8, with improvements in scores evident within one week of treatment. In addition, patients receiving 300 mg of quetiapine daily demonstrated significant improvements compared to placebo recipients in overall quality of life and satisfaction related to various areas of functioning.

Dosage and Administration

■ **Administration** Quetiapine is administered orally. While food reportedly can marginally increase the peak concentration and oral bioavailability of quetiapine, the drug generally can be administered without regard to meals.

Dispensing and Administration Precautions Because of similarity in spelling between Seroquel® (the trade name for quetiapine fumarate) and Serzone® (the former trade name for nefazodone hydrochloride, an antidepressant agent; no longer commercially available in the US under this trade name), dispensing errors have been reported to the US Food and Drug Administration (FDA) and the manufacturer of Seroquel® (AstraZeneca). Accordiog to the medication error reports, the overlapping strengths (100 and 200 mg), dosage forms (tablets), and dosing intervals (twice daily) and the fact that these 2 drugs were stored closely together in pharmacies also were critical in causing these errors. Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Seroquel® and Serzone®. Although the Serzone brand was discontinued in June 2004, clinicians may continue to refer to nefazodone by the former brand name in prescribing. Some experts recommend that pharmacists assess the measures of avoiding dispensing errors and implement them as appropriate (e.g., by verifying all orders for these agents by spelling both the trade and generic names to prescribers, using computerized name alerts, attaching reminders to drug containers and pharmacy shelves, separating the drugs on pharmacy shelves, counseling patients). (See Dispensing and Administration Precautions under Warnings/Precautions: General Precautions in Cautions.)

■ **Dosage** Dosage of quetiapine fumarate is expressed in terms of quetiapine and must be carefully adjusted according to individual requirements and response, using the lowest possible effective dosage.

Higher maintenance dosages of quetiapine may be required in patients receiving the antipsychotic drug concomitantly with phenytoin or other hepatic enzyme-inducing agents (e.g., carbamazepine, barbiturates, rifampin, glucocorticoids), and an increase in the maintenance dosage of quetiapine may be required to reestablish efficacy in patients receiving such concomitant therapy. (See Drug Interactions: Drugs Affecting Hepatic Microsomal Enzymes and also Phenytoin.)

Patients receiving quetiapine should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustments. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

The manufacturer states that if quetiapine therapy is reinitiated after a drug-free period of less than 1 week, dosage titration is not necessary. However, if quetiapine therapy is reinitiated after a drug-free period exceeding 1 week, dosage generally should be titrated as with initial therapy.

Schizophrenia For the management of schizophrenia, the recommended initial dosage of quetiapine in adults is 25 mg twice daily. Dosage may be increased in increments of 25–50 mg 2 or 3 times daily on the second or third day, as tolerated, to a target dosage of 300–400 mg daily in 2 or 3 divided doses by the fourth day. Because steady-state plasma concentrations of quetiapine may not be attained for 1–2 days at a given dosage, subsequent dosage adjustments generally should be made at intervals of not less than 2 days, usually in increments or decrements of 25–50 mg twice daily. Effective dosages of quetiapine in clinical trials generally ranged from 150–750 mg daily. While the manufacturer states that increasing quetiapine dosages beyond 300 mg daily usually does not result in additional therapeutic effect, dosages of 400–500 mg daily apparently have been required in some patients, and a dosage range of 300–800 mg daily has been recommended. Safety of quetiapine in dosages exceeding 800 mg daily has not been established.

The optimum duration of quetiapine therapy currently is not known, but the efficacy of maintenance therapy with antipsychotic agents used in the treatment of schizophrenia is well established. Patients responding to quetiapine therapy should continue to receive the drug as long as clinically necessary and tolerated but at the lowest possible effective dosage, and the need for continued therapy with the drug should be reassessed periodically. The American Psychiatric Association (APA) states that prudent long-term treatment options in patients with remitted first- or multiple-episodes include either indefinite maintenance therapy or gradual discontinuance of the antipsychotic agent with close follow-up and a plan to reinstitute treatment upon symptom recurrence. Discontinuance of antipsychotic therapy should be considered only after a period of at least 1 year of symptom remission or optimal response while receiving the antipsychotic agent. In patients who have had multiple previous psychotic episodes or 2 psychotic episodes within 5 years, indefinite maintenance antipsychotic treatment is recommended.

If antipsychotic therapy is to be discontinued in patients with schizophrenia, precautions should include slow, gradual dose reduction over many months, more frequent clinician visits, and use of early intervention strategies. Patients and their family and caregivers should be advised about early signs of relapse, and clinicians should collaborate with them to develop plans for action should they emerge. The treatment program should be designed to respond quickly to evidence of prodromal symptoms or behaviors or exacerbations of schizophrenic symptoms.

Bipolar Disorder For the management of depressive episodes associated with bipolar I or II disorder, the recommended dosage of quetiapine in adults is 50 mg administered once daily at bedtime on the first day of therapy. The dosage of quetiapine should then be increased to 100 mg once daily on the second day of therapy, 200 mg once daily on the third day of therapy, and 300 mg once daily on the fourth day of therapy. In clinical trials demonstrating clinical efficacy, quetiapine was given in a dosing schedule of 50, 100, 200, and 300 mg once daily on days 1–4, respectively; patients who received 600 mg daily received 400 mg daily on day 5 and 600 mg daily on day 8. Although antidepressant efficacy was demonstrated with quetiapine at dosages of 300 mg daily and 600 mg daily, no additional benefit was seen in the 600-mg daily group.

For the management of acute mania associated with bipolar I disorder (alone or in conjunction with lithium or divalproex sodium), the recommended initial dosage of quetiapine in adults is 100 mg daily, administered in 2 divided doses. The dosage of quetiapine should be increased in increments of up to 100 mg daily in 2 divided doses to 400 mg daily on the fourth day of therapy. Subsequent dosage adjustments up to 800 mg daily by the sixth day of therapy should be made in increments not exceeding 200 mg daily. Data indicate that most patients respond to 400–800 mg daily. The safety of quetiapine dosages exceeding 800 mg daily has not been established.

The APA states that for patients treated with an antipsychotic agent during an acute episode in bipolar disorder, the need for ongoing antipsychotic treatment should be reassessed upon entering the maintenance phase. The APA recommends that antipsychotics be slowly tapered and discontinued unless they are required to control persistent psychosis or provide prophylaxis against recurrence. While maintenance therapy with atypical antipsychotics may be considered, there currently is limited evidence regarding their efficacy in the maintenance phase compared with that of agents such as lithium or valproate. The manufacturer of quetiapine states that efficacy of the drug has not been systematically evaluated for more than 12 weeks as monotherapy of acute manic episodes associated with bipolar I disorder or for more than 3 weeks as combined therapy with divalproex or lithium. In addition, the manufacturer of quetiapine states that efficacy of the drug has not been systematically evaluated for more than 8 weeks in the management of depressive episodes in patients with bipolar I or II disorder. If quetiapine is used for extended periods, the need for continued therapy should be reassessed periodically on an individualized basis.

Switching to or Concomitant Use with Other Antipsychotic Agents The manufacturer states that there are no systematically collected data that specifically address switching from other antipsychotic agents to quetiapine or concerning concomitant use of quetiapine with other antipsychotic agents. Although abrupt discontinuance of the previous antipsychotic agent may be acceptable for some patients with schizophrenia, gradual discontinuance may be most appropriate for others. In all cases, the period of overlapping antipsychotic administration should be minimized. In patients being switched from long-acting (depot) parenteral antipsychotic therapy to oral quetiapine therapy, the first oral dose of quetiapine should be administered in place of the next scheduled dose of the long-acting preparation. The need for continuing existing drugs used for the symptomatic relief of extrapyramidal manifestations should be reevaluated periodically.

■ **Special Populations** The manufacturer states that because quetiapine is substantially metabolized in the liver and because the pharmacokinetics of quetiapine appear to be altered in patients with hepatic impairment, an initial dosage of 25 mg daily should be used in adults with hepatic impairment. The dosage should be increased by 25–50 mg daily according to clinical response and tolerability until an effective dosage is reached.

Although elimination of quetiapine was reduced in patients with severe renal impairment (e.g., creatinine clearance of 10–30 mL/minute), the plasma quetiapine concentrations were similar to those in patients with normal renal function; therefore, the manufacturer states that dosage adjustment is not necessary in such patients.

Geriatric or debilitated patients and patients predisposed to hypotension or in whom hypotension would pose a risk (e.g., patients with dehydration or hypovolemia, those receiving antihypertensive drugs, patients with known cardiovascular or cerebrovascular disease) should have a slower rate of dosage titration and should receive lower target dosages of quetiapine. The risk of orthostatic hypotension can be minimized by limiting the initial dosage of quetiapine to 25 mg twice daily. If orthostatic hypotension occurs during titration to the target dosage, the manufacturer recommends a return to the previous dosage in the titration schedule.

Cautions

■ **Contraindications** Known hypersensitivity to quetiapine or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** **Increased Mortality in Geriatric Patients with Dementia-related Psychosis.** Geriatric patients with dementia-related psychosis treated with atypical antipsychotic drugs appear to be at an increased risk of death compared with that among patients receiving placebo. Analyses of 17 placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6- to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., quetiapine, aripiprazole, olanzapine, risperidone) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. The manufacturer states that quetiapine is not approved for the treatment of dementia-related psychosis. (See Dosage and Administration: Special Populations and see also Geriatric Use under Warnings/Precautions: Specific Populations, in Cautions.)

Worsening of Depression and Suicidality Risk. Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs with therapy. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared to placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or

other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider.

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

Bipolar Disorder. It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression). Quetiapine is approved for use in treating bipolar depression in adults. (See Bipolar Disorder under Uses.)

Neuroleptic Malignant Syndrome. Neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment, has been reported in patients receiving antipsychotic agents, including quetiapine. For additional information on NMS, see Extrapyramidal Reactions under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia. Use of antipsychotic agents, including quetiapine, may be associated with tardive dyskinesias, a syndrome of potentially irreversible, involuntary, dyskinetic movements. For additional information on tardive dyskinesia, see Tardive Dyskinesia under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Hyperglycemia and Diabetes Mellitus. Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving all atypical antipsychotic agents, including quetiapine. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., quetiapine, clozapine, olanzapine, risperidone).

Precise risk estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., clozapine, olanzapine) than with others in the class (e.g., quetiapine, risperidone), available data are conflicting and insufficient to provide reliable estimates of relative risk associated with use of the various atypical antipsychotics.

The manufacturers of atypical antipsychotic agents state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia (e.g., polydipsia, polyphagia, polyuria, weakness) during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the suspect drug; in other cases, hyperglycemia resolved with discontinuance of the antipsychotic.

For further information on the risk of hyperglycemia and diabetes mellitus associated with atypical antipsychotic agents, see Cautions: Endocrine and Metabolic Effects and see also Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications, in Clozapine 28:16.08.04.

Sensitivity Reactions Contact dermatitis, maculopapular rash, and photosensitivity reactions were reported infrequently during clinical trials. Anaphylaxis and Stevens-Johnson syndrome have been reported during postmarketing surveillance.

General Precautions **Cardiovascular Effects.** Orthostatic hypotension with associated dizziness, tachycardia, and/or syncope, particularly during the initial dosage titration period, has been reported. The risk of orthostatic hypotension and syncope may be minimized by limiting initial dosage. (See Dosage and Administration: Special Populations.) Use with caution in patients with known cardiovascular (e.g., history of myocardial infarction or ischemia, heart failure, conduction abnormalities) or cerebrovascular disease and/or conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy).

Ocular Effects. The development of cataracts in association with quetiapine was observed in animal studies. Lens changes also have been reported in some patients receiving long-term quetiapine therapy, although a causal relationship has not been established. Because the possibility of lens changes cannot be excluded, the manufacturer recommends ophthalmologic examination of the lens by methods adequate to detect cataract formation (e.g., slit lamp exam) be performed at the initiation of quetiapine therapy, or shortly thereafter, and at 6-month intervals during chronic quetiapine therapy.

Nervous System Effects. Seizures occurred in 0.6% of patients receiving quetiapine in controlled clinical trials. Use with caution in patients with a history of seizures or with conditions known to lower the seizure threshold (e.g., dementia of the Alzheimer's type, geriatric patients).

Somnolence occurred in 16–18 or 34% of patients receiving quetiapine as monotherapy (for the treatment of schizophrenia or bipolar disorder) or in conjunction with lithium or divalproex sodium (for the treatment of bipolar disorder), respectively, during clinical studies compared with 4–11% of those receiving placebo.

Endocrine Effects. Dose-related decreases in total and free thyroxine (T4) of approximately 20% were observed in patients receiving quetiapine dosages at the higher end of the therapeutic dosage range during clinical studies. These decreases were maximal during the first 2–4 weeks of therapy and were maintained without adaptation or progression during more chronic therapy. Generally, these changes were not considered clinically important and were reversible upon discontinuance of quetiapine, regardless of duration of therapy. Increases in TSH were observed in about 0.4 or 12% of patients receiving quetiapine alone or in conjunction with lithium or divalproex sodium, respectively. In patients receiving quetiapine monotherapy, thyroid replacement therapy was necessary in some patients who experienced increases in TSH.

Although not observed in patients receiving quetiapine during clinical trials, increases in prolactin concentrations and associated increases in mammary gland neoplasia were reported in animal studies.

Metabolic Effects. During clinical studies, 23 or 21% of patients with schizophrenia or acute mania receiving quetiapine gained at least 7% of their baseline weight compared with 6–7% of those receiving placebo. In patients receiving quetiapine as adjunctive therapy for acute mania, 13% gained at least 7% of their baseline weight compared with 4% of those receiving placebo.

Increases from baseline in cholesterol and triglyceride concentrations of 11 and 17%, respectively, were reported in patients receiving quetiapine compared with slight decreases in patients receiving placebo in clinical studies in patients with schizophrenia. These changes were weakly related to increases in weight observed in patients receiving quetiapine. For additional information on metabolic effects, see Hyperglycemia and Diabetes Mellitus under Warnings/Precautions, in Cautions.

Hepatic Effects. Asymptomatic, transient, and reversible increases in serum transaminases, principally ALT, have been reported in patients receiving quetiapine; these changes usually occurred within the first 3 weeks and resolved despite continued quetiapine therapy.

Sexual Dysfunction. One case of drug-induced priapism was reported in clinical studies of quetiapine.

Body Temperature Regulation. Although not reported in clinical studies with quetiapine, disruption of the body's ability to reduce core body temperature has been associated with use of antipsychotic agents. Use caution when quetiapine is administered in patients exposed to conditions that may contribute to an elevation in core body temperature (e.g., dehydration, extreme heat, strenuous exercise, concomitant use of anticholinergic agents).

GI Effects. Esophageal dysmotility and aspiration have been associated with the use of antipsychotic agents. Use with caution in patients at risk for aspiration pneumonia (e.g., geriatric patients, those with advanced Alzheimer's dementia).

Suicide. Attendant risk with bipolar disorder and psychotic illnesses; closely supervise high-risk patients. In clinical studies in patients with bipolar depression, the incidence of treatment-emergent suicidal ideation or suicide attempt in quetiapine-treated patients was low (1.7–2.6%) and similar to that observed with placebo (2%). Prescribe in the smallest quantity consistent with good patient management to reduce the risk of overdosage. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Dispensing and Administration Precautions. Because of similarity in spelling between Seroquel® (the trade name for quetiapine fumarate) and Serzone® (the former trade name for nefazodone hydrochloride, an antidepressant agent; no longer commercially available in the US under this trade name), dispensing errors have been reported to the US Food and Drug Administration (FDA) and the manufacturer of Seroquel® (AstraZeneca). According to the medication error reports, the overlapping strengths (100 and 200 mg), dosage forms (tablets), and dosing intervals (twice daily) and the fact that these 2 drugs were stored closely together in pharmacies also were critical in causing these errors. These medication errors may be associated with adverse CNS (e.g., mental status deterioration, hallucination, paranoia, muscle weakness, lethargy, dizziness) and GI effects (e.g., nausea, vomiting, diarrhea). As of November 2001, 4 patients had required emergency room visits and 3 patients reportedly had been hospitalized because of dispensing errors involving these 2 agents. One female patient 25 years of age experienced fever and respiratory arrest after mistakenly taking Seroquel® for 3 days instead of taking Serzone®, and even-

tually died, although a causal relationship has not been established. FDA also is concerned that several patients unintentionally ingested Serzone® or Seroquel® for a prolonged period of time before the error was discovered. Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Seroquel® and Serzone®. Although the Serzone brand was discontinued in June 2004, clinicians may continue to refer to nefazodone by the former brand name in prescribing. Some experts recommend that pharmacists assess the measures of avoiding dispensing errors and implement them as appropriate (e.g., by verifying all orders for these agents by spelling both the trade and generic names to prescribers, using computerized name alerts, attaching reminders to drug containers and pharmacy shelves, separating the drugs on pharmacy shelves, counseling patients).

Patients should be advised to question the dispensing pharmacist regarding any changes in the appearance of their prescription in terms of shape, color, or size of the tablets. Dispensing errors involving Seroquel® (quetiapine) and Serzone® (nefazodone) should be reported to the manufacturers or directly to the FDA MedWatch program by phone (800-FDA-1088), by fax (800-FDA-0178), by the Internet (http://www.fda.gov/Safety/MedWatch/default.htm), or by mail (FDA Safety Information and Adverse Event Reporting Program, FDA, 5600 Fishers Lane, Rockville, MD 20852-9787).

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Quetiapine is distributed into milk in animals. Not known whether quetiapine is distributed into milk in humans. The manufacturer states that women receiving quetiapine should not breast-feed.

Pediatric Use. Safety and efficacy not established in children younger than 18 years of age.

FDA warns that a greater risk of suicidal thinking or behavior (suicidality) occurred during first few months of antidepressant treatment (4%) compared with placebo (2%) in children and adolescents with major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders based on pooled analyses of 24 short-term, placebo-controlled trials of 9 antidepressant drugs (selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants). However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

Carefully consider these findings when assessing potential benefits and risks of quetiapine in a child or adolescent for any clinical use. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Geriatric Use. In clinical studies, approximately 7% of 3400 patients were 65 years of age or older. While no substantial differences in safety relative to younger adults were observed, factors that decrease pharmacokinetic clearance, increase the pharmacodynamic response, or cause poorer tolerance (e.g., orthostasis) may be present in geriatric patients. (See Dosage and Administration: Special Populations and see also Increased Mortality in Geriatric Patients with Dementia-related Psychosis under Warnings/Precautions: Warnings, in Cautions.)

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Worsening of Depression and Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Hepatic Impairment. Increased plasma concentrations expected in patients with hepatic impairment; dosage adjustment may be necessary. (See Dosage and Administration: Special Populations.)

Renal Impairment. Clearance may be decreased in patients with severe renal impairment, but dosage adjustment is not necessary.

■ **Common Adverse Effects** The most common adverse effects reported in 5% or more of patients receiving quetiapine therapy for schizophrenia or bipolar disorder and at a frequency twice that reported among patients receiving placebo in clinical trials include somnolence, sedation, asthenia, lethargy, dizziness, dry mouth, constipation, increased ALT, weight gain, dyspepsia, abdominal pain, postural hypotension, and pharyngitis.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes** Inhibitors of cytochrome P-450 (CYP) isoenzyme 3A4 (e.g., erythromycin, fluconazole, itraconazole, ketoconazole): potential pharmacokinetic interaction (increased serum quetiapine concentrations). Use with caution.

Inducers of CYP3A4 (e.g., barbiturates, carbamazepine, glucocorticoids, phenytoin, rifampin): potential pharmacokinetic interaction (increased quetiapine metabolism and decreased serum quetiapine concentrations). Dosage adjustment may be necessary if these drugs are initiated or discontinued in patients receiving quetiapine. (See Drug Interactions: Phenytoin.)

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Substrates of CYP1A2, CYP3A4, CYP2C9, CYP2C19, or CYP2D6: pharmacokinetic interaction unlikely.

■ **Alcohol** Potential pharmacologic interaction (additive CNS effects). Avoid alcoholic beverages during quetiapine therapy.

■ **Cimetidine** Concomitant use of cimetidine (400 mg 3 times daily for 4 days) and quetiapine (150 mg 3 times daily) decreased mean clearance of quetiapine by 20%. However, dosage adjustment of quetiapine is not necessary.

■ **Divalproex** Potential pharmacokinetic interaction. Increased maximum plasma quetiapine concentrations, with no effect on extent of quetiapine absorption or mean clearance. Decreased maximum plasma valproic acid concentrations and extent of absorption (not clinically important).

■ **Fluoxetine, Haloperidol, Imipramine, Risperidone** No effect on steady-state pharmacokinetics of quetiapine observed.

■ **Hypotensive Agents** Potential pharmacologic interaction (additive hypotensive effects).

■ **Levodopa and Dopamine Agonists** Potential pharmacologic interaction (antagonistic effects).

■ **Lithium** No effect on steady-state lithium pharmacokinetics observed.

■ **Lorazepam** Potential pharmacokinetic interaction (decreased clearance of lorazepam). Concomitant use of quetiapine (250 mg 3 times daily) and lorazepam (single 2-mg dose) resulted in a 20% decrease in the mean clearance of lorazepam.

■ **Phenytoin** Concomitant use of quetiapine (250 mg 3 times daily) and phenytoin (100 mg 3 times daily) resulted in a fivefold increase in quetiapine clearance. An increase in quetiapine dosage may be required; caution advised if phenytoin is withdrawn and replaced with a noninducer of CYP3A4 (e.g., valproate).

■ **Thioridazine** Potential pharmacokinetic interaction (increased oral clearance of quetiapine).

■ **Other CNS Agents** Potential pharmacologic interaction (additive CNS effects). Use with caution.

Description

Quetiapine is a dibenzothiazepine-derivative antipsychotic agent. The drug is pharmacologically similar to clozapine, but differs pharmacologically from other currently available first-generation (typical) antipsychotic agents (e.g., phenothiazines, butyrophenones). Because of these pharmacologic differences, quetiapine is considered an atypical or second-generation antipsychotic agent.

The exact mechanism of quetiapine's antipsychotic action in schizophrenia and its mood stabilizing action in bipolar disorder has not been fully elucidated but may involve antagonism at serotonin type 1 (5-hydroxytryptamine [5-HT_{1A}]) and type 2 (5-HT_{2A}, 5-HT_{2C}) receptors, and at dopamine (D_1, D_2) receptors.

Current evidence suggests that the clinical potency and antipsychotic efficacy of both typical and atypical antipsychotic drugs generally are related to their affinity for and blockade of central dopamine D_2 receptors; however, antagonism at dopamine D_2 receptors does not appear to account fully for the antipsychotic effects of quetiapine. Results of in vivo and in vitro studies indicate that quetiapine is a comparatively weak antagonist at dopamine D_2 receptors. Receptor binding studies show quetiapine is a weak antagonist at D_1 receptors. Although their role in eliciting the pharmacologic effects of antipsychotic agents remains to be fully elucidated, dopamine D_3, D_4, and D_5 receptors also have been identified; quetiapine possesses no affinity for the dopamine D_4 receptor.

The therapeutic effects of antipsychotic drugs are thought to be mediated by dopaminergic blockade in the mesolimbic and mesocortical areas of the CNS, while antidopaminergic effects in the neostriatum appear to be associated with extrapyramidal effects. The apparently low incidence of extrapyramidal effects associated with quetiapine therapy suggests that the drug is more active in the mesolimbic than in the neostriatal dopaminergic system. In contrast to typical antipsychotic agents (e.g., chlorpromazine) but like other atypical antipsychotic drugs (e.g., clozapine), quetiapine does not cause sustained elevations in serum prolactin concentrations and therefore is unlikely to produce adverse effects such as amenorrhea, galactorrhea, and impotence.

Quetiapine exhibits α_1- and α_2-adrenergic blocking activity; blockade of α_1-adrenergic receptors may explain the occasional orthostatic hypotension associated with the drug. Quetiapine also blocks histamine H_1 receptors, which may explain the sedative effects associated with the drug. Quetiapine possesses little or no affinity for β-adrenergic, γ-aminobutyric acid (GABA), benzodiazepine, or muscarinic receptors.

Quetiapine is extensively metabolized in the liver principally via sulfoxidation and oxidation to inactive metabolites. In vitro studies suggest that the cytochrome P-450 (CYP) 3A4 isoenzyme is involved in the metabolism of quetiapine to the inactive sulfoxide metabolite, which is the principal metabolite. The mean terminal half-life of quetiapine is about 6 hours. Following oral administration of a single dose of quetiapine, approximately 73 and 20% of the dose is excreted in urine and feces, respectively; less than 1% of the dose is excreted unchanged. Based on in vitro studies, quetiapine and 9 of its metabolites do not appear likely to inhibit CYP isoenzymes 1A2, 3A4, 2C9, 2C19, or 2D6.

Advice to Patients

Risk of suicidality; importance of patients, family, and caregivers being alert to and immediately reporting emergence of suicidality, worsening depression, or unusual changes in behavior, especially during the first few months

of therapy or during periods of dosage adjustment. FDA recommends providing written patient information (medication guide) explaining risks of suicidality each time the drug is dispensed.

Risk of orthostatic hypotension, especially during initial dosage titration and at times of reinitiation of therapy or increases in dosage.

Risk of somnolence and impairment of judgment, thinking, or motor skills; avoid driving, operating machinery, or performing hazardous tasks until effects on the individual are known.

Importance of avoiding alcohol during quetiapine therapy.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses (e.g., diabetes mellitus).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of avoiding overheating or dehydration.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview (see Users Guide). **For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.**

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Quetiapine Fumarate

Oral

Tablets, film-coated	25 mg (of quetiapine)	Seroquel®, AstraZeneca
	50 mg (of quetiapine)	Seroquel®, AstraZeneca
	100 mg (of quetiapine)	Seroquel®, AstraZeneca
	200 mg (of quetiapine)	Seroquel®, AstraZeneca
	300 mg (of quetiapine)	Seroquel®, AstraZeneca
	400 mg (of quetiapine)	Seroquel®, AstraZeneca

Risperidone

■ Risperidone has been described as an atypical or second-generation antipsychotic agent.

Uses

■ **Psychotic Disorders** Risperidone is used for the symptomatic management of psychotic disorders. Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia and Other Psychotic Disorders Efficacy of oral risperidone for the management of psychotic disorders has been established by controlled studies of 4–8 weeks' duration principally in patients with schizophrenic disorders in hospital settings. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention. For additional information on the symptomatic management of schizophrenia, including treatment recommendations and results of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

In clinical studies principally in patients with schizophrenia, oral risperidone was more effective than placebo and at least as effective as typical (e.g., haloperidol, perphenazine) and certain atypical (e.g., olanzapine) antipsychotics in the treatment of schizophrenia. Data from limited clinical studies indicate that risperidone improves both positive and negative manifestations of schizophrenia, but that such improvements may not be substantially greater than those achieved by haloperidol, a typical antipsychotic. Risperidone was more effective than haloperidol in preventing relapse in adult outpatients with clinically stable schizophrenia or schizoaffective disorders who were assigned to receive either drug for a minimum of 1 year. In this study, approximately 25% of patients who received usual dosages of risperidone had relapsed by the end of the study compared with approximately 40% of those receiving usual dosages of haloperidol. In these studies, improvement in manifestations of schizophrenia was based on the results of various psychiatric rating scales, including the Brief Psychiatric Rating Scale (BPRS) that assesses factors such as anergy, thought disturbances, activation, hostility/suspiciousness, and anxiety/depression; the BPRS psychosis cluster that assesses factors such as conceptual disorganization, hallucinatory behavior, suspiciousness, and unusual thought content in actively psychotic schizophrenic patients; the Scale for the Assessment of Negative Symptoms (SANS); the Positive and Negative Syndrome Scale (PANSS); and the Clinical Global Impression (CGI) scale.

Because of their safety and efficacy, some authorities consider conventional antipsychotic agents or risperidone to be reasonable first-line drugs for the management of the acute phase of schizophrenia. Risperidone may be particularly useful in patients who experience extrapyramidal reactions with typical antipsychotic agents since the drug appears to cause fewer extrapyramidal reactions at clinically effective dosages. Some authorities state that risperidone or newer atypical antipsychotic agents (such as olanzapine) also may be advantageous in patients who have not responded adequately to therapy with a conventional antipsychotic agent. However, the efficacy of atypical antipsychotics, other than clozapine, in treatment-resistant schizophrenia has yet to be established, and the possible clinical benefits of risperidone therapy should be weighed against the potential drawbacks, including its higher cost compared with standard agents and the lack of a parenteral preparation of the drug.

Geriatric Considerations. Although risperidone has been studied for use in the management of psychosis and aggression in institutionalized geriatric patients with moderate to severe dementia of the Alzheimer's† type (Alzheimer's disease, presenile or senile dementia), vascular dementia†, or a combination of the 2 types of dementia (i.e., mixed dementia†), there is evidence that use of the drug in geriatric patients with dementia may be associated with an increased risk of adverse cerebrovascular events. In randomized, placebo-controlled studies in nursing home residents with dementia, oral risperidone at a dosage of approximately 1 mg daily was more effective than placebo in decreasing psychotic and behavioral symptoms (e.g., aggression, agitation) of dementia, as assessed by the Behavioral Pathology in Alzheimer's Disease scale (BEHAVE-AD) and the Cohen-Mansfield Agitation Inventory (CMAI). However, evidence from these studies showed a significantly higher incidence of adverse cerebrovascular events such as stroke and transient ischemic attacks (TIAs) associated with risperidone therapy relative to placebo. In addition, geriatric patients with dementia-related psychosis treated with atypical antipsychotic agents appear to be at an increased risk of death compared with that among patients receiving placebo. (See Cautions: Geriatric Precautions.) Risperidone is not approved for the treatment with dementia-related psychosis.

■ **Bipolar Disorder** Risperidone is used alone or in conjunction with lithium or valproate for the management of manic and mixed episodes associated with bipolar I disorder. Efficacy of risperidone monotherapy in the treatment of acute manic and mixed episodes has been demonstrated in 2 placebo-controlled trials of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder with acute manic or mixed episodes with or without psychotic features. The principal rating instrument used for assessing manic symptoms in these trials was the Young Mania Rating Scale (Y-MRS), an 11-item clinician-rated scale traditionally used to assess the degree of manic symptomatology in a range from 0 (no manic features) to 60 (maximum score). In the first 3-week, placebo-controlled trial, which was limited to patients with manic episodes, risperidone monotherapy was given at an initial dosage of 3 mg daily and subsequently in a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 4.1 mg daily. In the second 3-week, placebo-controlled trial, patients also were given an initial dosage of risperidone 3 mg daily and subsequently a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 5.6 mg daily. Risperidone was found to be superior to placebo in the reduction of the Y-MRS total score in both studies.

Efficacy of risperidone when used in conjunction with lithium or valproate in the treatment of acute manic or mixed episodes has been demonstrated in one placebo-controlled trial of 3 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder (with or without a rapid cycling course) and who met diagnostic criteria for an acute manic or mixed episode (with or without psychotic features). In this study, inpatients and outpatients with bipolar disorder experiencing manic or mixed episodes who had not adequately responded to lithium or valproate monotherapy were randomized to receive risperidone, haloperidol, or placebo in conjunction with their original therapy. Risperidone therapy was given in an initial dosage of 2 mg daily and subsequently given in a flexible dosage ranging from 1–6 mg daily; the mean modal dosage was 3.8 mg daily. Lithium and valproate were given in conjunction with risperidone and plasma drug concentrations were maintained within ther-

desipramine recommends that the drug *not* be used in children. Although a causal relationship between the use of desipramine and the risk of sudden death has not been established, many clinicians recommend that desipramine *not* be used in children with this disorder when tricyclic antidepressant therapy is contemplated.

The US Food and Drug Administration (FDA) also has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. Anyone considering the use of desipramine in a child or adolescent for any clinical use must therefore balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

■ **Geriatric Precautions** Geriatric patients may be at risk of drug-induced toxicity when treated with desipramine, a tricyclic antidepressant that is known to be eliminated mainly by the kidneys. In this patient population, the ratio of plasma concentrations of the principal metabolite, 2-hydroxydesipramine, to desipramine appears to be increased, most likely because of decreased renal elimination that occurs with aging. Therefore, particular attention should be paid to desipramine dosage and it may be useful to monitor renal function in these patients. Desipramine use in geriatric patients also has been associated with an increased risk of falling and mental confusion. (See Cautions: Geriatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Pharmacokinetics

■ **Absorption** Desipramine hydrochloride appears to be well absorbed from the GI tract. Peak plasma concentrations occur within 4–6 hours after oral administration.

■ **Distribution** Limited data indicate that desipramine is distributed into milk in concentrations similar to those present in maternal plasma.

■ **Elimination** The plasma half-life of desipramine ranges from 7 to longer than 60 hours. Desipramine is metabolized principally via oxidation to 2-hydroxydesipramine, which retains some of the parent compound's ability to block the uptake of amines and may have particularly prominent cardiac depressant activity.

Chemistry and Stability

■ **Chemistry** Desipramine is a dibenzazepine-derivative tricyclic antidepressant that is the active metabolite of imipramine. Desipramine hydrochloride occurs as a white to off-white crystalline powder and is soluble in water and in alcohol. The drug has pK_as of 1.5 and 10.2.

■ **Stability** Desipramine hydrochloride tablets should be stored in tight containers at room temperature, preferably less than 30°C, and protected from excessive heat. Commercially available desipramine hydrochloride tablets have expiration dates of 5 years following the date of manufacture.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of desipramine, see the Tricyclic Antidepressants General Statement 28:16.04.28.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Doxepin Hydrochloride

■ Doxepin hydrochloride is a dibenzoxepin-derivative tricyclic antidepressant.

Uses

■ **Depressive and Anxiety Disorders** Doxepin shares the pharmacologic actions of the other tricyclic antidepressants and is used principally in the treatment of depression and/or anxiety in psychoneurotic patients, depression and/or anxiety associated with alcoholism or organic disease, and psychotic depressive disorders with associated anxiety, including involutional depression and manic-depressive disorders. Symptoms of psychoneurosis that respond well to doxepin include anxiety, tension, depression, somatic symptoms and concerns, sleep disturbances, guilt, lack of energy, fear, apprehension, and worry.

For further information on treatment of major depression and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidality risks, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in the Tricyclic Antidepressants General Statement 28:16.04.28.

■ **Chronic Idiopathic Urticaria** Doxepin also has been effective in the management of chronic idiopathic urticaria and may be used as an alternative to antihistamines, which generally are considered as first-line therapy in patients with this condition.

Dosage and Administration

■ **Administration** Doxepin hydrochloride is administered orally. Although doxepin has been administered in up to 3 divided doses throughout the day, it is long-acting and the entire daily dose may be administered at one time. Administration of the entire daily dose at bedtime may reduce daytime sedation.

Each dose of the oral concentrate should be diluted with approximately 120 mL of water, whole or skimmed milk, or orange, grapefruit, tomato, prune, or pineapple juice just prior to administration; the solution is physically incompatible with many carbonated beverages. For patients requiring doxepin therapy while on methadone maintenance, doxepin solution and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water, but not with grape juice. Bulk dilution and storage are not recommended by the manufacturers.

Doxepin is applied topically to the skin as an antipruritic. (See Doxepin Hydrochloride 84:08.)

■ **Dosage** Dosage of doxepin hydrochloride is expressed in terms of doxepin. There is a wide range of dosage requirements, and dosage must be carefully individualized. Initial dosages should be low and generally range from 30–150 mg daily, depending on the severity of the condition being treated. Dosage may be gradually adjusted to the level which produces maximal therapeutic effect with minimal toxicity and may range up to 300 mg daily. The manufacturers state that dosages exceeding 300 mg daily rarely produce additional therapeutic benefits. Hospitalized patients under close supervision may generally be given higher dosages than outpatients. Patients with very mild symptomatology or organic brain syndrome should usually be given lower than average dosages and may obtain satisfactory improvement with 25–50 mg of doxepin daily. The manufacturers state that appropriate dosage in geriatric patients should be selected with caution, usually initiating therapy at the low end of the dosage range since decreased hepatic, renal, or cardiac function occurs more frequently in these patients.

When doxepin is administered as a single daily dose, the maximum daily dose recommended by the manufacturers is 150 mg. Commercially available 150-mg capsules of doxepin are intended for maintenance therapy only and are not recommended for initial therapy. Maximum antidepressant effects may not occur for 2 or more weeks after therapy is begun, although anxiolytic effects may develop more rapidly.

After symptoms are controlled, dosage should be gradually reduced to the lowest level which will maintain relief of symptoms. To avoid the possibility of precipitating withdrawal symptoms, doxepin should not be terminated abruptly in patients who have received high dosages for prolonged periods.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Cautions

Doxepin shares the pharmacologic actions and toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. Patients should be fully advised about the risks, especially suicidal thinking and behavior (suicidality), associated with tricyclic antidepressant therapy. For a complete discussion, see Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.

■ **Pediatric Precautions** Safety of doxepin in children younger than 12 years of age has not been established.

The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. Anyone considering the use of doxepin in a child or adolescent for any clinical use must therefore balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

■ **Lactation** Limited data indicate that doxepin and its active *N*-demethylated metabolite are distributed into milk. Sedation and serious respiratory depression were reported in a nursing infant whose mother was receiving 75 mg of doxepin daily; substantial concentrations of the active metabolite of the drug were detected in the infant's serum and urine. In addition, poor sucking and swallowing while nursing, drowsiness, muscle hypotonia, and vomiting were reported in a nursing infant whose mother was receiving 35 mg of doxepin daily. Because of the potential for serious adverse reactions to doxepin and/or its active metabolite in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Pharmacokinetics

■ **Absorption** The pharmacokinetics of doxepin have not been extensively studied, but the drug is well absorbed from the GI tract in animals. Peak plasma concentrations usually occur within 2 hours after oral administration of the drug.

■ **Distribution** Doxepin is highly bound to plasma proteins.

Limited data indicate that doxepin and its active *N*-demethylated metabolite are distributed into milk in concentrations reportedly ranging from about 30–140% and 10–115%, respectively, of those in maternal serum and that substantial concentrations of the active metabolite have been detected in the serum and urine of nursing infants whose mothers were receiving 75–150 mg of doxepin daily.

■ **Elimination** The plasma half-life of doxepin is 6–24.5 hours. The drug appears to be metabolized via the same pathways as are other tricyclic antidepressants; its *N*-demethylated metabolite is pharmacologically active.

Chemistry and Stability

■ **Chemistry** Doxepin hydrochloride is a dibenzoxepin-derivative tricyclic antidepressant. The drug occurs as a white powder, is freely soluble in water and in alcohol, and has a pK_a of 8. Doxepin hydrochloride oral concentrate has a pH of 4–7.
