■ **Stability** Doxepin hydrochloride capsules should be stored in tight, light-resistant containers at a temperature between 15–30°C and the oral concentrate should be stored at a temperature between 20–25°C. Commercially available doxepin hydrochloride capsules have an expiration date of 36 months and the oral concentrate has an expiration date of 24 months following the date of manufacture.

Doxepin hydrochloride oral concentrate is physically incompatible with many carbonated beverages, but is compatible with some other beverages. (See Dosage and Administration: Administration.) Bulk preparation and storage of dilutions of the commercially available oral concentrate are not recommended by the manufacturers.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of doxepin, see the Tricyclic Antidepressants General Statement 28:16.04.28.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Imipramine Hydrochloride
Imipramine Pamoate

■ Imipramine is a dibenzazepine-derivative tricyclic antidepressant.

Dosage and Administration

■ **Administration** Imipramine hydrochloride and imipramine pamoate are administered orally. Although imipramine hydrochloride has been administered in up to 4 divided doses throughout the day, it is long-acting and the entire oral daily dose may be administered at one time. Imipramine pamoate may also be used to administer the daily oral dose of imipramine, but it has no advantages over the hydrochloride. Administration of the entire daily dose at bedtime may reduce daytime sedation; patients who experience insomnia and stimulation may be given the entire daily dose in the morning.

■ **Dosage** Dosage of imipramine salts is expressed in terms of imipramine hydrochloride.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Major Depressive Disorder There is a wide range of oral dosage requirements, and dosage must be carefully individualized. Initial dosages of imipramine should be low and generally range from 75–100 mg daily, depending on the severity of the condition being treated. Dosage may be gradually adjusted to the level that produces maximal therapeutic effect with minimal toxicity and may range up to 300 mg daily. Hospitalized patients under close supervision may generally be given higher dosages than outpatients, and manufacturers state that dosages of greater than 200 mg daily are not recommended for outpatients. Geriatric patients should usually be given lower than average dosages. Manufacturers state that therapy should be initiated with 25–50 mg daily as imipramine hydrochloride (e.g., Tofranil®) in these patients and that optimal dosage rarely exceeds 100 mg daily. If the daily dosage is established at 75 mg or more, imipramine pamoate (e.g., Tofranil-PM®) may be administered. Maximum antidepressant effects may not occur for 2 or more weeks after therapy is begun.

After symptoms are controlled, dosage should be gradually reduced to the lowest level that will maintain relief of symptoms. If maintenance therapy is necessary, manufacturers recommend an adult dosage of 50–150 mg daily. To avoid the possibility of precipitating withdrawal symptoms, imipramine should not be terminated abruptly in patients who have received high dosage for prolonged periods.

Functional Enuresis in Children For the treatment of functional enuresis in children who are at least 6 years of age, the usual initial oral dosage of imipramine hydrochloride is 25 mg daily, administered 1 hour prior to bedtime. If a satisfactory response is not obtained within 1 week, dosage may be increased to 50 mg nightly for children younger than 12 years of age or 75 mg nightly for children 12 years of age and older. Dosages higher than 75 mg daily do not improve results and may increase the risk of adverse reactions. For children who are early-night bedwetters, better results may be obtained by administering 25 mg in midafternoon and again at bedtime. Dosage of imipramine hydrochloride for the treatment of functional enuresis in children should not exceed 2.5 mg/kg daily. Long-term effects of the drug in children have not been determined; therefore, after a satisfactory response has been maintained, imipramine hydrochloride should be gradually withdrawn. If dosage is gradually reduced after a favorable response of many weeks, relapses may be less frequent; children who relapse may not respond to subsequent treatment with imipramine. (See Cautions: Pediatric Precautions.)

Cautions

Imipramine shares the pharmacologic actions, uses, and toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. Patients should be fully advised about the risks, especially suicidal thinking and behavior (suicidality), associated with tricyclic antidepressant therapy. For a complete discussion, see Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.

Although the clinical importance is not known, ECG changes have been reported in pediatric patients receiving twice the recommended maximum daily dosage.

quently in patients receiving acamprosate than in those receiving placebo (2.4 versus 0.8%). Completed suicide occurred in 0.13% of patients receiving acamprosate in clinical studies and in 0.1% of those receiving placebo. While many of these events occurred in the context of alcohol relapse, a consistent pattern between recovery from alcoholism and the emergence of suicidality was not identified. These studies excluded patients with severe psychiatric impairment, and review of safety data did not show a difference in the incidence of adverse events designated as depression between those receiving acamprosate and those receiving placebo. The existence of a relationship between alcohol dependence, depression, and suicidality is well known.

Closely monitor patients for symptoms of depression and suicidal thinking.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Acamprosate is distributed into milk in rats; caution if used in nursing women.

Pediatric Use. Safety and efficacy not established in children younger than 18 years of age. Acamprosate has been evaluated in a limited number of adolescents 16–19 years of age.

Geriatric Use. Experience in those 65 years of age or older insufficient to determine whether they respond differently than younger adults.

Pharmacokinetics not evaluated in geriatric individuals. Because geriatric patients frequently have decreased renal function, plasma concentrations of acamprosate are expected to be higher in geriatric individuals than in younger adults. Select drug dosage carefully. Consider monitoring renal function.

Hepatic Impairment. Pharmacokinetics not altered in patients with mild or moderate hepatic impairment (Child-Pugh class A or B). Safety and pharmacokinetics not evaluated in patients with severe hepatic impairment.

Renal Impairment. Acamprosate is eliminated in urine as unchanged drug; clearance depends on renal function. Dosage adjustment recommended in patients with creatinine clearance of 30–50 mL/minute. (See Dosage and Administration: Special Populations.) Contraindicated in patients with creatinine clearance less than 30 mL/minute.

■ **Common Adverse Effects** Adverse effects reported in 5% or more of patients receiving acamprosate and more frequently than placebo include diarrhea and asthenia.

Drug Interactions

Safety profile in patients receiving acamprosate in conjunction with anxiolytics, hypnotics and sedatives (including benzodiazepines), or nonopiate analgesics in clinical studies was similar to that in patients receiving these drugs with placebo.

Alcohol. Pharmacokinetic interaction unlikely.

Antidepressants. Changes in weight (i.e., loss or gain) reported more frequently in patients receiving acamprosate concomitantly with an antidepressant than in patients receiving either agent alone.

No change in the pharmacokinetics of desipramine or imipramine.

Diazepam. Pharmacokinetic interaction unlikely.

Disulfiram. Pharmacokinetic interaction unlikely.

Naltrexone. Pharmacokinetic interaction (increased plasma concentrations of acamprosate; no change in plasma concentrations of naltrexone or its major metabolite, 6-β-naltrexol). No dosage adjustment recommended.

Description

Acamprosate calcium is a synthetic homotaurine derivative and is structurally related to γ-aminobutyric acid (GABA).

While the precise mechanism of action of acamprosate in the maintenance of abstinence from alcohol ingestion remains to be determined, the drug decreases glutamatergic transmission and modulates neuronal hyperexcitability during withdrawal from alcohol. Acamprosate reduces voluntary intake of alcohol in alcohol-dependent animals. Acamprosate did not exhibit anticonvulsant, antidepressant, or anxiolytic activity in animal studies. Administration of acamprosate was not associated with the development of tolerance or dependence in animal studies. Acamprosate is not known to cause alcohol aversion. Ingestion of alcohol by individuals receiving acamprosate therapy does not result in a disulfiram-like reaction.

Acamprosate is eliminated principally in urine as unchanged drug. The drug is not metabolized in the liver. Acamprosate does not induce cytochrome P-450 (CYP) isoenzymes 1A2 or 3A4, nor does it inhibit CYP isoenzymes 1A2, 2C9, 2C19, 2D6, 2E1, or 3A4.

Advice to Patients

Risk of psychomotor impairment; importance of exercising caution while driving or operating hazardous machinery until the effects of the drug on the individual are known.

Importance of continuing acamprosate as directed by their clinician, even in the event of a relapse. Importance of discussing any renewed use of alcohol with their clinician.

Advise patients that acamprosate helps maintain abstinence only when used as part of a treatment program that includes counseling and other supportive measures.

Risk of suicidality: importance of patients, families, and caregivers notifying clinicians of emergence of suicidality or symptoms of depression.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as any concomitant illnesses.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview[A] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Oral		
Tablets, delayed-release (enteric-coated)	333 mg	Campral®, Forest

Atomoxetine Hydrochloride

■ Atomoxetine is a selective norepinephrine-reuptake inhibitor.

Uses

Atomoxetine hydrochloride is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention-deficit hyperactivity disorder (ADHD).

■ **Attention Deficit Hyperactivity Disorder** Atomoxetine hydrochloride is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in adults and children 6 years of age and older. Efficacy of the drug for this indication was established in short-term (6–9 weeks) controlled clinical studies in children and adolescents 6–18 years of age and also in 10-week controlled clinical studies in adults who met DSM-IV criteria for ADHD. Efficacy of atomoxetine in the treatment of ADHD also was established in one longer-term (12 months) controlled clinical study in children and adolescents 6–15 years of age.

In controlled clinical studies in children 7–13 years of age with ADHD, therapy with atomoxetine (mean final dosage of 1.6 mg/kg daily, administered in 2 divided doses in the morning and late afternoon for 9 weeks) was more effective than placebo in decreasing inattention and hyperactive/impulsive symptoms, as measured by the ADHD Rating Scale-IV-Parent Version (ADHDRS), Clinical Global Impressions-ADHD-Severity (CGI-ADHD-S), and Conners Parent Rating Scale-Revised: Short Form (CPRS-R:S). In another controlled clinical study in children and adolescents 6–16 years of age with ADHD, therapy with atomoxetine (mean final dosage of 1.3 mg/kg once daily in the morning for 6 weeks) was more effective than placebo in decreasing inattention and hyperactive/impulsive symptoms, as measured by the ADHDRS, Conners Parent Rating Scale, and Conners Teacher Rating Scale.

In a randomized, placebo-controlled, dose-response study with atomoxetine (0.5, 1.2, or 1.8 mg/kg daily, administered in 2 divided doses in the morning and late afternoon for 8 weeks) in children and adolescents 8–18 years of age with ADHD, therapy with atomoxetine 1.2 or 1.8 mg/kg daily was more effective than placebo in decreasing inattention and hyperactive/impulsive symptoms, as measured by the ADHDRS, and improving social and family functioning, as measured by the Child Health Questionnaire (CHQ). Patients receiving atomoxetine 0.5 mg/kg daily exhibited responses intermediate to those observed in patients receiving placebo or atomoxetine at higher dosages (1.2 or 1.8 mg/kg daily), but no differences in response were observed between patients receiving dosages of 1.2 versus 1.8 mg/kg daily.

In an open-label, multicenter study in boys 7–15 years of age and girls 7–9 years of age with ADHD, therapy with atomoxetine (up to 2 mg/kg daily, administered in 2 divided doses in the morning and late afternoon) or methylphenidate (up to 60 mg daily, administered once daily or in 2 or 3 divided doses) for 10 weeks produced similar results in the reduction of ADHD symptoms; however, double-blind clinical studies are needed to establish the comparative efficacy and tolerance of these therapies.

In a randomized, double-blind, placebo-controlled maintenance study, 604 children and adolescents 6–15 years of age with ADHD initially received open-label atomoxetine (1.2–1.8 mg/kg daily in 2 divided doses) for 10 weeks. Patients who responded to therapy during the open-label phase were randomized at week 12 to receive either atomoxetine (at the same dosage) or placebo for an additional 9 months. At study end point, relapse (defined as an increase in ADHDRS total score to 90% of baseline score *and* an increase of 2 or more

points on the CGI-S scale) occurred in fewer patients receiving atomoxetine compared with those receiving placebo (22 versus 38%). When the more-sensitive secondary definition of relapse (an increase in ADHDRS total score to 50% of baseline score *and* an increase of 2 or more points on the CGI-S scale) was used, the relapse rate also was substantially lower in atomoxetine-treated patients (28%) than in placebo-treated patients (48%). In addition, patients who continued receiving atomoxetine experienced a longer time to relapse and achieved superior psychosocial functioning compared to those receiving placebo.

In controlled clinical studies in adults with ADHD, therapy with atomoxetine (mean final dosage of 95 mg daily, administered in 2 equally divided doses in the morning and late afternoon/early evening for 10 weeks) was more effective than placebo in decreasing inattention and hyperactive/impulsive symptoms, as measured by the Conners Adult ADHD Rating Scale (CAARS).

Dosage and Administration

■ **Administration** Atomoxetine hydrochloride may be administered orally once daily in the morning or in 2 equally divided doses in the morning and late afternoon/early evening. The drug may be administered without regard to meals.

The manufacturer states that atomoxetine is an ocular irritant; therefore, the capsules should be swallowed whole and should not be broken or opened, nor should the capsule contents be sprinkled on food.

■ **Dosage** Dosage of atomoxetine hydrochloride is expressed in terms of atomoxetine.

The usual initial dosage of atomoxetine in adults or in children and adolescents weighing more than 70 kg is 40 mg daily; dosage may be increased after a minimum of 3 days to a target dosage of approximately 80 mg daily. If an optimum response has not been achieved after 2–4 additional weeks of therapy, dosage may be increased to a maximum of 100 mg daily; dosages exceeding 100 mg daily have not been shown in clinical trials to result in additional therapeutic benefit. In adults or in children and adolescents weighing more than 70 kg, if atomoxetine is used concomitantly with potent inhibitors of the cytochrome P-450 2D6 (CYP2D6) isoenzyme (e.g., paroxetine, fluoxetine, quinidine) or in patients with poor metabolizer phenotypes of the CYP2D6 isoenzyme, the initial atomoxetine dosage should be 40 mg daily and dosage should be increased to the usual target dosage of 80 mg daily only if ADHD symptoms fail to improve after 4 weeks of therapy and the initial dosage is well tolerated. The maximum recommended dosage of atomoxetine in adults or in children and adolescents weighing more than 70 kg is 100 mg daily. The safety of single doses exceeding 120 mg and total daily dosages exceeding 150 mg has not been established.

The usual initial dosage of atomoxetine in children and adolescents weighing 70 kg or less is approximately 0.5 mg/kg daily; dosage may be increased after a minimum of 3 days to a target dosage of approximately 1.2 mg/kg daily. In children and adolescents weighing 70 kg or less, if atomoxetine is used concomitantly with potent CYP2D6 inhibitors (e.g., paroxetine, fluoxetine, quinidine) or in patients with poor metabolizer phenotypes of the CYP2D6 isoenzyme, the initial atomoxetine dosage should be 0.5 mg/kg daily and dosage should be increased to the usual target dosage of 1.2 mg/kg daily only if ADHD symptoms fail to improve after 4 weeks of therapy and the initial dosage is well tolerated. Daily dosage of atomoxetine in children and adolescents weighing 70 kg or less should not exceed 100 mg or 1.4 mg/kg, whichever is less; dosages exceeding 1.2 mg/kg daily have not been shown in clinical trials to result in additional therapeutic benefit.

Because the effectiveness of atomoxetine for long-term use (i.e., more than 12 months in children and adolescents 6–15 years of age, more than 9 weeks in those 16–18 years of age, and more than 10 weeks in adults) has not been established, patients receiving atomoxetine for extended periods should be periodically reevaluated to assess the long-term usefulness of the drug.

Atomoxetine may be discontinued without tapering the dosage.

■ **Special Populations** The manufacturer recommends that usual initial and target dosages of atomoxetine be reduced by 50% in patients with moderate hepatic impairment (Child-Pugh class B) and by 75% in those with severe hepatic impairment (Child-Pugh class C).

Cautions

■ **Contraindications** Known hypersensitivity to atomoxetine or any ingredient in the formulation.

The manufacturer states that atomoxetine is contraindicated in patients currently receiving or having recently received (i.e., within 2 weeks) monoamine oxidase (MAO) inhibitor therapy. In addition, at least 2 weeks should elapse after discontinuing atomoxetine before initiating MAO inhibitor therapy. Severe, potentially fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) have been reported in patients receiving other drugs that affect brain monoamine concentrations concomitantly with MAO inhibitor therapy.

The manufacturer also states that atomoxetine should not be used in patients with angle-closure glaucoma, since the drug was associated with an increased risk of mydriasis in some patients during controlled clinical trials.

■ **Warnings/Precautions** ***Warnings*** **Suicidality Risk.** Atomoxetine may increase the risk of suicidal ideation in children and adolescents with attention deficit hyperactivity disorder (ADHD). (See Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions.) Pediatric patients should be closely monitored for clinical worsening, suicidality (suicidal ideation or behaviors), or unusual changes in behavior, particularly during the first few months after initiation of therapy and during periods of dosage adjustments. Monitoring should include daily observation by family members and caregivers and frequent contact with the prescribing clinician, particularly if the patient's behavior changes or is a concern. The manufacturer recommends face-to-face contact between clinicians and patients or their family members or caregivers at least weekly during the first 4 weeks of therapy and then every other week for the next 4 weeks, with subsequent face-to-face contact at 12 weeks and as clinically indicated thereafter; additional contact via telephone may be appropriate between visits.

Discontinuance of therapy should be considered in patients with emergent suicidality or manifestations that may be precursors to emerging suicidality (e.g., anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, mania), particularly if such manifestations are severe or abrupt in onset or were not part of the patient's presenting symptoms.

Sensitivity Reactions Allergic reactions, including angioedema, urticaria, and rash, have been reported rarely in patients receiving atomoxetine.

Other Warnings and Precautions **Severe Hepatic Injury.** Severe hepatic injury was reported during postmarketing surveillance in 2 patients (an adolescent and an adult) who had received atomoxetine for several months. In one patient, hepatic injury was manifested by increased hepatic enzymes (up to 40 times the upper limit of normal [ULN]) and jaundice (bilirubin up to 12 times the ULN); manifestations recurred upon rechallenge with atomoxetine and resolved upon discontinuance of the drug, providing evidence that the hepatic injury was caused by atomoxetine. Both patients recovered and did not require liver transplantation. However, the manufacturer notes that severe drug-related hepatic injury may progress to acute hepatic failure resulting in death or requiring liver transplantation in a small percentage of patients. The actual incidence of hepatic injury in patients receiving atomoxetine is unknown because of possible underreporting of postmarketing adverse effects.

Adverse hepatic effects may occur several months after initiation of atomoxetine, and laboratory abnormalities may continue to worsen for several weeks after discontinuance of the drug. Hepatic enzyme concentrations should be determined after the first manifestation of hepatic dysfunction (e.g., pruritus, dark urine, jaundice, right upper quadrant tenderness, unexplained flu-like symptoms) in patients receiving atomoxetine. Atomoxetine should be discontinued in patients with jaundice or laboratory evidence of hepatic injury, and therapy with the drug should *not* be reinitiated in such patients.

Sudden Death and Serious Cardiovascular Events. Although a causal relationship to atomoxetine has not been established, sudden unexplained death, stroke, and myocardial infarction have been reported in adults receiving usual dosages of atomoxetine for the treatment of ADHD. Sudden unexplained death also has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of atomoxetine. Children, adolescents, and adults who are being considered for atomoxetine therapy should undergo a thorough medical history review (including evaluation for a family history of sudden death or ventricular arrhythmia) and physical examination to detect the presence of cardiac disease, and should receive further cardiac evaluation (e.g., ECG, echocardiogram) if initial findings suggest such disease. Although some serious cardiac conditions are independently associated with an increased risk of sudden death, atomoxetine generally should *not* be used in children, adolescents, or adults with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious cardiac conditions. Patients who develop exertional chest pain, unexplained syncope, or other manifestations suggestive of cardiac disease during atomoxetine therapy should undergo prompt cardiac evaluation.

For further information on screening for cardiac conditions, selecting appropriate candidates for stimulant therapy, and monitoring for treatment-emergent cardiac conditions, see Cardiovascular Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.

Psychiatric Effects. Atomoxetine should be used with caution in the management of ADHD in patients with comorbid bipolar disorder because of the potential for precipitation of mixed or manic episodes in such patients. Prior to initiating atomoxetine therapy, patients with ADHD and comorbid depressive symptoms should be carefully screened to determine if they are at risk for bipolar disorder; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, or depression).

Psychotic or manic symptoms (e.g., hallucinations, delusional thinking, mania) have been reported in children and adolescents without prior history of psychotic illness or mania who received usual dosages of atomoxetine. In a pooled analysis of multiple short-term, placebo-controlled studies, such symptoms occurred in about 0.2% of patients receiving usual dosages of atomoxetine compared with 0% of those receiving placebo. If psychotic or manic symptoms occur, a causal relationship to atomoxetine should be considered, and discontinuance of therapy may be appropriate.

Cardiovascular Effects. Increased blood pressure and heart rate were reported in children, adolescents, and adults receiving atomoxetine in controlled clinical studies. The drug should be used with caution in patients with hyper-

tension, tachycardia, or cardiovascular or cerebrovascular disease that might be affected by increases in blood pressure or heart rate. Blood pressure and pulse rate should be measured before initiation of atomoxetine, following any increase in dosage, and periodically during therapy.

Orthostatic hypotension and syncope also were reported in patients receiving atomoxetine in controlled clinical studies. The drug should be used with caution in patients with conditions that would predispose them to hypotension.

Peripheral Vascular Effects. Exacerbation or precipitation of Raynaud's phenomenon was reported during postmarketing surveillance in patients receiving atomoxetine.

Genitourinary Effects. Urinary retention and urinary hesitation were reported in adults receiving atomoxetine in controlled clinical studies.

Growth Effects. Temporary suppression of normal weight and height patterns has been observed in pediatric patients receiving atomoxetine therapy. Gains in weight and height generally lag behind predicted population values for about the first 9–12 months of therapy; however, weight and height gains rebound with continued treatment. Similar growth patterns have been observed regardless of metabolizer phenotype (poor or extensive metabolizer of the drug) or pubertal status upon initiation of treatment. The manufacturer states that growth should be monitored in patients receiving therapy with atomoxetine.

Children and adolescents 6–18 years of age receiving atomoxetine for up to 9 weeks in controlled clinical studies had an average weight loss of 0.4 kg compared with an average weight gain of 1.5 kg in those receiving placebo for the same time period; similar rates of weight loss have been reported in other controlled clinical studies with the drug. In one clinical trial, decreases in body weight of at least 3.5% occurred in 7–29% of patients receiving atomoxetine at various dosages, compared with 1.3% of patients receiving placebo. However, in patients receiving atomoxetine for 3 years, weight increased by an average of 17.9 kg (0.5 kg more than predicted by baseline data) and height increased by an average of 19.4 cm (0.4 cm less than predicted by baseline data) at 3 years. Gain in height stabilized at about 12 months.

Behavioral Effects. Aggressive behavior and hostility frequently are observed in pediatric patients with ADHD and have been reported in patients receiving drug therapy (including atomoxetine) for the disorder. In controlled clinical studies in pediatric patients, aggressive behavior or hostility was reported slightly (overall risk ratio of 1.33), but not significantly, more frequently in those receiving atomoxetine compared with those receiving placebo. Patients beginning treatment for ADHD should be monitored for the onset or worsening of aggressive behavior or hostility.

Priapism. Priapism was reported rarely during postmarketing surveillance in pediatric and adult patients receiving atomoxetine; if priapism is suspected, prompt medical attention is required. (See Advice to Patients.)

Tics. In a controlled study, atomoxetine did not worsen tics in patients with ADHD and comorbid Tourette's disorder.

Specific Populations **Pregnancy.** Category C. (See Users Guide.)

Lactation. Atomoxetine and/or its metabolites are distributed into milk in rats; it is not known whether the drug is distributed into milk in humans. Therefore, atomoxetine should be used with caution in nursing women.

Pediatric Use. Safety and efficacy of atomoxetine have not been established in children younger than 6 years of age.

Atomoxetine may increase the risk of suicidal ideation in children and adolescents with ADHD. In a pooled analysis of 12 short-term controlled clinical studies in pediatric patients with ADHD (11 studies) or enuresis (1 study), the risk of suicidal ideation was about 0.4% in those receiving atomoxetine versus 0% in those receiving placebo. One child receiving the drug attempted suicide; no completed suicides were reported. All events representing suicidal behavior or thinking occurred in children 12 years of age or younger and occurred during the first month of therapy. It is not known whether the risk of suicidal ideation in pediatric patients extends to long-term use of the drug. A similar analysis of data from adults with ADHD or major depressive disorder found no increased risk of suicidal ideation or behavior in those receiving atomoxetine. The potential risks of suicidality should be weighed against the clinical need for the drug prior to initiating atomoxetine therapy in children or adolescents. (See Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Sudden death has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of stimulants. (See Sudden Death and Serious Cardiovascular Events under Warnings/Precautions: Other Warnings and Precautions, in Cautions.)

Temporary suppression of normal weight and/or height patterns has been reported during the first 9–12 months of atomoxetine therapy; however, weight and height gains have rebounded with continued treatment. (See Growth Effects under Warnings/Precautions: Other Warnings and Precautions, in Cautions.) The growth of pediatric patients receiving atomoxetine should be monitored.

Geriatric Use. Safety and efficacy of atomoxetine have not been established in geriatric patients.

Hepatic Impairment. Systemic exposure to atomoxetine concentrations is increased twofold in patients with moderate hepatic impairment (Child-Pugh class B) and fourfold in those with severe hepatic impairment (Child-Pugh class C). (See Dosage and Administration: Special Populations.)

■ **Common Adverse Effects** Abdominal pain, decreased appetite, vomiting, somnolence, hubsea, fatigue, irritability, and dizziness each occurred in 5% or more of children and adolescents receiving atomoxetine in controlled clinical studies and were at least twice as frequent in patients receiving the drug as in those receiving placebo. Dry mouth, nausea, insomnia, decreased appetite, constipation, fatigue, erectile dysfunction, hot flush, urinary disorders (urinary hesitation, urinary retention), and dysmenorrhea each occurred in 5% or more of adults receiving atomoxetine in controlled clinical studies and were at least twice as frequent in patients receiving the drug as in those receiving placebo.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes** Potential pharmacokinetic interaction (decreased metabolism of atomoxetine) when atomoxetine is used concomitantly with drugs that inhibit the activity of the cytochrome P-450 2D6 (CYP2D6) isoenzyme. Inhibitors of CYP2D6 may increase plasma concentrations of atomoxetine in patients with the extensive-metabolizer phenotype to such an extent that plasma concentrations of the drug are similar to those achieved in poor metabolizers. When atomoxetine is used concomitantly with potent CYP2D6 inhibitors (e.g., paroxetine, fluoxetine, quinidine), or in patients with poor-metabolizer phenotypes of the CYP2D6 isoenzyme, the manufacturer states that dosage adjustment of atomoxetine should be considered. (See Dosage and Administration: Dosage.) However, in vitro studies suggest that concomitant use of atomoxetine with CYP2D6 inhibitors will not increase plasma concentrations of atomoxetine in patients with the poor-metabolizer phenotype.

■ **Drugs Metabolized by Hepatic Microsomal Enzymes** Pharmacokinetic interaction unlikely; evidence to date suggests that atomoxetine does not cause clinically important inhibition or induction of cytochrome P-450 enzymes, including CYP1A2, CYP3A, CYP2D6, and CYP2C9.

■ **GI Drugs** No important pharmacokinetic interactions reported with drugs that increase gastric pH (e.g., antacids containing magnesium hydroxide and aluminum hydroxide, omeprazole).

■ **Protein-bound Drugs** Pharmacokinetic interaction unlikely. In vitro studies indicate that atomoxetine is not displaced from binding sites by, and does not displace from binding sites, other highly protein-bound drugs (e.g., warfarin, aspirin, phenytoin, diazepam) in therapeutic concentrations.

■ **Alcohol** No change in the intoxicating effects of alcohol when alcohol was ingested by individuals receiving atomoxetine.

■ **β-Adrenergic Agonists** Potential pharmacologic interaction (increased cardiovascular effects [e.g., increased heart rate and blood pressure]) when atomoxetine is used concomitantly with oral or parenteral β_2-adrenergic agonists (e.g., albuterol). Use with caution.

■ **Cardiovascular Agents** Potential pharmacologic interaction (increased hypertensive effects) with concomitant use of pressor agents (e.g., dopamine, dobutamine) and atomoxetine. Use with caution.

■ **Methylphenidate** No increase in cardiovascular effects with concomitant use of methylphenidate and atomoxetine relative to use of methylphenidate alone.

■ **Monoamine Oxidase Inhibitors** Potential pharmacologic interaction (inhibition of catecholamine metabolism). (See Cautions: Contraindications.)

Description

Atomoxetine is a selective norepinephrine-reuptake inhibitor. Atomoxetine is not considered a stimulant and also is structurally unrelated to other agents used for the treatment of attention deficit hyperactivity disorder (ADHD). The exact mechanism(s) of action of atomoxetine in the management of ADHD has not been fully elucidated but, based on in vitro studies, appears to be related to selective inhibition of the presynaptic norepinephrine transporter; the drug appears to have minimal affinity for other noradrenergic receptors or for other neurotransmitter transporters or receptors.

Atomoxetine is readily absorbed following oral administration. The drug is approximately 98% bound to plasma proteins, principally albumin, at therapeutic concentrations. Atomoxetine is metabolized principally via oxidation by the cytochrome P-450 2D6 (CYP2D6) isoenzyme and subsequent glucuronidation. Individuals who extensively metabolize atomoxetine via the CYP2D6 pathway exhibit the extensive-metabolizer phenotype, while those who have an impaired ability to metabolize the drug by this pathway exhibit the poor-metabolizer phenotype. In patients with the poor-metabolizer phenotype (about 7% of Caucasians and 2% of African-Americans), metabolic clearance of atomoxetine may be decreased; a fivefold increase in peak plasma concentrations of atomoxetine and a tenfold increase in area under the plasma concentration-time curve (AUC) have been reported in individuals with the poor-metabolizer phenotype relative to those with the extensive-metabolizer phenotype. The mean elimination half-life of atomoxetine is 5.2 or 21.6 hours in extensive or poor metabolizers, respectively. Atomoxetine does not inhibit or induce CYP2D6.

Advice to Patients

Importance of providing patient or caregiver with a copy of the manufacturer's patient information (medication guide); discuss and answer questions about its contents (e.g., benefits and risks of atomoxetine therapy, appropriate use) as needed. Importance of instructing the patient or caregiver to read and

understand the contents of the medication guide before initiating therapy and each time the prescription is refilled.

Risk of suicidal thinking. Importance of patients, caregivers, and family members immediately informing clinician if clinical worsening, anxiety, agitation, panic attacks, insomnia, irritability, aggressive behaviors, hostility, impulsivity, restlessness, mania, depression, suicidal ideation or behaviors, or unusual changes in behavior occur, particularly during the first few months after initiation of therapy or following dosage adjustments.

Patients and/or caregivers should be advised that hepatic dysfunction may develop rarely. Importance of informing clinician immediately if symptoms of hepatic injury occur (e.g., pruritus, jaundice, dark urine, upper right-sided abdominal tenderness, unexplained flu-like symptoms).

Importance of informing clinician immediately if adverse cardiovascular effects (e.g., chest pain, shortness of breath, fainting) occur.

Importance of informing clinician immediately if precipitation of psychotic (e.g., hallucinations, delusional thinking) or manic symptoms occurs.

Importance of exercising caution when driving or operating machinery until the effects of the drug on the individual are known.

Risk of priapism. Importance of seeking immediate medical attention if an erection persists for more than 4 hours.

Importance of taking atomoxetine exactly as prescribed. If a patient misses a dose of the drug, the missed dose should be taken as soon as it is remembered, but the amount of atomoxetine taken within a 24-hour period should not exceed the prescribed total daily dosage of the drug.

Importance of advising patient and/or caregivers that atomoxetine capsules should not be opened because the drug is an ocular irritant; if eye contact occurs, flush the affected eye(s) with water immediately, obtain medical advice, and wash hands and potentially contaminated surfaces as soon as possible.

Importance of informing clinician of any history of physical or mental disorders (e.g., cardiovascular disease, liver disease, depression).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, dietary supplements, and herbal products, as well as any concomitant illnesses/conditions (e.g., glaucoma, suicidal ideation or behaviors, cardiac/cardiovascular disease, mental/psychiatric disorder, hepatic disease).

Importance of informing patients and/or caregivers of other important precautionary information. (See Cautions.)

Overview[a] (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Flumazenil

■ Flumazenil, a 1,4-imidazobenzodiazepine derivative, is a benzodiazepine antagonist.

Uses

Flumazenil is used in adults for the complete or partial reversal of benzodiazepine-induced sedation when benzodiazepines are used for induction or maintenance of general anesthesia or for diagnostic or therapeutic procedures (i.e., conscious sedation) and for the management of benzodiazepine intoxication. Flumazenil also is used in children 1–17 years of age for the reversal of benzodiazepine-induced sedation when benzodiazepines are used for diagnostic or therapeutic procedures. The manufacturer states that the safety and efficacy of flumazenil have *not* been established in pediatric patients for reversal of benzodiazepine-induced sedation when benzodiazepines are used for induction of general anesthesia, for the management of benzodiazepine intoxication, nor for the resuscitation of neonates. (See Special Populations: Pediatric Use.)

■ **Reversal of General Anesthesia** Flumazenil has been shown to be effective in reversing sedation and restoring psychomotor function in adults who received midazolam for induction or maintenance of general anesthesia. Efficacy was established in 4 clinical studies in adults who received 5–80 mg of midazolam alone or in conjunction with skeletal muscle relaxants, nitrous oxide, regional or local anesthetics, opiates, and/or inhalational anesthetics. A 0.2-mg dose of flumazenil was administered, followed by additional 0.2-mg doses as needed to reach a complete response (up to a maximum of 1 mg). In these studies, 81% of patients became completely alert or remained only slightly drowsy following total flumazenil doses of 0.4–0.6 mg (36%) or 0.8–1 mg (64%). However, resedation occurred in 10–15% of patients who responded to flumazenil. (See Warnings: Resedation.) Flumazenil failed to restore memory completely as tested by picture recall. In addition, flumazenil was not as effective in the reversal of sedation in patients who received multiple anesthetic agents in addition to benzodiazepines.

■ **Reversal of Conscious Sedation** Flumazenil has been shown to be effective in reversing the sedative and psychomotor effects of benzodiazepines when these drugs are used for diagnostic or therapeutic procedures but was less effective in completely and consistently reversing benzodiazepine-induced amnesia. Efficacy was established in 4 clinical studies in adults who received an average of 30 mg of diazepam or 10 mg of midazolam for sedation (with or without an opiate) for both inpatient and outpatient diagnostic or surgical procedures. Flumazenil was administered as an initial dose of 0.4 mg (2 doses of 0.2 mg each), with additional 0.2-mg doses administered as needed to achieve complete awakening, up to a maximum of 1 mg. In these studies, 78% of patients receiving flumazenil achieved complete consciousness, but approximately 50% of these patients required 2–3 additional doses of the drug in order to achieve this level of consciousness. In addition, while most patients remained alert throughout the 3-hour postprocedure observation period, resedation occurred in 3–9% of these patients.

Pediatric Considerations The safety and efficacy of flumazenil for the reversal of benzodiazepine-induced conscious sedation have been established in children 1 year of age and older. In one uncontrolled clinical trial involving 107 children 1–17 years of age who had received midazolam for conscious sedation, flumazenil was administered at doses of 0.01 mg/kg (maximum of 0.2 mg) up to a maximum of 5 doses or a total dose of 1 mg. In this study, 56% of the children achieved complete consciousness within 10 minutes of flumazenil administration, but 51% of them required the maximum number of doses of the drug allowed for initial treatment in order to achieve this level of consciousness. In addition, approximately 12% of the patients (all of whom were 1–5 years of age) who achieved complete consciousness following flumazenil administration experienced resedation within 19–50 minutes of initial administration of the drug. Episodes of resedation were reversed by additional doses of flumazenil. However, the manufacturer states that the safety and efficacy of repeated flumazenil administration in pediatric patients experiencing resedation have *not* been established.

■ **Benzodiazepine Overdosage** Flumazenil is used in adults for the management of benzodiazepine overdosage. The drug is an adjunct to, not a replacement for, appropriate supportive and symptomatic measures (e.g., ventilatory and circulatory support) in the management of benzodiazepine overdosage. Because patients admitted to hospitals for drug overdoses may have ingested multiple substances and/or are being treated for concomitant illnesses (e.g., depression, substance abuse), the presence of contraindications or precautions, which may limit the use of flumazenil therapy, should be considered. (See Contraindications under Warnings/Precautions, in Cautions.) Flumazenil has no known benefit other than reversal of benzodiazepine-induced sedation in seriously ill patients with multiple-drug overdosage, and the drug should *not* be used in cases where seizures (from any cause) are likely. In addition, the manufacturer warns that flumazenil should *not* be used in patients with serious cyclic depressant overdosage. (See Drug Interactions: Cyclic Antidepressants.) For information on the pathogenesis, manifestations, and treatment of benzodiazepine overdosage, see Acute Toxicity in the Benzodiazepines General Statement 28:24.08.

Efficacy of flumazenil has been established in 2 studies in patients who were presumed to have taken an overdose of a benzodiazepine, either alone or in combination with a variety of other agents. In these studies, of patients who were proven to have taken a benzodiazepine, 80% of those who received flumazenil responded with an improvement in level of consciousness. Of those who responded to flumazenil, 75% responded to a total dose of 1–3 mg. However, reversal of sedation was associated with an increased frequency of symptoms of CNS excitation, and 1–3% of patients who received flumazenil were treated for agitation or anxiety.

■ **Other Uses** The manufacturer states that the safety and efficacy of flumazenil for the treatment of benzodiazepine dependence or for the management of protracted benzodiazepine abstinence syndrome have not been established and therefore such use currently is not recommended.

Dosage and Administration

■ **General** Flumazenil is administered by rapid (over 15–30 seconds) IV injection through a freely flowing IV infusion into a large vein. Because of the risk of local irritation, the drug is recommended for IV use only, and extravasation into perivascular tissues should be avoided. Patients should have a secure airway and established IV access prior to administration of the drug.

Phenytoin appears to be distributed into milk in small amounts.

■ **Elimination** Following oral administration, the plasma half-life of phenytoin averages about 22 hours, although the half-life has ranged from 7–42 hours in individual patients. The plasma half-life of phenytoin in humans following IV administration ranges from 10–15 hours.

The major route of metabolism of phenytoin is oxidation by the liver to the inactive metabolite 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (HPPH). Because this metabolism is a saturable process, small increases in dosage may produce substantial increases in plasma phenytoin concentrations; the steady-state plasma concentration may double or triple from a 10% or more increase in dosage, possibly resulting in toxicity. HPPH undergoes enterohepatic circulation and is excreted in urine via glomerular filtration and tubular secretion, mainly as the glucuronide. Approximately 60–75% of the daily dose of the drug is excreted in this form. Other minor metabolites also appear in urine. In therapeutic doses, approximately 1% is excreted unchanged in urine; in toxic doses, up to 10% of the ingested drug may be excreted unchanged by the kidneys.

Following equal doses of phenytoin, total plasma phenytoin concentrations are lower in chronic uremic patients than in non-uremic patients which suggests an altered metabolic disposition of the drug in patients with uremia.

Chemistry and Stability

■ **Chemistry** Phenytoin is a hydantoin-derivative anticonvulsant. Phenytoin occurs as a white powder and is practically insoluble in water, soluble in hot alcohol, and slightly soluble in cold alcohol. The drug has an apparent pK_a of 8.06–8.33. Phenytoin sodium occurs as a white, hygroscopic powder and is freely soluble in water, soluble in alcohol, and freely soluble in warm propylene glycol.

Aqueous solutions of phenytoin sodium gradually absorb carbon dioxide, and the drug undergoes partial hydrolysis to phenytoin, resulting in turbid solutions. The drug is more stable in propylene glycol. Commercially available phenytoin sodium injection is a sterile solution of the drug containing 40% propylene glycol and 10% alcohol in water for injection. Sodium hydroxide is added during manufacture of the injection to adjust the pH to 12. Each 100-mg phenytoin sodium capsule contains approximately 0.35 mEq of sodium, and phenytoin sodium injection contains about 0.2 mEq of sodium per mL.

Extended phenytoin sodium capsules are formulated so that they undergo slower dissolution with more prolonged absorption than prompt phenytoin sodium capsules.

■ **Stability** Commercially available phenytoin oral suspension and tablets, and extended and prompt phenytoin sodium capsules generally should be stored in tight containers at a room temperature less than 30°C, although one manufacturer recommends storage of their extended phenytoin sodium capsules (Phenytek®) at controlled room temperatures of 15–30°C; the extended capsules should be protected from light and moisture and the oral suspension should be protected from freezing and light. Phenytoin sodium injection should be stored at 15–30°C; freezing should be avoided. A precipitate may form if the injection is refrigerated or frozen; however, this will dissolve after warming to room temperature. Slight yellowish discoloration of the injection will not affect potency or efficacy, but the injection should not be used if the solution is not clear or if a precipitate is present. Precipitation of free phenytoin will occur at a pH of 11.5 or less.

Phenytoin sodium injection is physically and/or chemically incompatible with some drugs, but the compatibility depends on several factors (e.g., concentrations of the drugs, specific diluents used, resulting pH, temperature). Specialized references should be consulted for specific compatibility information.

For further information on chemistry and stability, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of phenytoin, see the Anticonvulsants General Statement 28:12.

ANTICONVULSANTS, MISCELLANEOUS 28:12.92

Carbamazepine

■ Carbamazepine is an iminostilbene derivative that is used as both an anticonvulsant and for the relief of pain associated with trigeminal neuralgia (tic douloureux) as well as for various psychiatric disorders.

Uses

■ **Seizure Disorders** Carbamazepine is used in adults and children in the prophylactic management of partial seizures with complex symptomatology (psychomotor or temporal lobe seizures), generalized tonic-clonic (grand mal) seizures, and mixed seizure patterns that include partial seizures with complex symptomatology, generalized tonic-clonic seizures, or other partial or generalized seizures. Patients with partial seizures with complex symptomatology appear to show greater improvement during carbamazepine therapy than patients with other types of seizures. Although the drug is useful in the management of mixed seizures, the response in patients with mixed seizures may be variable. The drug is ineffective in the management of absence (petit mal) seizures or myoclonic and akinetic seizures.

Carbamazepine may be administered concomitantly with other anticonvulsants such as phenytoin, phenobarbital, or primidone. However, the drug should be administered with caution in conjunction with those anticonvulsants that produce toxic effects similar to carbamazepine such as phenacemide (no longer commercially available in the US), mephenytoin, or trimethadione or paramethadione (both no longer commercially available in the US).

■ **Neuropathic Pain** Carbamazepine is used in the symptomatic treatment of pain associated with true trigeminal neuralgia. *Carbamazepine is not a simple analgesic and should not be administered casually for relief of trivial facial pain.* Although some patients with glossopharyngeal neuralgia may respond to carbamazepine, the drug usually does not provide relief in facial pain from causes other than trigeminal neuralgia. Some patients with trigeminal neuralgia who did not respond to carbamazepine have been successfully treated with combined carbamazepine-phenytoin therapy.

Like certain other anticonvulsants, carbamazepine also has been used for the symptomatic treatment of chronic pain arising from other peripheral neuropathic syndromes†, including pain of diabetic neuropathy†. (See Uses: Neuropathic Pain, in the Anticonvulsants General Statement 28:12.)

■ **Schizophrenia** Carbamazepine has been used in the symptomatic management of the acute phase of schizophrenia† as an adjunct to therapy with an antipsychotic agent in patients who fail to respond to an adequate trial of the antipsychotic agent alone. For adjunctive therapy with an antipsychotic agent, carbamazepine generally is administered at the same range in dosage and therapeutic plasma concentrations as in the management of seizure disorders and bipolar disorder. The American Psychiatric Association (APA) states that, with the exception of schizophrenic patients whose illness has strong affective components, carbamazepine therapy *alone* (i.e., monotherapy rather than adjunctive therapy) has not been shown to be substantially effective in the long-term treatment of schizophrenia. For additional information on the management of schizophrenia, see Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ **Bipolar Disorder** Carbamazepine has been used alone or in combination with other drugs (e.g., antipsychotic agents) for the treatment and prevention of acute manic or mixed episodes in patients with bipolar disorder. However, results of clinical studies of the drug in the management of bipolar disorder have been inconsistent, and the APA currently recommends that carbamazepine be reserved for patients unable to tolerate or who had an inadequate therapeutic response to lithium and valproate (e.g., valproic acid, divalproex). For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

■ **Other Uses** Carbamazepine has been used for the management of aggression (e.g., uncontrolled rage outbursts) and/or loss of control (dyscontrol) in patients with or without an underlying seizure disorder (e.g., as features of intermittent explosive disorder, conduct disorder, antisocial personality disorder, borderline personality disorder, dementia)†, alcohol withdrawal syndrome†, relief of neurogenic pain and/or control of seizures in a variety of conditions including "lightning" pains of tabes dorsalis†, pain and control of paroxysmal symptoms of multiple sclerosis†, paroxysmal kinesigenic choreoathetosis†, Klüver-Bucy syndrome†, post-hypoxic action myoclonus†, acute idiopathic polyneuritis (Landry-Guillain-Barré syndrome)†, pain of posttraumatic paresthesia†, and, in children, hemifacial spasm† and dystonia†. The drug also has been used for its antidiuretic effects in the management of neurohypophyseal diabetes insipidus†; however, other less toxic agents are available, and patients with primary polydipsia and polyuria have shown signs of water intoxication during carbamazepine therapy.

Dosage and Administration

■ **Administration** Carbamazepine conventional tablets and suspension are administered orally with meals. The oral suspension should be shaken well before administration. To minimize loss of carbamazepine oral suspension during oral administration via a nasogastric tube (secondary to adherence to PVC tubing), the suspension can be diluted with an equal volume of diluent (e.g., sterile water, 5% dextrose, 0.9% sodium chloride) prior to administration, combined with flushing of the tube with 100 mL of the diluent after administration.

Because a rubbery, orange substance was noticed in the stool of a patient who ingested chlorpromazine oral solution immediately after ingesting carbamazepine oral suspension and subsequent testing has shown that mixing carbamazepine oral suspension with chlorpromazine or thioridazine oral solution results in a rubbery, orange precipitate, the manufacturer recommends that carbamazepine oral suspension not be administered with other liquid preparations. In addition, it is not known whether the development of this precipitate results in decreased bioavailability of carbamazepine or the other drugs.

Extended-release tablets of carbamazepine (Tegretol®-XR) should be swallowed whole and not be broken or chewed. The manufacturer states that the extended-release tablets should be inspected visually for chips or cracks and that damaged tablets should not be used. Because the coating of the extended-release tablet is not absorbed, it may be noticeable in the stools. The extended-release tablet formulation of carbamazepine is administered twice daily. When patients are switched from conventional dosage forms to the extended-release tablets of carbamazepine, the same total daily dosage is then administered in 2 divided doses.

Extended-release capsules of carbamazepine (Carbatrol®) may be opened and the beads sprinkled over food (e.g., a teaspoonful of applesauce). Extended-release capsules of carbamazepine and their contents should not be chewed or crushed. In addition, the extended-release capsules of carbamazepine may be taken without regard to meals. Patients receiving total daily carbamazepine dosages of 400 mg or greater in other preparations may be switched to the extended-release capsules; the same total daily dosage is then administered in 2 divided doses.

Patients who are currently receiving or beginning therapy with carbamazepine and/or any other anticonvulsant for any indication should be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. (See Cautions: Nervous System Effects and see Cautions: Precautions and Contraindications.)

Dispensing and Administration Precautions Because of similarity in spelling between Tegretol® or Tegretol®-XR (trade names for carbamazepine) and Toprol-XL® (a trade name for metoprolol succinate, a β-adrenergic blocking agent), the potential exists for dispensing errors involving these drugs. According to medication error reports, the overlapping tablet strengths (100 and 200 mg) between Tegretol® or Tegretol®-XR and Toprol-XL® and the fact that these drugs were stored closely together in pharmacies also may have been contributing factors in causing these errors. Therefore, extra care should be exercised to ensure the accuracy of both oral and written prescriptions for these drugs. The manufacturer of Toprol-XL® also recommends that pharmacists assess various measures of avoiding dispensing errors and implement them as appropriate (e.g., by verifying all orders for these drugs by citing both the trade and generic names to prescribers, attaching reminders to pharmacy shelves, separating the drugs on pharmacy shelves, counseling patients). (See Cautions: Precautions and Contraindications.)

■ **Dosage** Dosage of carbamazepine must be carefully and slowly adjusted according to individual requirements and response. It is important to begin therapy with a low dosage and to proceed slowly when increasing or decreasing the dosage of the drug. When carbamazepine is added to an anticonvulsant therapeutic regimen, the drug should usually be added gradually while the other anticonvulsant(s) is maintained or gradually decreased. Carbamazepine should be withdrawn slowly to avoid precipitating seizures or status epilepticus.

Because a given dose of carbamazepine administered as the oral suspension will produce higher peak concentrations of the drug than when administered as tablets, therapy with the oral suspension should be initiated with low, frequent doses (e.g., 50 mg 4 times daily for children 6–12 years of age) and increased slowly to reduce the risk of adverse effects (e.g., sedation). Alternatively, if rapid achievement of therapeutic plasma concentrations and control of seizures is necessary, an oral loading-dose regimen with carbamazepine oral suspension can be employed. When transferring patients from therapy with oral tablets to the oral suspension, the total daily dose administered as tablets should be divided into smaller, more frequent doses of the suspension (e.g., transfer from twice-daily divided dosing of tablets to thrice [3 times]-daily divided dosing of the suspension).

Seizure Disorders The usual initial dosage of carbamazepine for the management of seizure disorders in adults and children older than 12 years of age is 200 mg twice daily as tablets or 100 mg 4 times daily as the oral suspension. Dosage is increased by up to 200 mg daily at weekly intervals using a 3 or 4 times daily divided dosing regimen until the optimum response is obtained. Dosage generally should not exceed 1 g daily in children 12–15 years of age and 1.2 g daily in patients older than 15 years of age; however, some patients have required up to 1.6–2.4 g daily. When adequate seizure control is achieved, dosage should be adjusted to the minimum effective level, which is usually 800 mg to 1.2 g daily in adults and children older than 12 years of age.

In children 6–12 years of age, the usual initial dosage of carbamazepine is 100 mg twice daily as tablets or 50 mg 4 times daily as the oral suspension. Dosage is increased by up to 100 mg daily at weekly intervals using a 3 or 4 times daily divided dosing regimen until the optimum response is obtained. Dosage generally should not exceed 1 g daily in children 6–12 years of age. When adequate seizure control is achieved, dosage should be adjusted to the minimum effective level, which is usually 400–800 mg daily in children 6–12 years of age.

In children younger than 6 years of age, the initial daily dosage of carbamazepine given as conventional tablets or oral suspension is 10–20 mg/kg in 2 or 3 divided doses (as tablets) or 4 divided doses (as the oral suspension). Optimal clinical response in children younger than 6 years of age generally is achieved at daily maintenance dosages of less than 35 mg/kg. If satisfactory clinical response has not been achieved, plasma carbamazepine concentrations should be obtained to determine whether they are in the therapeutic range. The manufacturers state that safety of carbamazepine dosages exceeding 35 mg/kg in 24 hours in children younger than 6 years of age has not been established.

Therapeutic serum carbamazepine concentrations can be achieved more rapidly (in about 2 hours) by the use of an oral loading-dose regimen with the oral suspension, preferably in a clinic or hospital setting where plasma concentrations and the patient can be monitored closely. In this regimen, an initial oral loading dose (as the oral suspension) of 8 mg/kg in children 12 years of age and older or 10 mg/kg in children younger than 12 years of age is administered for the rapid control of seizures.

Neuropathic Pain For the symptomatic treatment of pain associated with trigeminal neuralgia, the usual initial adult dosage of carbamazepine on the first day of therapy is 100 mg twice daily as tablets or 50 mg 4 times daily as the oral suspension. Dosage may be increased gradually by up to 200 mg daily using 100-mg increments every 12 hours for tablets or by using 50-mg increments 4 times daily for the oral suspension until pain is relieved. The dosage necessary to relieve pain may range from 200 mg to 1.2 g daily; daily dosage should not exceed 1.2 g. After control of pain is achieved, maintenance dosages of 400–800 mg daily usually are adequate; however, some patients may require as little as 200 mg daily while others may require 1.2 g daily. At least once every 3 months throughout carbamazepine therapy for trigeminal neuralgia, an attempt should be made to decrease dosage to the minimum effective level or to discontinue the drug.

Bipolar Disorder Although dosage of carbamazepine for the management of bipolar disorder has not been established, experts generally recommend administering the drug at the same range in dosage and therapeutic plasma concentrations as in the management of seizure disorders. In patients older than 12 years of age, the usual initial dosage of carbamazepine for the management of bipolar disorder is 200–600 mg daily, given in 3 or 4 divided doses. Dosage may be titrated upward according to patient response and tolerability. In hospitalized patients with acute mania, dosages may be increased as tolerated in 200-mg daily increments up to 800 mg to 1 g daily, with slower increases thereafter as indicated. However, dosages should *not* exceed 1.6 g daily. In less acutely ill outpatients, dosage adjustments should be slower because rapid increases may cause patients to develop adverse GI (e.g., nausea, vomiting) or nervous system (e.g., drowsiness, dizziness, ataxia, clumsiness, diplopia) effects. If such adverse effects occur, temporary dosage reductions should be considered. Dosage may be increased again more slowly once these adverse effects have been resolved. Maintenance dosages of carbamazepine average about 1 g daily but may range from 200 mg to 1.6 g daily in routine clinical practice.

Cautions

■ **Hematologic Effects** Although transient or persistent, minor hematologic changes (e.g., decreased leukocyte counts) are not uncommon, the risk of serious carbamazepine-induced hematologic toxicity appears to be low. Deaths from aplastic anemia have occurred rarely following carbamazepine therapy. Other hematopoietic complications associated with the drug include leukopenia, agranulocytosis, eosinophilia, leukocytosis, thrombocytopenia, pancytopenia, bone marrow depression, and purpura. Although data from a population-based, case-control study indicate that the risk of developing aplastic anemia or agranulocytosis in patients receiving carbamazepine is 5–8 times greater than that in the general population, the overall risk of these reactions in the untreated general population is low (about 6 cases per million population per year for agranulocytosis and about 2 cases per million population per year for aplastic anemia). Transient or persistent decreases in platelet or leukocyte counts are not uncommonly associated with carbamazepine use, but currently available data do not permit accurate estimates of the incidence or outcome of

these effects; however, the vast majority of cases of leukopenia reportedly have not progressed to aplastic anemia or agranulocytosis. In addition, because the apparent frequency of minor hematologic changes progressing to agranulocytosis and aplastic anemia is very low, the vast majority of such changes observed during routine, periodic hematologic monitoring of carbamazepine-treated patients are unlikely to be signaling the impending development of either abnormality. Nonetheless, determination of baseline hematologic function should be performed prior to initiation of carbamazepine therapy, and patients exhibiting abnormalities during therapy with the drug should be monitored closely. (See Cautions: Precautions and Contraindications.)

■ **Dermatologic and Sensitivity Reactions** Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrolysis and Stevens-Johnson syndrome, have been reported in patients receiving carbamazepine therapy. These reactions are estimated to occur in 1–6 per 10,000 new users of the drug in countries with mainly Caucasian populations; however, the risk in some Asian countries is estimated to be approximately 10 times higher. Retrospective, case-control studies in patients of Asian ancestry have demonstrated a strong association between the risk of developing Stevens-Johnson syndrome and toxic epidermal necrolysis with carbamazepine therapy and the presence of human leukocyte antigen (HLA)-B*1502, an inherited allelic variant of the HLA-B gene. The HLA-B*1502 allele is found almost exclusively in patients with ancestry across broad areas of Asia (including Han Chinese, Filipinos, Malaysians, South Asian Indians, and Thais), although marked variation exists in its prevalence among various Asian populations. Greater than 15% of the population is reportedly HLA-B*1502-positive in Hong Kong, Thailand, Malaysia, and parts of the Philippines compared with about 10% in Taiwan and 4% in North China. South Asians, including Indians, appear to have an intermediate prevalence of HLA-B*1502, which averages about 2–4% but may be higher in some groups. HLA-B*1502 is present in less than 1% of the population in Japan and Korea and is largely absent in individuals not of Asian origin (e.g., Caucasians, African-Americans, Hispanics, Native Americans).

The US Food and Drug Administration (FDA) and the manufacturers of carbamazepine recommend that patients with ancestry in genetically at-risk populations be screened for the presence of the HLA-B*1502 allele prior to initiating carbamazepine therapy. In deciding which patients to screen, the rates provided above for the prevalence of the HLA-B*1502 allele may provide a rough guide; however, clinicians should keep in mind the limitations of these figures because of the wide variability in rates even within ethnic groups, the difficulty in ascertaining ethnic ancestry, and the likelihood of mixed ancestry. High-resolution HLA-B*1502 typing is recommended in genetically at-risk patients; the test is considered positive if 1 or 2 HLA-B*1502 alleles are detected and negative if no HLA-B*1502 alleles are detected. Patients testing positive for this allele should not receive carbamazepine therapy unless the benefit clearly outweighs the risk. Patients who are found to be negative for the allele are thought to have a low risk of developing Stevens-Johnson syndrome and toxic epidermal necrolysis. In addition, over 90% of carbamazepine-treated patients who will experience Stevens-Johnson syndrome and toxic epidermal necrolysis develop these reactions within the first few months of therapy; this information may be considered in determining the need for screening genetically at-risk patients currently receiving the drug.

The HLA-B*1502 allele has not been found to predict risk of less severe adverse dermatologic reactions associated with carbamazepine (e.g., multiple-organ hypersensitivity reactions, non-serious rash such as maculopapular eruption). However, limited evidence suggests that HLA-B*1502 may be a risk factor for the development of Stevens-Johnson syndrome and toxic epidermal necrolysis in patients of Asian ancestry who are receiving other anticonvulsants associated with these reactions (e.g., lamotrigine, fosphenytoin, phenytoin). Avoidance of such drugs should therefore be considered in HLA-B*1502-positive patients when alternative therapies are otherwise equally acceptable.

FDA and the manufacturers caution that application of HLA-B*1502 genotyping as a screening tool has important limitations and must never substitute for appropriate clinical vigilance and patient management. Many HLA-B*1502-positive Asian patients treated with carbamazepine will never develop Stevens-Johnson syndrome and toxic epidermal necrolysis, and such reactions may develop infrequently in HLA-B*1502-negative patients of any ethnicity. The role of other possible factors, such as anticonvulsant drug dosage, compliance, concomitant medications and illnesses, in the development of, and morbidity from, these reactions and the level of dermatologic monitoring has not been adequately studied to date.

Other adverse dermatologic effects of carbamazepine include pruritic, erythematous, and maculopapular rashes (e.g., maculopapular eruption); urticaria; photosensitivity reactions; alterations in skin pigmentation; and exfoliative dermatitis. In addition, erythema multiforme and nodosum and development of a lupus erythematosus-like syndrome or aggravation of systemic lupus erythematosus have been reported. Alopecia also may occur. Although a causal relationship has not been established, hirsutism has been reported rarely in patients receiving carbamazepine.

Multiple-organ hypersensitivity reactions occurring days to weeks or months after initiation of carbamazepine therapy have been reported rarely. Manifestations may include (but are not limited to) fever, rashes, vasculitis, lymphadenopathy, disorders mimicking lymphoma, arthralgia, leukopenia, eosinophilia, hepatosplenomegaly, and abnormal liver function test results. These manifestations may initially be mild and may occur in various combinations and not necessarily concurrently. Various organs, including but not limited to, liver, skin, immune system, lungs, kidneys, pancreas, myocardium, and colon, may be affected.

Other hypersensitivity reactions, including fever, rash, peripheral eosinophilia, and reversible aseptic meningitis (manifested by confusion, myoclonus, and CSF pleocytosis), have been reported rarely in patients receiving carbamazepine.

■ **Cardiovascular Effects** Adverse cardiovascular effects (some of which may be fatal), including congestive heart failure, aggravation of hypertension, hypotension, syncope and collapse, edema, thrombophlebitis, thromboembolism, aggravation of coronary artery disease, arrhythmias, and AV block, have been reported. Myocardial infarction has been associated with tricyclic compounds.

■ **Hepatic Effects** Hepatic complications associated with the long-term administration of carbamazepine include abnormalities in liver function test results, cholestatic and hepatocellular jaundice, hepatitis, and very rare cases of hepatic failure.

■ **Genitourinary Effects** Genitourinary complications associated with carbamazepine include urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence. Albuminuria, glycosuria, elevated BUN concentrations, and microscopic deposits in the urine also have been reported.

■ **Nervous System Effects** Adverse neurologic and sensory effects of carbamazepine include dizziness, vertigo, drowsiness, fatigue, ataxia, disturbances of coordination, confusion, headache, nystagmus, blurred vision, transient diplopia, visual hallucinations, hyperacusis, oculomotor disturbances, speech disturbances, and abnormal involuntary movements. Rarely, peripheral neuritis and paresthesia, depression with agitation, talkativeness, and tinnitus may occur. Reports of associated paralysis and other symptoms of cerebral arterial insufficiency have been made, but the exact relationship of these reactions to the administration of carbamazepine has not been established.

The US Food and Drug Administration (FDA) has analyzed suicidality reports from placebo-controlled studies involving 11 anticonvulsants, including carbamazepine, and found that patients receiving anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%). FDA's analysis included 199 randomized, placebo-controlled studies of 11 anticonvulsants (carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, and zonisamide) involving over 43,000 patients 5 years of age or older; the studies evaluated the effectiveness of the anticonvulsants in epilepsy, psychiatric disorders or (e.g., bipolar disorder, depression, anxiety), and other conditions (e.g., migraine, neuropathic pain). This increased suicidality risk was observed as early as one week after beginning therapy and continued through 24 weeks. The results were generally consistent among the 11 drugs studied. In addition, patients who were treated for epilepsy, psychiatric disorders, and other conditions were all found to be at increased risk for suicidality when compared with placebo; there did not appear to be a specific demographic subgroup of patients to which the increased risk could be attributed. However, the relative risk for suicidality was found to be higher in patients with epilepsy compared with patients who were given one of the drugs for psychiatric or other conditions. (See Cautions: Precautions and Contraindications.)

Initiation of carbamazepine for the management of complex partial seizures has been associated with exacerbation of seizures, principally atypical absence and/or generalized convulsive seizures, in some children with mixed seizure disorders. In one group of children, video-EEG monitoring revealed a generalized paroxysmal spike-and-wave discharge in all of the children in whom exacerbation of seizures occurred during carbamazepine therapy. Children who developed frequent generalized convulsive seizures had a pattern of spikes and slow waves with a frequency of 1–2 cycles/second, and those who developed more frequent and severe atypical absence seizures had a generalized spike-and-wave discharge of 2.5–3 cycles/second. Although the mechanism is not known, it was suggested that exacerbation of seizures in these children may result from carbamazepine-induced activation of epileptiform discharges. It has been suggested that carbamazepine be used with caution for the management of complex partial seizures in children with mixed seizure disorders; particularly those who have a generalized absence or atypical absence component, and that the drug be avoided when there is generalized, synchronous, spike-and-wave discharges of 2.5–3 cycles/second in association with clinical seizures regardless of their clinical manifestation. The possibility that a worsening of atypical absence and/or generalized convulsive seizures following initiation of carbamazepine therapy may be drug induced rather than the natural history of the child's epilepsy should be considered.

■ **GI Effects** Adverse GI effects of carbamazepine include nausea, vomiting, gastric distress, abdominal pain, diarrhea, constipation, anorexia, dryness of the mouth and pharynx, glossitis, and stomatitis.

■ **Other Adverse Effects** Other adverse effects reported during carbamazepine therapy include diaphoresis, fever and chills, adenopathy or lymphadenopathy, acute intermittent porphyria, aching joints and muscles, leg cramps, and conjunctivitis. Decreased plasma calcium concentrations and hyponatremia have been reported. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) and cases of frank water intoxication, with hyponatremia and confusion, have also been reported. Pulmonary hypersensitivity, characterized by fever, dyspnea, pneumonitis, or pneumonia, also has occurred. Isolated cases of neuroleptic malignant syndrome have been reported with concomitant use of carbamazepine and psychotropic drugs.

Although scattered, punctate lens opacities have occurred only rarely in patients receiving carbamazepine, other drugs such as the phenothiazines have caused various ocular changes.

■ **Precautions and Contraindications** Carbamazepine may produce dangerous and alarming adverse effects, principally consisting of hematopoietic, dermatologic, cardiovascular, hepatic, and renal disturbances. The drug also shares the toxic potentials of the hydantoin-derivative anticonvulsants, and the usual precautions of anticonvulsant administration should be observed. When serious adverse effects occur requiring discontinuance of the drug, it is important to remember that abrupt withdrawal of any anticonvulsant drug in a responsive epileptic patient may precipitate seizures or status epilepticus. Carbamazepine therapy should be withdrawn gradually, whenever possible, to minimize the potential for increased seizure frequency. Patients must be carefully examined prior to initiation of carbamazepine therapy and should remain under close medical supervision throughout therapy with the drug. Carbamazepine should be prescribed only after careful benefit-to-risk evaluation in patients with a history of cardiac conduction disturbances; cardiac, hepatic, or renal damage; or adverse hematologic or hypersensitivity reaction to other drugs (e.g., other anticonvulsants) or who have had interrupted therapy with carbamazepine.

Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrolysis and Stevens-Johnson syndrome, have been reported in patients receiving carbamazepine therapy. These reactions are estimated to occur in 1–6 per 10,000 new users of the drug in countries with mainly Caucasian populations; however, the risk in some Asian countries is estimated to be about 10 times higher. Carbamazepine should be discontinued at the first sign of a skin rash, unless the rash is clearly not drug-related. If signs or symptoms suggest Stevens-Johnson syndrome or toxic epidermal necrolysis, carbamazepine therapy should not be resumed and alternative therapy should be considered. Retrospective case-control studies in patients of Asian ancestry have demonstrated a strong association between the risk of developing Stevens-Johnson syndrome and toxic epidermal necrolysis and the presence of human leukocyte antigen (HLA)-B*1502, an inherited allelic variant of the HLA-B gene; this allele is found almost exclusively in patients with ancestry across broad areas of Asia. Therefore, the US Food and Drug Administration (FDA) and the manufacturers of carbamazepine recommend that patients with ancestry in genetically at-risk populations be screened for the presence of the HLA-B*1502 allele prior to initiating carbamazepine therapy. Patients testing positive for this allele should not receive carbamazepine therapy unless the benefit clearly outweighs the risk. (See Cautions: Dermatologic and Sensitivity Reactions.)

Multiple-organ hypersensitivity reactions occurring days to weeks or months following initiation of carbamazepine have been reported rarely. (See Cautions: Dermatologic and Sensitivity Reactions.) Discontinuance of carbamazepine should be considered if any evidence of hypersensitivity develops. Because hypersensitivity reactions to carbamazepine have been reported in patients with a history of hypersensitivity reactions to other anticonvulsants (e.g., phenytoin, phenobarbital), a detailed drug history should be obtained from patients and their immediate family members. Carbamazepine should be used with caution in patients with a history of hypersensitivity reactions to other anticonvulsants. Approximately 25–30% of patients who demonstrated hypersensitivity reactions to carbamazepine also may experience hypersensitivity reactions to oxcarbazepine.

Close attention by the patient and clinician to signs and symptoms of the possible development of adverse hematologic, dermatologic, or hypersensitivity reactions is important in patients receiving carbamazepine. Patients should be informed of the early signs and symptoms of these potential problems, such as fever, sore throat, infection, rash, mouth ulcers, easy bruising, lymphadenopathy, and petechial or purpuric hemorrhage, and should be instructed to report to their physician immediately if any such sign or symptom occurs. In addition, patients should be advised that these manifestations should be reported even if they are mild in severity or if they occur after extended use.

Although the manufacturers previously recommended initial frequent (possibly weekly during the first 3 months of therapy) and then less frequent, periodic (monthly for at least 2–3 years) testing of hematologic function in any patient receiving carbamazepine, they currently state that, because the frequency of minor hematologic changes progressing to aplastic anemia and agranulocytosis is very low, the vast majority of such changes observed during routine, periodic monitoring are unlikely to be signaling the impending development of either abnormality. Therefore, the manufacturers currently recommend that complete blood counts, including platelet and possibly reticulocyte counts and serum iron determinations, be performed prior to initiating carbamazepine therapy and that subsequent monitoring be individualized by the clinician. Guidelines for periodic monitoring of hematologic function have been suggested by some clinicians, and clinicians experienced in the use of carbamazepine and knowledgeable about the drug's potential toxicity can be consulted for more specific information. Patients exhibiting baseline abnormalities and those receiving other potentially myelotoxic drugs or with a history of adverse hematologic reactions to any drug should be considered at special risk, and carbamazepine therapy should be monitored closely or avoided in these patients. The manufacturers recommend that patients with a history of bone marrow depression *not* receive the drug. Patients who exhibit low or decreased leukocyte or platelet counts during the course of carbamazepine therapy should be monitored closely. Discontinuance of carbamazepine therapy should be considered if any evidence of significant bone marrow depression develops. In addition, if such evidence develops, particularly if it occurs as a result of overdosage, it has been suggested that complete blood counts, platelet counts, and reticulocyte counts be performed daily and bone marrow aspiration and trephine biopsy be done immediately and repeated as often as necessary to monitor recovery. Alternatively, one manufacturer suggests that the frequency of this monitoring in patients who develop evidence of significant bone marrow depression during the usual course of carbamazepine therapy (i.e., not resulting from overdosage) may be individualized by the clinician. Other special periodic hematologic studies may also be helpful in patients with evidence of significant bone marrow depression. Fully developed aplastic anemia requires appropriate, intensive monitoring and therapy for which specialized consultation should be sought. Some clinicians also advise hematologic consultation if neutropenia and depressed platelet and reticulocyte counts occur during therapy with the drug.

Adverse hepatic effects, ranging from slight elevations in hepatic enzymes to rare cases of hepatic failure, have been reported. In some cases, hepatic effects may progress despite discontinuance of the drug. Liver function tests should be performed prior to carbamazepine therapy, particularly in patients with a history of liver disease, and periodically thereafter. Carbamazepine should be immediately discontinued if evidence of liver dysfunction or active liver disease is observed. In addition, patients should be advised of the early manifestations of adverse hepatic effects (e.g., anorexia, nausea/vomiting, jaundice) and instructed to report such symptoms to their clinician immediately, even if the symptoms are mild or occur after extended use. Complete urinalysis and BUN determinations also should be performed prior to and periodically during carbamazepine therapy.

FDA has informed healthcare professionals about an increased risk of suicidality (suicidal behavior or ideation) observed in an analysis of studies using various anticonvulsants compared with placebo. (See Cautions: Nervous System Effects.) FDA recommends that all patients who are currently receiving or beginning therapy with any anticonvulsant for any indication be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or unusual changes in mood or behavior. Symptoms such as anxiety, agitation, hostility, mania, and hypomania may be precursors to emerging suicidality. Clinicians should inform patients, their families, and caregivers of the potential for an increased risk of suicidality so that they are aware and able to notify their clinician of any unusual behavioral changes. Patients, family members, and caregivers also should be advised not to make any changes to the medication regimen without first consulting with the responsible clinician. They should pay close attention to any day-to-day changes in mood, behavior, and actions; since changes can happen very quickly, it is important to be alert to any sudden differences. In addition, patients, family members, and caregivers should be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). If these or any new and worrisome behaviors occur, the responsible clinician should be contacted immediately. FDA also recommends that clinicians who prescribe carbamazepine or any other anticonvulsant balance the risk of suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician must consider whether the emergence of these symptoms in any given patient may be related to the illness being treated.

Carbamazepine may exacerbate seizures in some children with mixed seizure disorders. Some clinicians recommend that prolonged video-EEG monitoring be performed prior to initiating carbamazepine therapy in children with mixed seizure disorders in an attempt to identify those children who may be at risk for carbamazepine-induced exacerbation of seizures. (See Cautions: Nervous System Effects.)

Persons who perform hazardous tasks requiring mental alertness or physical coordination should be warned about the possible adverse neurologic and sensory effects of carbamazepine. Patients receiving carbamazepine also should be advised that there is a potential for additive CNS effects if alcohol is used concomitantly with carbamazepine. Because of the relationship of carbamazepine to other tricyclic compounds, the possibility of activation of a latent psychosis or, in geriatric patients, confusion or agitation should be kept in mind.

Baseline and periodic eye examinations including slit-lamp, funduscopy, and tonometry are recommended in patients receiving carbamazepine. Carbamazepine has shown mild anticholinergic activity; therefore, patients with increased intraocular pressure should be closely observed during carbamazepine therapy.

Because of similarity in spelling between Tegretol® or Tegretol®-XR (trade names for carbamazepine) and Toprol-XL® (metoprolol succinate, a β-adrenergic blocking agent), the potential exists for dispensing errors involving these drugs. These medication errors have been associated with serious adverse events sometimes requiring hospitalization as a result of either lack of the intended medication (e.g., seizure recurrence, return of hallucinations, suicide attempt, hypertension recurrence) or exposure to the wrong drug (e.g., bradycardia in a patient erroneously receiving metoprolol). Therefore, extra care should be exercised to ensure the accuracy of both oral and written prescriptions for these drugs. (See Dispensing and Administration Precautions under Dosage and Administration: Administration.) Dispensing errors involving Tegretol® or Tegretol®-XR (carbamazepine) and Toprol-XL® (metoprolol succinate) should be reported to the manufacturers, the USP/ISMP (Institute for Safe Medication Practices) Medication Errors Reporting Program by phone (800-233-7767), or directly to the FDA MedWatch program by phone (800-FDA-1088), fax (800-FDA-0178), or internet (http://www.fda.gov/Safety/MedWatch).

Carbamazepine is contraindicated in patients with a history of previous bone marrow depression, acute intermittent porphyria, and/or hypersensitivity to the drug or in patients who have demonstrated sensitivity to any of the tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline, protriptyline). The drug also is contraindicated in patients currently re-

ceiving, or having recently received (i.e., within 2 weeks), monoamine oxidase (MAO) inhibitor therapy. (See Drug Interactions: Monoamine Oxidase Inhibitors.) Concomitant use of carbamazepine and nefazodone is contraindicated. (See Drug Interactions: Nefazodone.) In addition, the manufacturer of voriconazole states that concomitant use of carbamazepine and voriconazole is contraindicated. (See Drug Interactions: Azole Antifungal Agents.)

■ **Pediatric Precautions** Efficacy of carbamazepine for management of seizures in children is based on extrapolation of the demonstrated efficacy of carbamazepine in adults and also on in vitro studies that confirmed that the pathogenetic mechanisms associated with seizure propagation in adults are essentially the same as those in children; in addition, mechanism of action of carbamazepine in the treatment of seizures is the same in adults and children. The therapeutic range for plasma carbamazepine concentrations (i.e., 4–12 mcg/mL) is the same in children and adults. Safety of carbamazepine in children is based on clinical studies in which the drug was administered for up to 6 months. Data from long-term clinical studies in children are not available.

■ **Mutagenicity and Carcinogenicity** Bacterial and mammalian mutagenicity studies using carbamazepine have shown no evidence of mutagenicity. Carbamazepine has produced dose-related increases in the incidence of hepatocellular tumors in female rats and benign interstitial cell adenomas in male rats. The clinical importance of these findings is not known.

■ **Pregnancy and Lactation** Safe use of carbamazepine during pregnancy has not been established. Adverse fetal effects have been observed in reproduction studies in rats. Although several reports suggest an association between use of anticonvulsants in pregnant, epileptic women and an increased incidence of birth defects in children born to these women, a causal relationship to many of these drugs has not been established. However, epidemiologic data do suggest that an association between carbamazepine use during pregnancy and certain congenital abnormalities such as spina bifida may exist. Other congenital anomalies and developmental disorders (e.g., craniofacial defects, cardiovascular malformations, anomalies involving various body systems) also have been reported in association with carbamazepine use. Anticonvulsants should *not* be discontinued in pregnant women in whom the drugs are administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases, when the severity and frequency of the seizure disorder are such that discontinuance of therapy does not pose a serious threat to the patient, discontinuance of the drugs may be considered prior to and during pregnancy; however, it cannot be said with any certainty that even minor seizures do not pose some hazard to the fetus. Clinicians should carefully weigh these considerations in treating or counseling epileptic women of childbearing potential. Because carbamazepine can cause fetal harm when administered to pregnant women, the benefits of therapy must be weighed against the risks in women of childbearing potential. If carbamazepine is used during pregnancy, or if the patient becomes pregnant while receiving the drug, the patient should be apprised of the potential hazard to the fetus. Tests to detect fetal abnormalities using currently accepted procedures should be considered part of routine prenatal care in women of childbearing potential receiving carbamazepine.

There have been a few cases of seizures and/or respiratory depression in neonates born to women receiving carbamazepine concomitantly with other anticonvulsant agents. A few cases of vomiting, diarrhea, and/or decreased feeding also have been reported in neonates born to women receiving carbamazepine; these symptoms may represent a neonatal withdrawal syndrome.

To provide information regarding the effects of in utero exposure to carbamazepine, clinicians are advised to recommend that pregnant patients receiving carbamazepine enroll themselves in the North American Antiepileptic Drug (NAAED) Pregnancy Registry by calling 888-233-2334.

Carbamazepine and its epoxide metabolite (CBZ-E) are distributed into milk. Safe use of carbamazepine during lactation has not been established. Because of the potential for serious adverse reactions from carbamazepine in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman. Following daily oral administration of carbamazepine in nursing women, the milk-to-maternal plasma ratio of carbamazepine is about 0.4 and that of CBZ-E is about 0.5; it is estimated that neonates may receive about 2–5 and 1–2 mg of carbamazepine and CBZ-E, respectively, daily.

Drug Interactions

■ **Alcohol** Because of the risk of additive sedative effects, caution should be exercised if carbamazepine is used concomitantly with alcohol.

■ **Anticonvulsants** Because carbamazepine is an inducer of the cytochrome P-450 (CYP) 3A4 isoenzyme, concomitant use with certain other anticonvulsants (e.g., clonazepam, ethosuximide, lamotrigine, methsuximide, phensuximide [not commercially available in the US], phenytoin, tiagabine, topiramate, valproic acid, zonisamide) has been shown, or would be expected, to decrease plasma concentrations of the other anticonvulsant. It may be desirable to monitor serum concentrations of concomitantly administered anticonvulsants, making dosage adjustments as necessary.

Concomitant use of carbamazepine with other anticonvulsants that induce (e.g., methsuximide, phenobarbital, phenytoin, primidone) or inhibit (e.g., acetazolamide) CYP3A4 has been shown, or would be expected, to decrease or increase plasma carbamazepine concentrations, respectively. In addition, carbamazepine may decrease the half-life of phenytoin. Increased plasma concentrations of phenytoin and primidone have been reported following concomitant use with carbamazepine.

Felbamate and valproic acid apparently can affect both plasma carbamazepine and carbamazepine 10,11-epoxide (CBZ-E, an active metabolite) concentrations, but the interactions appear to be complex and resultant changes may be unpredictable. The effect of valproic acid on concentrations of the drug may depend principally on increases in plasma CBZ-E concentrations relative to parent drug (possibly secondary to inhibition of epoxide hydrolase activity), but other mechanisms (e.g., displacement of carbamazepine from protein binding sites) also have been suggested and may contribute to the overall effect. The importance of determining CBZ-E concentrations in patients exhibiting toxicity during concomitant carbamazepine and valproic acid therapy should be considered.

Recent evidence suggests that the human leukocyte antigen (HLA)-B *1502 allele, which is found almost exclusively in patients with ancestry across broad areas of Asia, may be a risk factor for the development of Stevens-Johnson syndrome and toxic epidermal necrolysis in patients of Asian ancestry who are receiving carbamazepine and some other anticonvulsants associated with these reactions (e.g., lamotrigine, fosphenytoin, phenytoin). Avoidance of such drugs should therefore be considered in HLA-B *1502-positive patients when alternative therapies are otherwise equally acceptable. The role of other possible factors, such as concomitant medications, anticonvulsant dosage, compliance, and illnesses, in the development of, and morbidity from, these reactions, and the level of dermatologic monitoring have not been adequately studied to date. (See Cautions: Dermatologic and Sensitivity Reactions and see Cautions: Precautions and Contraindications.)

Alterations of thyroid function have been reported with concomitant use of carbamazepine and other anticonvulsants.

■ **Lithium** Concomitant use of carbamazepine with lithium may increase the risk of adverse neurologic effects.

■ **Calcium-channel Blocking Agents** Concomitant use of carbamazepine and diltiazem or verapamil may result in increased plasma carbamazepine concentrations and subsequent toxicity. In several patients receiving 1–2 g of carbamazepine daily, initiation of 360 mg of verapamil hydrochloride daily resulted in development of neurologic manifestations (e.g., dizziness, ataxia, nystagmus) of carbamazepine toxicity within 36–96 hours. Plasma total and unbound carbamazepine concentrations increased by a mean of 46 and 33%, respectively, but returned to baseline values within 1 week after discontinuance of verapamil; manifestations of toxicity also resolved during this period. The ratio of plasma carbamazepine 10,11-epoxide to unchanged drug decreased during verapamil therapy but returned toward pretreatment levels following discontinuance of verapamil. Limited experience suggests that a similar interaction also may occur when diltiazem, but not nifedipine, is administered concomitantly with carbamazepine. It appears that verapamil and diltiazem inhibit hepatic metabolism of carbamazepine via the CYP3A4 isoenzyme.

If verapamil is initiated in patients receiving carbamazepine, a 40–50% reduction in carbamazepine dosage may be necessary during concomitant therapy. Patients should be monitored closely for manifestations of carbamazepine toxicity and for alterations in the pharmacokinetics of carbamazepine during concomitant therapy, adjusting carbamazepine dosage accordingly. If verapamil is discontinued, dosage of carbamazepine should be increased to avoid loss of seizure control.

Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with dihydropyridine calcium-channel blocking agents (e.g., felodipine) has been shown, or would be expected, to decrease plasma concentrations of the dihydropyridine calcium-channel blocking agent.

■ **Macrolides** Concomitant use of carbamazepine with certain macrolide antibiotics that inhibit CYP3A4 (e.g., clarithromycin, erythromycin, troleandomycin) has been shown, or would be expected, to increase plasma carbamazepine concentrations. Increased plasma concentrations of carbamazepine and subsequent signs of carbamazepine toxicity (e.g., ataxia, dizziness, drowsiness, vomiting) have occurred in adults or children following concomitant use of carbamazepine and erythromycin. Studies in adults indicate that erythromycin can substantially decrease serum clearance of carbamazepine, presumably by inhibiting hepatic metabolism of the drug. Patients receiving carbamazepine and erythromycin concomitantly should be monitored for evidence of carbamazepine toxicity; carbamazepine dosage should be reduced when necessary. Some clinicians suggest that use of an alternative anti-infective agent, instead of erythromycin, may be necessary in patients receiving carbamazepine.

■ **Doxycycline** Preliminary studies indicate that carbamazepine may decrease the half-life of doxycycline, probably by inducing hepatic microsomal enzymes that metabolize the antibiotic. Concomitant administration of doxycycline and carbamazepine should be avoided if possible. If concomitant therapy is necessary, doxycycline probably should be administered at 12-hour intervals and/or serum doxycycline concentrations should be closely monitored.

■ **Selective Serotonin-reuptake Inhibitors** Fluoxetine can increase plasma carbamazepine and carbamazepine 10,11-epoxide (CBZ-E, an active metabolite) concentrations, and carbamazepine toxicity (e.g., ocular changes, vertigo, tremor) has been reported in some patients maintained on carbamazepine following initiation of fluoxetine. It has been suggested that fluoxetine-induced inhibition of hepatic metabolism (e.g., inhibition of epoxide hydrolase) of carbamazepine and/or CBZ-E may be principally responsible for such increases; alteration in protein binding does not appear to be principally responsible for this interaction. The patient and plasma concentrations of carbamazepine and its metabolite should be monitored closely whenever fluoxetine therapy is initiated or discontinued; carbamazepine dosage should be adjusted accordingly.

Concomitant use of carbamazepine with fluvoxamine, an inhibitor of CYP3A4, has been shown, or would be expected, to increase plasma carbamazepine concentrations.

■ **Antipsychotic Agents** Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with some antipsychotic agents (e.g., aripiprazole, clozapine, haloperidol, risperidone, ziprasidone) has been shown, or would be expected, to decrease plasma concentrations of the antipsychotic agent. Reductions in antipsychotic efficacy with reemergence of symptoms has occurred in some, but not all, such patients. If carbamazepine therapy is added in patients receiving aripiprazole, the dosage of aripiprazole should be doubled and additional increases in aripiprazole dosage should be made based on clinical evaluation; if carbamazepine is withdrawn from combination therapy with aripiprazole, the dosage of aripiprazole should be reduced accordingly. Patients receiving carbamazepine and haloperidol concomitantly should be monitored carefully for loss of antipsychotic control and, if an interaction is suspected, haloperidol dosage adjusted accordingly. The possibility that haloperidol toxicity may occur following discontinuance of carbamazepine also should be considered.

Clozapine Concomitant use of carbamazepine and clozapine has been shown to decrease clozapine concentrations by about 40–50%. Both carbamazepine and clozapine also have the potential to cause adverse hematologic effects, including agranulocytosis. In addition, neuroleptic malignant syndrome (NMS) has been reported rarely during concomitant therapy with these drugs. Therefore, the manufacturers of clozapine and the American Psychiatric Association (APA) state that concomitant use of carbamazepine and clozapine generally is not recommended. However, if carbamazepine and clozapine are used concomitantly, it should be considered that discontinuance of carbamazepine may result in increased plasma concentrations of clozapine.

■ **Monoamine Oxidase Inhibitors** Combined therapy using carbamazepine and monoamine oxidase (MAO) inhibitors is contraindicated. A medication-free period of at least 14 days should be observed when transferring patients from MAO inhibitors to carbamazepine. Therapy with carbamazepine should then be initiated cautiously with gradual increases in dosage to obtain the desired response.

■ **Anticoagulants** Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with dicumarol or warfarin has been shown, or would be expected, to decrease plasma concentrations of the anticoagulant. In one study when carbamazepine was administered to patients being treated with warfarin, the serum concentration of warfarin decreased after about 10 days of carbamazepine therapy. Carbamazepine also shortened the half-life of warfarin in some patients. If warfarin and carbamazepine must be used together, the patient should be closely monitored and the dosage of both drugs adjusted as required.

■ **Theophylline** It has been suggested that concomitant administration of carbamazepine and theophylline may induce each other's metabolism, with resultant changes in elimination half-life and plasma concentrations. If carbamazepine and theophylline are used concomitantly, the patient and plasma concentrations of the drugs should be monitored and dosage adjusted accordingly.

■ **Hormonal Contraceptives** Concomitant use of carbamazepine and hormonal contraceptives (e.g., oral contraceptives, levonorgesterol subdermal implant contraceptives [no longer commercially available]) may cause increased metabolism of the contraceptive resulting from induction of hepatic microsomal enzymes. Breakthrough bleeding and unintended pregnancies have been reported in patients receiving carbamazepine and hormonal contraceptives. Because the reliability of hormonal contraceptive therapy may be adversely affected during concomitant administration of carbamazepine, a nonhormonal method of birth control should be considered.

■ **Antihistamines** Concomitant use of carbamazepine with antihistamines that inhibit CYP3A4 (e.g., loratadine, terfenadine [no longer commercially available]) has been shown, or would be expected, to increase plasma carbamazepine concentrations.

■ **Antituberculosis Agents** Concomitant use of carbamazepine with antituberculosis agents that inhibit CYP3A4 (e.g., isoniazid) has been shown, or would be expected, to increase plasma carbamazepine concentrations. Conversely, concomitant use of carbamazepine with antituberculosis agents that induce CYP3A4 (e.g., rifampin) has been shown, or would be expected, to decrease plasma carbamazepine concentrations.

■ **Antineoplastic Agents** Concomitant use of carbamazepine with antineoplastic agents that induce CYP3A4 (e.g., cisplatin, doxorubicin) has been shown, or would be expected, to decrease plasma carbamazepine concentrations.

■ **Azole Antifungal Agents** Concomitant use of carbamazepine with azole antifungal agents that inhibit CYP3A4 (e.g., fluconazole, itraconazole, ketoconazole, voriconazole) has been shown, or would be expected, to increase plasma carbamazepine concentrations.

Concomitant use of carbamazepine and fluconazole has resulted in increased carbamazepine concentrations and associated toxicity, presumably as the result of fluconazole inhibiting CYP isoenzymes involved in metabolism of the anticonvulsant. It has been suggested that carbamazepine concentrations be monitored in patients receiving fluconazole concomitantly.

Because carbamazepine also is an inducer of the CYP3A4 isoenzyme, concomitant use with itraconazole has been shown, or would be expected, to decrease plasma concentrations of itraconazole.

Although the interaction has not been specifically studied to date, carbamazepine would be expected to substantially decrease plasma voriconazole concentrations due to potent induction of CYP enzymes; therefore, the manufacturer of voriconazole states that concomitant use of carbamazepine and voriconazole is contraindicated.

■ **Corticosteroids** Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with corticosteroids metabolized by CYP3A4 (e.g., dexamethasone, prednisolone) has been shown, or would be expected, to decrease plasma concentrations of the corticosteroid.

■ **HIV Protease Inhibitors** Concomitant use of carbamazepine with HIV protease inhibitors that inhibit CYP3A4 has been shown, or would be expected, to increase plasma carbamazepine concentrations. Because carbamazepine is an inducer of CYP3A4, concomitant use with HIV protease inhibitors that are metabolized by CYP3A4 has been shown, or would be expected, to decrease plasma concentrations of the HIV protease inhibitor.

■ **Tricyclic Antidepressants** Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with tricyclic antidepressants metabolized by CYP3A4 (e.g., amitriptyline, imipramine, nortriptyline) has been shown, or would be expected, to decrease plasma concentrations of the tricyclic antidepressant.

■ **Nefazodone** Concomitant use of carbamazepine and nefazodone is contraindicated since this may reduce plasma concentrations of nefazodone and its active metabolite, hydroxynefazodone, by 95% resulting in levels insufficient to achieve an antidepressant effect.

■ **Trazodone** Because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with trazodone has been shown to decrease plasma concentrations of trazodone. Concomitant use of carbamazepine (400 mg daily) with trazodone (100–300 mg daily) decreased plasma concentrations of trazodone and an active metabolite, *m*-chlorophenylpiperazine, by 76 and 60%, respectively. Patients receiving carbamazepine and trazodone concomitantly should be closely monitored and dosage of trazodone increased if necessary.

■ **Other Drugs** Concomitant use of carbamazepine with drugs or foods that inhibit CYP3A4 (e.g., cimetidine, danazol, grapefruit juice, niacinamide, propoxyphene) has been shown, or would be expected, to increase plasma carbamazepine concentrations. In addition, because carbamazepine is an inducer of the CYP3A4 isoenzyme, concomitant use with drugs metabolized by CYP3A4 (e.g., acetaminophen, alprazolam, cyclosporine, levothyroxine, methadone, midazolam, praziquantel, tramadol) has been shown, or would be expected, to decrease plasma concentrations of the other drug.

Laboratory Test Interferences

■ **Pregnancy Tests** Carbamazepine interferes with some pregnancy tests.

Acute Toxicity

■ **Pathogenesis** The lowest known lethal dose of carbamazepine is 3.2 and 1.6 g in adults and children, respectively.

■ **Manifestations** Carbamazepine overdosage produces dizziness, ataxia, drowsiness, stupor, nausea, vomiting, opisthotonos, restlessness, agitation, disorientation, tremor, involuntary movements, adiadochokinesis, abnormal reflexes (hypoactive or hyperactive), mydriasis, nystagmus, flushing, cyanosis, and urinary retention. Hypotension or hypertension may develop. Coma may follow. Laboratory findings in some cases of overdosage have included leukocytosis, reduced leukocyte count, glycosuria, and acetonuria. EEG may show dysrhythmias.

A 24-year-old woman who ingested 3.2 g of carbamazepine died of cardiac arrest, and a 24-year-old man died of pneumonia and hypoxic encephalopathy ingesting the same dose. A 14-year-old girl who ingested 4 g of carbamazepine died of cardiac arrest, and a 3-year-old girl who ingested 1.6 g of carbamazepine died of aspiration pneumonia.

■ **Treatment** Treatment of carbamazepine overdosage consists of inducing emesis or gastric lavage and general supportive therapy. Because of the relationship of carbamazepine to the tricyclic antidepressants, the ECG should be monitored, especially in children, to detect cardiac dysfunction.

Pharmacology

The pharmacologic actions of carbamazepine appear to be qualitatively similar to those of the hydantoin-derivative anticonvulsants. The anticonvulsant activity of carbamazepine, like phenytoin, principally involves limitation of seizure propagation by reduction of posttetanic potentiation (PTP) of synaptic transmission. Carbamazepine appears to provide relief of pain in trigeminal neuralgia by reducing synaptic transmission within the trigeminal nucleus. The drug has also demonstrated sedative, anticholinergic, antidepressant, muscle relaxant, antiarrhythmic, antidiuretic, and neuromuscular transmission-inhibitory actions. Carbamazepine has only slight analgesic properties.

Pharmacokinetics

The pharmacokinetic parameters of carbamazepine disposition are similar in children and in adults; however, there is a poor correlation between dosage and plasma concentrations of carbamazepine in children. The effects of race and gender on carbamazepine pharmacokinetics have not been systematically evaluated. However, retrospective, case-control studies in patients of Chinese ancestry have demonstrated a strong pharmacogenomic association between the risk of developing Stevens-Johnson syndrome and toxic epidermal necrolysis and the presence of HLA-B*1502, an inherited allelic variant of the HLA-B gene. (See Cautions: Dermatologic and Sensitivity Reactions.)

■ **Absorption** Carbamazepine is slowly absorbed from the GI tract. Following chronic oral administration of carbamazepine tablets, suspension, extended-release tablets, or extended-release capsules, peak plasma concentra-

tions are reached in 4.5, 1.5, 3–12, or 4.1–7.7 hours, respectively. The oral bioavailabilities of carbamazepine tablets and suspension reportedly are equivalent, although the rate of absorption is faster for the suspension. The bioavailability of the extended-release tablets is reportedly 89% of that of the suspension, and the absorption of the extended-release tablets is slightly slower than that of the conventional tablets. Peak plasma concentrations of the drug are higher and trough concentrations are lower for the suspension compared with tablets when the drug is administered once or twice daily, but steady-state concentrations reportedly are comparable when the suspension is administered in 3 divided doses daily and the tablets are administered in 2 divided doses daily. Following oral administration of carbamazepine extended-release capsules or tablets every 12 hours, steady-state plasma carbamazepine concentrations were comparable to those achieved with corresponding dosages of the conventional (immediate-release) tablets every 6 hours. Although one manufacturer states that peak plasma concentrations may be higher with chewable tablets than with conventional tablets, a crossover study employing this manufacturer's tablets in adults with seizure disorders showed no such difference. In this study, the oral pharmacokinetics, including bioavailability, and peak and trough plasma concentrations, were comparable for conventional and chewable tablets of the drug, although individual patients may have achieved somewhat higher concentrations for one or the other tablet formulation.

Two to 4 days of therapy may be required to achieve steady-state plasma concentrations. Although optimal therapeutic plasma concentrations suitable for all patients have not yet been determined, therapeutic plasma concentrations of carbamazepine (for both anticonvulsant effects and relief of pain of trigeminal neuralgia) are usually 3–14 mcg/mL. Some investigators have noted that nystagmus frequently occurs when plasma concentrations are greater than 4 mcg/mL and that ataxia, dizziness, and anorexia often occur when plasma concentrations are 10 mcg/mL or greater. There appears to be a wide variation in steady-state plasma concentrations produced by specific daily dosages of carbamazepine (e.g., daily dosages of 800 mg, 1.2 g, or 1.6 g may produce plasma concentrations of 2–10 mcg/mL).

In one study, when carbamazepine extended-release capsules (Carbatrol®) were administered as a single 400-mg dose with a high-fat meal, the rate, but not the extent, of carbamazepine absorption was increased when compared with administration of the capsules in the fasting state. Results of a multiple-dose study of the extended-release capsules indicate that when these capsules are administered after a meal, peak steady-state plasma concentrations are within the therapeutic range. When the extended-release capsules of carbamazepine (Carbatrol®) are broken and the beads sprinkled over applesauce prior to administration, the pharmacokinetic profile of the drug is similar to that following oral administration of the intact capsule to fasting individuals. The manufacturer of carbamazepine extended-release capsules states that the elimination half-life of the drug does not differ substantially between fasted and nonfasted conditions of administration.

■ **Distribution** Carbamazepine is widely distributed in the body; the drug has been detected in CSF (approximately 15–22% of serum concentrations), the brain (at autopsy), duodenal fluids, bile, and saliva. A major metabolite, carbamazepine 10,11-epoxide, has also been detected in CSF. Carbamazepine rapidly crosses the placenta (i.e., 30–60 minutes) and accumulates in fetal tissues, with higher concentrations in the liver and kidney than in brain and lungs. Carbamazepine and its epoxide metabolite are distributed in breast milk. The ratio of the concentration in breast milk to that in plasma is approximately 0.4 for the drug and 0.5 for the epoxide metabolite.

In vitro studies indicate that at plasma concentrations of 1–50 mcg/mL, 75–90% of the drug is bound to plasma proteins.

■ **Elimination** Carbamazepine has a relatively long plasma half-life, variously reported to be 8–72 hours. The variability results in part because carbamazepine can induce its own metabolism; autoinduction of metabolism usually is completed after 3–5 weeks of a fixed dosing regimen. The plasma half-life generally ranges from 25–65 hours initially and from 12–17 hours with multiple dosing.

The metabolic fate of carbamazepine has not been completely elucidated. A major metabolic pathway appears to be oxidation by microsomal enzymes in the liver (principally cytochrome P-450 isoform 3A4) to form carbamazepine 10,11-epoxide (CBZ-E), which is almost completely metabolized to *trans*-10,11-dihydroxy-10,11-dihydrocarbamazepine (*trans*-CBZ-diol) and excreted in urine mainly unconjugated. CBZ-E has anticonvulsant activity in animals and potent analgesic activity in patients with trigeminal neuralgia. CBZ-E also has been implicated as contributing to adverse neurologic effects of the drug. Carbamazepine is more rapidly metabolized to CBZ-E in children than in adults. In children younger than 15 years of age, there is an inverse relationship between the CBZ-E/CBZ ratio and increasing age; this ratio was reported to be 0.44 in children younger than 1 year old and 0.18 in children 10–15 years of age. Carbamazepine also undergoes aromatic hydroxylation to form 2-hydroxycarbamazepine and 3-hydroxycarbamazepine. The pathway is not clearly determined, but the drug also undergoes metabolism to form 9-hydroxymethyl-10-carbamoyl-acridan. Carbamazepine and its metabolites are excreted in urine. Only about 1–3% of the drug is excreted in urine unchanged. Carbamazepine induces liver microsomal enzymes and thus may accelerate its own metabolism and that of other concomitantly administered drugs that are metabolized by these enzymes. (See Drug Interactions.)

Chemistry and Stability

■ **Chemistry** Carbamazepine is an iminostilbene derivative that is used as both an anticonvulsant and for the relief of pain associated with trigeminal neuralgia (tic douloureux). Carbamazepine is structurally related to the tricyclic antidepressants such as amitriptyline and imipramine. Carbamazepine occurs as a white to off-white powder and is practically insoluble in water and soluble in alcohol and in acetone.

The multi-compartment, extended-release capsule formulation of carbamazepine (Carbatrol®) contains 3 different types of beads: immediate-, extended-, and enteric-release beads. The 3 bead types are combined in a specific ratio to allow for twice-daily dosing.

■ **Stability** Carbamazepine tablets, extended-release tablets, and chewable tablets should be stored in tight, light-resistant containers at temperatures not exceeding 30°C. Carbamazepine extended-release capsules should be stored in tight, light-resistant containers at 15–25°C. Because dissolution characteristics and associated oral bioavailability of carbamazepine tablets may be affected substantially by moisture, patients should be cautioned to keep containers of the tablets tightly closed and in a dry location; away from areas with excessive moisture (e.g., showers, bathrooms, humidifiers). Carbamazepine tablets may lose one-third or more of their oral bioavailability when exposed to excessive moisture. Tablets continuously exposed to 97% relative humidity at room temperature for 2 weeks become hardened and dissolve poorly.

Carbamazepine oral suspension should be stored in tight, light-resistant containers at temperatures not exceeding 30°C; freezing of the oral suspension should be avoided.

Testing has shown that mixing carbamazepine oral suspension either with chlorpromazine oral solution or with liquid thioridazine preparations results in a rubbery, orange precipitate. It is not known whether the development of this precipitate results in decreased bioavailability of either carbamazepine or the other drugs. The extent to which this interaction occurs with other liquid preparations also is not known. Therefore, the manufacturer recommends that carbamazepine oral suspension not be administered simultaneously with other liquid preparations.

For further information on pharmacology, cautions, and dosage and administration of carbamazepine, see the Anticonvulsants General Statement 28:12.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Felbamate

■ Felbamate, a dicarbamate, is an anticonvulsant.

Uses

In July 1993, felbamate (Felbatol®) originally was approved by the US Food and Drug Administration (FDA) for use as monotherapy or in combination with other anticonvulsant agents in the management of partial seizures with or without secondary generalization in adults. Felbamate also was approved by FDA at that time for use in combination with other anticonvulsant agents in the management of partial and generalized seizures associated with Lennox-Gastaut syndrome in children and has been designated an orphan drug by FDA for the treatment of this latter syndrome. However, because use of the drug has since been associated with marked increases in the incidences of **aplastic anemia** and **acute hepatic failure**, the manufacturer in conjunction with FDA warns that the drug should *only* be initiated or continued in the management

The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. Anyone considering the use of doxepin in a child or adolescent for any clinical use must therefore balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

■ **Lactation** Limited data indicate that doxepin and its active *N*-demethylated metabolite are distributed into milk. Sedation and serious respiratory depression were reported in a nursing infant whose mother was receiving 75 mg of doxepin daily; substantial concentrations of the active metabolite of the drug were detected in the infant's serum and urine. In addition, poor sucking and swallowing while nursing, drowsiness, muscle hypotonia, and vomiting were reported in a nursing infant whose mother was receiving 35 mg of doxepin daily. Because of the potential for serious adverse reactions to doxepin and/or its active metabolite in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Pharmacokinetics

■ **Absorption** The pharmacokinetics of doxepin have not been extensively studied, but the drug is well absorbed from the GI tract in animals. Peak plasma concentrations usually occur within 2 hours after oral administration of the drug.

■ **Distribution** Doxepin is highly bound to plasma proteins.

Limited data indicate that doxepin and its active *N*-demethylated metabolite are distributed into milk in concentrations reportedly ranging from about 30–140% and 10–115%, respectively, of those in maternal serum and that substantial concentrations of the active metabolite have been detected in the serum and urine of nursing infants whose mothers were receiving 75–150 mg of doxepin daily.

■ **Elimination** The plasma half-life of doxepin is 6–24.5 hours. The drug appears to be metabolized via the same pathways as are other tricyclic antidepressants; its *N*-demethylated metabolite is pharmacologically active.

Chemistry and Stability

■ **Chemistry** Doxepin hydrochloride is a dibenzoxepin-derivative tricyclic antidepressant. The drug occurs as a white powder, is freely soluble in water and in alcohol, and has a pK_a of 8. Doxepin hydrochloride oral concentrate has a pH of 4–7.

■ **Stability** Doxepin hydrochloride capsules should be stored in tight, light-resistant containers at a temperature between 15–30°C and the oral concentrate should be stored at a temperature between 20–25°C. Commercially available doxepin hydrochloride capsules have an expiration date of 36 months and the oral concentrate has an expiration date of 24 months following the date of manufacture.

Doxepin hydrochloride oral concentrate is physically incompatible with many carbonated beverages, but is compatible with some other beverages. (See Dosage and Administration: Administration.) Bulk preparation and storage of dilutions of the commercially available oral concentrate are not recommended by the manufacturers.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of doxepin, see the Tricyclic Antidepressants General Statement 28:16.04.28.

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Imipramine Hydrochloride
Imipramine Pamoate

■ Imipramine is a dibenzazepine-derivative tricyclic antidepressant.

Dosage and Administration

■ **Administration** Imipramine hydrochloride and imipramine pamoate are administered orally. Although imipramine hydrochloride has been administered in up to 4 divided doses throughout the day, it is long-acting and the entire oral daily dose may be administered at one time. Imipramine pamoate may also be used to administer the daily oral dose of imipramine, but it has no advantages over the hydrochloride. Administration of the entire daily dose at bedtime may reduce daytime sedation; patients who experience insomnia and stimulation may be given the entire daily dose in the morning.

■ **Dosage** Dosage of imipramine salts is expressed in terms of imipramine hydrochloride.

Patients should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Major Depressive Disorder There is a wide range of oral dosage requirements, and dosage must be carefully individualized. Initial dosages of imipramine should be low and generally range from 75–100 mg daily, depending on the severity of the condition being treated. Dosage may be gradually adjusted to the level that produces maximal therapeutic effect with minimal toxicity and may range up to 300 mg daily. Hospitalized patients under close supervision may generally be given higher dosages than outpatients, and manufacturers state that dosages of greater than 200 mg daily are not recommended for outpatients. Geriatric patients should usually be given lower than average dosages. Manufacturers state that therapy should be initiated with 25–50 mg daily as imipramine hydrochloride (e.g., Tofranil®) in these patients and that optimal dosage rarely exceeds 100 mg daily. If the daily dosage is established at 75 mg or more, imipramine pamoate (e.g., Tofranil®-PM) may be administered. Maximum antidepressant effects may not occur for 2 or more weeks after therapy is begun.

After symptoms are controlled, dosage should be gradually reduced to the lowest level that will maintain relief of symptoms. If maintenance therapy is necessary, manufacturers recommend an adult dosage of 50–150 mg daily. To avoid the possibility of precipitating withdrawal symptoms, imipramine should not be terminated abruptly in patients who have received high dosage for prolonged periods.

Functional Enuresis in Children For the treatment of functional enuresis in children who are at least 6 years of age, the usual initial oral dosage of imipramine hydrochloride is 25 mg daily, administered 1 hour prior to bedtime. If a satisfactory response is not obtained within 1 week, dosage may be increased to 50 mg nightly for children younger than 12 years of age or 75 mg nightly for children 12 years of age and older. Dosages higher than 75 mg daily do not improve results and may increase the risk of adverse reactions. For children who are early-night bedwetters, better results may be obtained by administering 25 mg in midafternoon and again at bedtime. Dosage of imipramine hydrochloride for the treatment of functional enuresis in children should not exceed 2.5 mg/kg daily. Long-term effects of the drug in children have not been determined; therefore, after a satisfactory response has been maintained, imipramine hydrochloride should be gradually withdrawn. If dosage is gradually reduced after a favorable response of many weeks, relapses may be less frequent; children who relapse may not respond to subsequent treatment with imipramine. (See Cautions: Pediatric Precautions.)

Cautions

Imipramine shares the pharmacologic actions, uses, and toxic potentials of the tricyclic antidepressants, and the usual precautions of tricyclic antidepressant administration should be observed. Patients should be fully advised about the risks, especially suicidal thinking and behavior (suicidality), associated with tricyclic antidepressant therapy. For a complete discussion, see Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.

Although the clinical importance is not known, ECG changes have been reported in pediatric patients receiving twice the recommended maximum daily dosage.

■ **Pediatric Precautions** Imipramine hydrochloride is used for the treatment of enuresis in children 6 years of age or older, but safety and efficacy of the drug for the treatment of this condition in younger children or for the treatment of any other condition in pediatric patients have not been established. The manufacturer of imipramine *pamoate* states that the drug should not be used in children of any age because of the high potency and risk of acute overdose.

The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. However, FDA also states that depression and certain other psychiatric disorders are themselves associated with an increased risk of suicide. Anyone considering the use of imipramine in a child or adolescent for any clinical use must therefore balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions, in the Tricyclic Antidepressants General Statement 28:16.04.28.)

Pharmacokinetics

■ **Absorption** In studies with radiolabeled imipramine, the drug was completely absorbed from the GI tract. Peak plasma concentrations of imipramine occur within 1–2 hours after oral administration and 30 minutes after IM administration (no longer commercially available in the US).

■ **Distribution** Limited data indicate that imipramine and its active metabolite, desipramine, are distributed into milk in concentrations similar to those present in maternal plasma.

■ **Elimination** The plasma half-life of imipramine ranges from 8–16 hours. Imipramine is metabolized via the same pathways as are other tricyclic antidepressants; desipramine, its *N*-monodemethylated metabolite, is pharmacologically active. Approximately 40% of a dose of imipramine is excreted in urine as inactive metabolites within 24 hours and 70% within 72 hours; small amounts are excreted in feces via biliary elimination.

Chemistry and Stability

■ **Chemistry** Imipramine is a dibenzazepine-derivative tricyclic antidepressant. The drug is commercially available as the hydrochloride and pamoate salts.

Imipramine hydrochloride occurs as a white to off-white, odorless or practically odorless, crystalline powder and is freely soluble in water and in alcohol. Imipramine pamoate occurs as a fine yellow powder and is insoluble in water and soluble in alcohol. Imipramine hydrochloride has a pK_a of 9.5.

■ **Stability** Imipramine hydrochloride turns yellowish or reddish on exposure to light; slight discoloration does not affect potency, but marked discoloration is associated with loss of potency. Solutions of imipramine hydrochloride are stable at pH 4–5. During storage, minute crystals may form in imipramine hydrochloride injection (no longer commercially available in the US); the efficacy of the preparation is unaltered if the crystals are redissolved by immersing the ampul in hot water for 1 minute.

Imipramine hydrochloride tablets and imipramine pamoate capsules should be stored in tight containers at a temperature between 15–30°C. Commercially available oral imipramine hydrochloride preparations have expiration dates of 3–5 years (depending on the manufacturer) following the date of manufacture. Commercially available imipramine pamoate capsules have an expiration date of 3 years following the date of manufacture.

For further information on chemistry, pharmacology, pharmacokinetics, uses, cautions, acute toxicity, drug interactions, and dosage and administration of imipramine, see the Tricyclic Antidepressants General Statement 28:16.04.28.

Maprotiline Hydrochloride

■ Maprotiline hydrochloride is a tetracyclic antidepressant that is pharmacologically similar to the tricyclic antidepressants.

Uses

Maprotiline hydrochloride is used in the treatment of depressive affective (mood) disorders, including dysthymic disorder (depressive neurosis) and major depressive disorder. The drug has been used for the depressive phase of bipolar disorder; however, hypomanic or manic episodes may occur when the drug is given to patients with this disorder and other antidepressants (e.g., bupropion, selective serotonin-reuptake inhibitors) generally are preferred when an antidepressant is considered necessary in such patients. (See Considerations in Choosing Therapy for Depressive Episodes under Uses: Bipolar Disorder, in Lithium Salts 28:28.) Maprotiline is effective for the relief of anxiety associated with depression. Most studies comparing maprotiline with amitriptyline or imipramine in the treatment of patients with various types of depression have not demonstrated superiority of maprotiline over these tricyclic antidepressants. Although maprotiline has been reported to have a slightly more rapid onset of action than either amitriptyline or imipramine in some studies, this finding has not been adequately established.

For further information on treatment of major depressive disorder and considerations in choosing the most appropriate antidepressant for a particular patient, including considerations related to patient tolerance, patient age, and cardiovascular, sedative, and suicidal risks, see Considerations in Choosing Antidepressants under Uses: Major Depressive Disorder, in the Tricyclic Antidepressants General Statement 28:16.04.28.

Dosage and Administration

■ **Administration** Maprotiline hydrochloride is administered orally. Although maprotiline has been administered in 3 divided doses throughout the day, it is long-acting and the entire daily dose may be administered at one time.

Dispensing and Administration Precautions Dispensing errors have occurred because of the similarity in spelling between Ludiomil® (the former trade name for maprotiline hydrochloride; no longer commercially available under this trade name in the US) and Lamictal® (the trade name for lamotrigine, an anticonvulsant). Therefore, extra care should be exercised in ensuring the accuracy of both oral and written prescriptions for Ludiomil® and Lamictal®. The manufacturer of Lamictal® (GlaxoSmithKline) recommends that clinicians consider including the intended use of the particular drug on the prescription, in addition to alerting patients to carefully check the drug they receive and promptly bring any question or concern to the attention of the dispensing pharmacist. The manufacturer of Lamictal® also recommends that pharmacists assess various measures of avoiding dispensing errors and implement them as appropriate (e.g., by computerized filling and handling of prescriptions, patient counseling). (See Cautions.)

■ **Dosage** There is a wide range of dosage requirements, and dosage of maprotiline hydrochloride must be carefully individualized. The manufacturer suggests that the risk of seizures may be decreased by initiating therapy with low dosages of the drug. Initial dosages should be low, generally 75 mg daily in outpatients with mild to moderate depression, although a lower initial dosage may be used in some patients (e.g., geriatric patients). Because of the long elimination half-life of maprotiline, the initial dosage should be maintained for 2 weeks. Depending on tolerance and response, the daily dose may then be gradually increased in 25-mg increments. In most outpatients, a maximum dosage of 150 mg daily will be effective; it is recommended that this dosage be exceeded only in very severely depressed patients. Severely depressed hospitalized patients under close supervision may generally be given higher dosages than outpatients; such patients may be given an initial dosage of 100–150 mg daily which may be increased cautiously. Most hospitalized patients with moderate to severe depression will respond to a dosage of 150 mg daily, but dosages as high as 225 mg daily may be necessary in some patients; dosage should not exceed 225 mg daily. Geriatric patients (i.e., patients older than 60 years of age) should usually be given lower than average dosages; 50–75 mg daily is generally satisfactory for these patients. Antidepressant effects usually occur within 2–3 weeks in most patients who respond to maprotiline therapy and may occur within 3–7 days.

fate, dosage of these agents must be carefully adjusted because of the additive central depressant effects.

■ **Neuromuscular Blocking Agents** Excessive neuromuscular blockade has occurred in patients receiving parenteral magnesium sulfate and a neuromuscular blocking agent; these drugs should be administered concomitantly only with caution.

■ **Cardiac Glycosides** Magnesium salts should be administered with extreme caution in digitalized patients, because serious changes in cardiac conduction which can result in heart block may occur if administration of calcium is required to treat magnesium toxicity.

Pharmacology

Magnesium is the fourth most abundant cation in the body and is essential for the function of important enzymes, including those related to the transfer of phosphate groups, all reactions involving ATP, and every step related to the replication and transcription of DNA and the translation of mRNA. Magnesium also is required for cellular energy metabolism and is involved in membrane stabilization, nerve conduction, iron transport, and calcium-channel activity.

When administered parenterally in doses sufficient to produce hypermagnesemia (serum magnesium concentrations greater than 2.5 mEq/L), the drug may depress the CNS and block peripheral neuromuscular transmission, producing anticonvulsant effects. The exact mechanism of this depressant activity is not fully known; however, excess magnesium appears to decrease the amount of acetylcholine liberated by the motor nerve impulse. When serum concentrations of magnesium exceed 4 mEq/L, deep-tendon reflexes may be depressed. At serum concentrations of 10 mEq/L, deep-tendon reflexes may disappear and respiratory paralysis may occur. Serum magnesium concentrations in excess of 12 mEq/L may be fatal. Complete heart block can also occur at high serum concentrations of magnesium (approximately 10 mEq/L). Animal studies suggest that the effect of magnesium ions on cardiac muscle is to slow the rate of the sinoatrial node impulse formation and prolong conduction time. Limited data in patients with no evidence of heart disease indicate that IV infusion of magnesium prolongs PR interval, H(atria-His bundle) interval, antegrade AV nodal effective refractory period, and sinoatrial conduction time. Available data also suggest that magnesium produces systemic and coronary vasodilatation, possesses antiplatelet activity, suppresses automaticity in partially depolarized cells, and protects myocytes against calcium overload under conditions of ischemia by inhibiting calcium influx especially at the time of reperfusion. However, the clinical benefit of administering magnesium in patients with acute myocardial infarction has not been fully determined. (See Uses: Acute Myocardial Infarction.) Magnesium also acts peripherally, producing vasodilation. Moderate doses produce flushing and sweating; and higher doses lower blood pressure. Both the CNS depression and the peripheral neuromuscular transmission blockade produced by hypermagnesemia can be antagonized by administration of excess calcium.

Pharmacokinetics

When magnesium sulfate is administered IV, the onset of action is immediate and the duration of action is about 30 minutes. Following IM administration of the drug, the onset of action occurs in about 1 hour and the duration of action is 3–4 hours. As an anticonvulsant, effective serum concentrations of magnesium have been reported to range from 2.5–7.5 mEq/L.

Magnesium readily crosses the placenta and is distributed into milk following parenteral administration of magnesium sulfate. Milk concentrations of magnesium are increased for only about 24 hours after discontinuance of parenteral magnesium sulfate therapy; the amount of magnesium ingested by a nursing infant during this period is probably too small to be of clinical importance.

Magnesium sulfate is excreted by the kidneys at a rate that varies from one patient to another but that is directly proportional to the serum concentration and glomerular filtration.

Chemistry and Stability

■ **Chemistry** Parenteral magnesium sulfate exhibits anticonvulsant properties. Magnesium sulfate occurs as small, colorless crystals; usually needle-like, with a cooling, saline, bitter taste and is freely soluble in water and sparingly soluble in alcohol. The drug effloresces in warm, dry air. Each gram of magnesium sulfate heptahydrate contains 8.1 mEq of magnesium. The pHs of commercially available magnesium sulfate injection and magnesium sulfate in 5% dextrose injection are adjusted with sodium hydroxide and/or sulfuric acid; the injections have pHs of 3.5–7.

■ **Stability** Magnesium sulfate injection and magnesium sulfate in 5% dextrose injection should be stored at a temperature less than 40°C, preferably between 15–30°C; freezing should be avoided.

Magnesium sulfate is converted to the monohydrate when heated to 150–160°C. Magnesium sulfate is incompatible with alkali hydroxides (forming insoluble magnesium hydroxide), with alkali carbonates (forming basic carbonates), and with salicylates (forming basic salicylates). The drug reacts with arsenates, phosphates, and tartrates, precipitating the corresponding magnesium salts. Lead, barium, strontium, and calcium react with magnesium sulfate resulting in precipitation of the respective sulfates. Specialized references should be consulted for specific compatibility information. Following withdrawal of a dose from one of the solutions which do not contain preservatives, any unused portion should be discarded.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Magnesium Sulfate

Oxcarbazepine

■ Oxcarbazepine is an anticonvulsant agent.

Uses

■ **Seizure Disorders** ***Partial Seizures*** Oxcarbazepine is used as monotherapy or in combination with other anticonvulsants in the management of partial seizures in adults and children 4 years of age and older.

Monotherapy. Efficacy of oxcarbazepine monotherapy in patients with partial seizures has been established in several multicenter, randomized, double-blind clinical trials. These studies have included adults and children 8 years of age or older. In one placebo-controlled, randomized clinical trial in patients with refractory partial seizures (undergoing evaluation for epilepsy surgery) who had been withdrawn from anticonvulsants prior to randomization, oxcarbazepine at dosages up to 2400 mg daily for 10 days was more effective than placebo. Results of another placebo-controlled clinical trial in patients with newly diagnosed or recent-onset partial seizures indicate that oxcarbazepine dosages up to 1200 mg daily for 84 days were more effective than placebo. In addition, therapy with oxcarbazepine 2400 mg daily for up to 126 days was substantially more effective than oxcarbazepine 300 mg daily in 2 other clinical trials in patients with partial seizures who had been withdrawn from therapy with 1 or 2 anticonvulsants because of inadequate control.

Results of several multicenter, randomized, double-blind monotherapy trials in patients with newly diagnosed or previously untreated partial or generalized seizures indicate that oxcarbazepine exhibits anticonvulsant activity similar to carbamazepine, phenytoin, or valproate sodium.

Combination Therapy Efficacy of oxcarbazepine as adjunctive therapy in patients with partial seizures was established in 2 multicenter, placebo-controlled, randomized, double-blind clinical trials in patients with partial seizures (one in adults and one in children 3–17 years of age). In both studies, patients initially were stabilized with optimum dosages of 1–3 anticonvulsants during an 8-week baseline period; those experiencing at least 8 (minimum 1–4 per month) partial seizures during this phase were randomized to receive oxcarbazepine or placebo during a dosage titration period of 2 weeks followed by a 14- or 24-week maintenance period in children or adults, respectively. Efficacy of oxcarbazepine in these studies was evaluated in terms of the change in seizure frequency (i.e., the median decrease [or increase] in average monthly [28-day] seizure rate). Adult patients receiving oxcarbazepine 600, 1200, or 2400 mg daily or placebo experienced a median decrease in seizure frequency of about 26, 40, 50, or 8%, respectively, while pediatric patients receiving oxcarbazepine maintenance dosages ranging from 30–46 mg/kg daily (depending on baseline body weight) or placebo experienced a median decrease in seizure frequency of about 35 or 9%, respectively.

■ **Bipolar Disorder** Oxcarbazepine has been used alone or in combination with other drugs (e.g., antipsychotic agents) for the treatment and prevention of acute manic or mixed episodes in patients with bipolar disorder†. Limited data suggest that oxcarbazepine may have equivalent efficacy and better tolerability than carbamazepine for this indication. However, the American Psychiatric Association (APA) currently recommends that oxcarbazepine be reserved for patients unable to tolerate or who had an inadequate therapeutic response to first-line agents such as lithium and valproate (e.g., valproic acid, divalproex). For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Dosage and Administration

■ **General** Oxcarbazepine tablets and suspension are administered orally twice daily without regard to meals.

Oxcarbazepine suspension should be shaken well prior to administration of each dose. The appropriate measured dose of the suspension should be administered using an oral dosing syringe. The oral suspension may be added to a small glass of water or swallowed directly from the syringe. After each use, the oral syringe should be rinsed with warm water and allowed to dry thoroughly.

The manufacturer of Trileptal® states that oral bioavailability of oxcarbazepine tablets appears to be similar to that of the suspension and, therefore, these preparations can be used interchangeably on a mg-for-mg basis.

Patients currently receiving or beginning therapy with oxcarbazepine and/or any other anticonvulsant for any indication should be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or any unusual changes in mood or behavior. (See Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Partial Seizures **Monotherapy.** In adults and children older than 16 years of age with partial seizures being transferred from other anticonvulsant drug therapy to monotherapy with oxcarbazepine, the recommended initial dosage of oxcarbazepine is 600 mg daily given in 2 equally divided doses. Oxcarbazepine dosage may be increased by 600-mg daily increments at approximately weekly intervals to a recommended daily dosage of 2400 mg, usually within 2–4 weeks. As oxcarbazepine replaces the existing anticonvulsant therapeutic regimen, dosage of the other anticonvulsant(s) is simultaneously reduced and discontinued over 3–6 weeks. Patients should be observed during this transition phase.

In adults not receiving anticonvulsant drug therapy, the recommended initial daily dosage of oxcarbazepine as initial monotherapy is 600 mg daily administered in 2 equally divided doses. Dosage should be increased by 300-mg daily increments every third day to a maximum daily dosage of 1200 mg.

In children 4–16 years of age with partial seizures being transferred from other anticonvulsant drug therapy to monotherapy with oxcarbazepine, the recommended initial dosage of oxcarbazepine is 8–10 mg/kg daily given in 2 equally divided doses. Oxcarbazepine dosage may be increased in increments of up to 10 mg/kg daily at weekly intervals to achieve the recommended maintenance dosage. (See Table 1.) As oxcarbazepine replaces the existing anticonvulsant therapeutic regimen, dosage of the other anticonvulsant(s) is simultaneously reduced and discontinued over 3–6 weeks.

Children 4–16 years of age not receiving anticonvulsant drug therapy may initiate therapy with oxcarbazepine at a dosage of 8–10 mg/kg daily given in 2 equally divided doses. Dosage may be increased in increments of 5 mg/kg daily every third day until the recommended maintenance dosage is achieved. (See Table 1.)

Table 1. Recommended Range of Maintenance Dosages in Children Receiving Oxcarbazepine Monotherapy

Weight (kg)	Dosage Range (mg/day)
20	600–900
25	900–1200
30	900–1200
35	900–1500
40	900–1500
45	1200–1500
50	1200–1800
55	1200–1800
60	1200–2100
65	1200–2100
70	1500–2100

Combination Therapy. For adjunctive therapy in the management of partial seizures in adults and children older than 16 years of age, the initial dosage of oxcarbazepine is 600 mg daily administered in 2 equally divided doses. Oxcarbazepine dosage may be increased by 600-mg daily increments at approximately weekly intervals to a recommended daily dosage of 1200 mg. Although efficacy may be somewhat higher in patients receiving oxcarbazepine dosages exceeding 1200 mg daily, most patients cannot tolerate daily dosages of 2400 mg, mainly because of adverse CNS effects. The manufacturers recommend that patients be observed closely and that plasma concentrations of concomitantly administered anticonvulsants be monitored during dosage titration of oxcarbazepine since plasma concentrations of these drugs may be altered when dosage of oxcarbazepine exceeds 1200 mg daily.

For adjunctive therapy in the management of partial seizures in children 4–16 years of age, the recommended initial dosage of oxcarbazepine (administered in 2 equally divided doses) is 8–10 mg/kg daily, generally not exceeding 600 mg daily. The target daily maintenance dosage of 900–1800 mg depends on patient weight (900, 1200, or 1800 mg in children weighing 20–29, 29.1–39, or more than 39 kg, respectively) and should be reached within 2 weeks. Since clearance of the drug appears to be increased (by 30–40%) in children younger than 8 years of age compared with that in adults, such children received the highest maintenance dosage in controlled clinical trials.

■ **Special Populations** The manufacturers state that the initial dosage of oxcarbazepine should be 300 mg daily (one-half of the usual starting dosage) in patients with renal impairment (creatinine clearance less than 30 mL/minute); dosage should be increased slowly to achieve the desired clinical response.

In general, no dosage adjustments are necessary in patients with mild to moderate hepatic impairment.

Cautions

■ **Contraindications** Known hypersensitivity to oxcarbazepine or any ingredient in the formulation.

■ **Warnings/Precautions** ***Warnings*** **Hyponatremia.** Clinically important hyponatremia (serum sodium concentrations less than 125 mEq/L) has been reported in 2.5% of patients receiving oxcarbazepine in clinical studies, versus 0% in patients receiving placebo or active controls (i.e., carbamazepine, phenobarbital, phenytoin, valproic acid). Generally, hyponatremia occurred during the first 3 months of oxcarbazepine therapy, although this adverse effect was reported in some patients more than 1 year after initiation of such therapy. In clinical studies, most patients with hyponatremia were asymptomatic. However, it should be considered that these patients were monitored frequently, and in some patients dosage of oxcarbazepine was reduced or discontinued or the fluid intake restricted. It is not known whether these measures prevented development of hyponatremia. Symptomatic hyponatremia was reported in some patients during postmarketing surveillance. In clinical trials in patients developing hyponatremia, serum sodium concentrations returned to baseline values a few days after discontinuance of the drug. The manufacturers state that monitoring serum sodium concentrations should be considered during maintenance therapy with oxcarbazepine, particularly in patients concurrently receiving other drugs known to decrease serum sodium concentrations (e.g., drugs associated with inappropriate antidiuretic hormone secretion [SIADH]) or in those with symptoms of hyponatremia (e.g., nausea, malaise, headache, lethargy, confusion, obtundation, increase in seizure frequency or severity).

Suicidality Risk. The US Food and Drug Administration (FDA) has alerted healthcare professionals about an increased risk of suicidality (suicidal behavior or ideation) observed in an analysis of studies using various anticonvulsants, including oxcarbazepine, compared with placebo. The analysis of suicidality reports from placebo-controlled studies involving 11 anticonvulsants (i.e., carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, zonisamide) in patients with epilepsy, psychiatric disorders (e.g., bipolar disorder, depression, anxiety), and other conditions (e.g., migraine, neuropathic pain) found that patients receiving anticonvulsants had approximately twice the risk of suicidal behavior or ideation (0.43%) compared with patients receiving placebo (0.24%). This increased suicidality risk was observed as early as one week after beginning therapy and continued through 24 weeks. Although patients treated with an anticonvulsant for epilepsy, psychiatric disorders, and other conditions were all found to have an increased suicidality risk compared with those receiving placebo, the relative suicidality risk was higher for patients with epilepsy compared with those receiving anticonvulsants for other conditions.

Based on the current analysis of the available data, FDA recommends that clinicians inform patients, their families, and caregivers about the potential for an increase in the risk of suicidality with anticonvulsant therapy and that all patients currently receiving or beginning therapy with any anticonvulsant for any indication be closely monitored for the emergence or worsening of depression, suicidal thoughts or behavior (suicidality), and/or unusual changes in mood or behavior. Symptoms such as anxiety, agitation, hostility, hypomania, and mania may be precursors to emerging suicidality. Clinicians who prescribe oxcarbazepine or any other anticonvulsant should balance the risk of suicidality with the risk of untreated illness. Epilepsy and many other illnesses for which anticonvulsants are prescribed are themselves associated with an increased risk of morbidity and mortality and an increased risk of suicidal thoughts and behavior. If suicidal thoughts and behavior emerge during anticonvulsant therapy, the clinician should consider whether these symptoms may be related to the illness being treated. (See Advice to Patients.)

Discontinuance of Oxcarbazepine. Because of the possibility of increased seizure frequency, anticonvulsant drugs, including oxcarbazepine, should be withdrawn gradually. If a hypersensitivity reaction occurs, discontinue oxcarbazepine and initiate alternative therapy.

Sensitivity Reactions **History of Carbamazepine Hypersensitivity.** Approximately 25–30% of patients with a history of carbamazepine hypersensitivity will develop hypersensitivity to oxcarbazepine. Therefore, oxcarbazepine should only be used in patients with a history of such hypersensitivity if the potential benefits justify the potential risk to the patient. If a hypersensitivity reaction develops, oxcarbazepine should be discontinued immediately.

Dermatologic and Hypersensitivity Reactions. Serious dermatologic reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis, have been reported in adults and children receiving oxcarbazepine; reactions have been life-threatening, have required hospitalization, and rarely have been fatal. The incidence of Stevens-Johnson syndrome and toxic epidermal necrolysis reported in patients receiving oxcarbazepine exceeds the rate in the general population by threefold to tenfold. The median time to onset of these reactions was 19 days. Recurrence of serious dermatologic reactions following rechallenge with oxcarbazepine has occurred.

If a skin reaction develops in a patient receiving oxcarbazepine, consider discontinuance of the drug and initiation of therapy with another anticonvulsant agent.

Multiorgan hypersensitivity reactions occurring days to weeks or months (range 4–60 days) after initiation of oxcarbazepine therapy have been reported in adults and pediatric patients. Although these reactions have been reported rarely, many of these patients required hospitalization, and some reactions were considered life-threatening. Manifestations may include (but are not limited to) fever, rash, lymphadenopathy, hepatitis, abnormal liver function test results, eosinophilia, thrombocytopenia, neutropenia, pruritus, nephritis, oliguria, hepatorenal syndrome, arthralgia, and asthenia.

If a multiorgan hypersensitivity reaction is suspected, discontinue oxcarbazepine and initiate alternative therapy.

Possibility of cross-sensitivity with other drugs that produce multiorgan hypersensitivity reactions exists.

General Precautions **Nervous System Effects.** Neuropsychiatric effects reported during oxcarbazepine treatment are classified into 3 categories: impaired cognitive or psychomotor performance including difficulties in concentrating, language, and speech; somnolence or fatigue; and coordination difficulties (e.g., ataxia, gait disturbances). (See Suicidality Risk under Warnings/Precautions: Warnings, in Cautions.)

Specific Populations **Pregnancy.** Category C. (See Users Guide.) North American Antiepileptic Drug (NAAED) Pregnancy Registry at 888-233-2334 (for patients); registry information also available on the website http://www.aedpregnancyregistry.org.

The effect of oxcarbazepine on labor and delivery is unknown.

Lactation. Both oxcarbazepine and its active 10-monohydroxy metabolite (MHD) are distributed into milk in humans. Discontinue nursing or the drug, taking into account the importance of the drug to the woman.

Pediatric Use. Safety and efficacy of oxcarbazepine as monotherapy or adjunctive therapy for partial seizures in children younger than 4 years of age have not been established.

Efficacy of oxcarbazepine as adjunctive therapy for partial seizures in children 4–16 years of age established in clinical studies. Efficacy as monotherapy for partial seizures in children 4–16 years of age based on clinical studies and pharmacokinetic and pharmacodynamic considerations.

Oxcarbazepine has not been evaluated in clinical studies in children younger than 2 years of age.

Severe dermatologic and other sensitivity reactions have been reported in pediatric patients. (See Dermatologic and Hypersensitivity Reactions under Warnings/Precautions: Sensitivity Reactions, in Cautions.)

Geriatric Use. Although peak plasma concentrations of MHD and the area under the plasma concentration-time curve (AUC) may be 30–60% higher in adults 60 years of age or older than in younger adults (possibly related to decreases in renal function with age), the manufacturers do not make specific recommendations for dosage adjustment in such patients.

■ **Common Adverse Effects** Adverse effects occurring in 5% or more of patients and more frequently than placebo include dizziness, somnolence, diplopia, fatigue, nausea, vomiting, ataxia, abnormal vision, abdominal pain, tremor, dyspepsia, abnormal gait.

Drug Interactions

■ **Drugs Affecting Hepatic Microsomal Enzymes**

Anticonvulsants Oxcarbazepine may inhibit metabolism of other anticonvulsants (e.g., phenobarbital, phenytoin), possibly via inhibition of the cytochrome P-450 (CYP) isoenzyme 2C19, resulting in increased plasma concentrations of these drugs. Oxcarbazepine dosages exceeding 1200 mg daily may increase plasma phenytoin concentrations by 40% and, therefore, when such dosages of oxcarbazepine are used concomitantly with phenytoin, dosage reduction of phenytoin may be required.

Potent inducers of CYP isoenzymes (e.g., carbamazepine, phenytoin, phenobarbital) may decrease plasma concentrations of oxcarbazepine and its active 10-monohydroxy metabolite (MHD).

Oral Contraceptives Oxcarbazepine may induce metabolism of oral estrogen-progestin contraceptives, possibly via induction of CYP3A4 and CYP3A5, resulting in decreased area under the plasma concentration-time curve (AUC) and consequent decreased efficacy of the contraceptives.

Calcium-channel Blocking Agents Oxcarbazepine may induce metabolism of some calcium-channel blocking agents (e.g., felodipine, verapamil), possibly via induction of CYP3A4 and CYP3A5 isoenzymes, resulting in decreased AUC of the calcium-channel blocking agents.

Description

Oxcarbazepine is an anticonvulsant agent that is structurally and chemically related to carbamazepine. Although the exact mechanism of action of oxcarbazepine is unknown, in vitro electrophysiologic studies indicate that the drug may stabilize excitatory neuronal membranes, inhibit repetitive neuronal firing, and decrease propagation of synaptic impulses by blocking voltage-sensitive sodium channels, actions that may prevent spread of epileptic seizures. Increased potassium conductance and modulation of high-voltage activated calcium channels also may contribute to the anticonvulsant activity of oxcarbazepine. No substantial interactions between the drug and neurotransmitter receptors in the brain have been observed to date.

Oxcarbazepine and its active 10-monohydroxy metabolite (MHD) exhibit anticonvulsant activity in several animal seizure models. Oxcarbazepine protects against electrically induced tonic extension seizures and, to a lesser degree, chemically induced clonic seizures and may abolish or reduce frequency of chronically recurring focal seizures.

Following oral administration, oxcarbazepine is completely absorbed and extensively metabolized in the liver by cytosolic enzymes to MHD (10,11-dihydro-10-hydroxy-5*H*-dibenz[*b*, *f*]azepine-5-carboxamide), which is believed to be responsible for the pharmacologic activity of oxcarbazepine. The oral bioavailabilities of oxcarbazepine tablets and suspension appear to be similar. More than 95% of an oral dose of oxcarbazepine is excreted in urine, mainly as metabolites with less than 1% as unchanged drug; less than 4% is excreted in feces.

Advice to Patients

Importance of providing copy of written patient information (medication guide) each time oxcarbazepine is dispensed.

Risk of hypersensitivity reaction; patients who have had previous hypersensitivity reaction to carbamazepine at increased risk. Importance of immediately reporting hypersensitivity reactions, skin reactions, or fever accompanied by signs and/or symptoms of other organ system involvement (e.g., rash, lymphadenopathy).

Risk of dizziness and somnolence; avoid driving or operating machinery while taking oxcarbazepine until effects of the drug on the individual are known.

Risk of low sodium concentrations in the blood; manifestations may include nausea, extreme drowsiness and/or fatigue, discomfort, headache, confusion, increase in seizure frequency or severity, or dullness.

Importance of patients, family members, and caregivers being aware that anticonvulsants, including oxcarbazepine, may increase the risk of having suicidal thoughts or actions in a very small number of people (about 1 in 500). Advise patients, family members, and caregivers to pay close attention to any day-to-day changes in mood, behavior, and actions; these changes can happen very quickly. They should also be aware of common warning signs that may signal suicide risk (e.g., talking or thinking about wanting to hurt oneself or end one's life, withdrawing from friends and family, becoming depressed or experiencing worsening of existing depression, becoming preoccupied with death and dying, giving away prized possessions). Advise patients, family members, and caregivers to contact the responsible clinician immediately if these or any new and worrisome behaviors occur.

Caution if alcohol is used concomitantly because additive sedative effects may occur.

Importance of not abruptly discontinuing therapy.

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed. Importance of informing women of childbearing age that concomitant use of oxcarbazepine with oral contraceptives may result in decreased efficacy of the contraceptives.

Importance of informing clinicians of existing or contemplated concomitant therapy, including prescription and OTC drugs, as well as concomitant illnesses.

Importance of advising patients of other important precautionary information. (See Cautions.)

Overview* (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Chemistry and Stability

■ **Chemistry** Dextroamphetamine is the dextrorotatory isomer of amphetamine. Dextroamphetamine sulfate occurs as a white, odorless, crystalline powder and has a bitter taste. Dextroamphetamine sulfate is freely soluble in water (about 1:10) and slightly soluble in alcohol (about 1:800). Dextroamphetamine sulfate also is commercially available as fixed-combination preparations with dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

■ **Stability** Preparations containing dextroamphetamine sulfate should be stored in tight, light-resistant containers at 15–30°C.

Preparations

Dextroamphetamine and dextroamphetamine sulfate preparations are subject to control under the Federal Controlled Substances Act of 1970 as schedule II (C-II) drugs.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

*available from one or more manufacturer, distributor, and/or repackager by generic (nonproprietary) name

Lisdexamfetamine Dimesylate

■ Prodrug of dextroamphetamine; noncatechol, sympathomimetic amine with CNS-stimulating activity.

Uses

■ **Attention-Deficit Hyperactivity Disorder** Lisdexamfetamine dimesylate is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD) (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction). Safety and efficacy for this indication have been established in controlled clinical trials in children 6–12 years of age and in adults.

Safety and efficacy of lisdexamfetamine dimesylate in the treatment of ADHD in children 6–12 years of age who met DSM-IV-TR criteria for ADHD (combined type or predominantly hyperactive-impulsive type) have been evaluated in 2 randomized, double-blind, placebo-controlled clinical studies (one phase 2 and one phase 3). The phase 2 crossover study was conducted in an analog classroom environment. In this study, dosage of amphetamines was titrated over a 3-week period using an extended-release formulation of mixed amphetamine salts (Adderall XR®) to a final dosage of 10, 20, or 30 mg daily; the children then were assigned to receive, in randomly determined sequence, 1 week each of treatment with extended-release mixed amphetamine salts (continued at the same dosage), lisdexamfetamine dimesylate (30, 50, or 70 mg

daily, respectively, depending on the titrated amphetamines dosage), and placebo. The primary measure of efficacy was the Swanson, Kotkin, Agler, M-Flynn, and Pelham (SKAMP) deportment score. Assessments performed on day 7 of each treatment period (at various intervals from 2–12 hours after dosing) suggested that behavioral and symptomatic improvements observed with lisdexamfetamine were superior to those observed with placebo and not substantially different from those observed with mixed amphetamine salts. In the phase 3 parallel-group study, improvement in symptom scores, as measured using the ADHD Rating Scale version IV (ADHD-RS-IV), the revised Conners' Parent Rating Scale (CPRS-R), and the Cognitive Global Impression of Improvement (CGI-I) scale, from baseline to study end (4 weeks) was greater in children receiving lisdexamfetamine dimesylate titrated to a fixed, final dosage of 30, 50, or 70 mg daily than in those receiving placebo. Mean changes in symptom scores generally were similar for all 3 lisdexamfetamine dosage levels; however, changes in ADHD-RS-IV scores were numerically greater with the 70-mg dose than with the 30- and 50-mg doses. Symptom control in patients receiving the drug was maintained throughout the day up to 6 p.m.

Safety and efficacy of lisdexamfetamine in adults have been established in one phase 3 forced-titration, double-blind, randomized, placebo-controlled clinical study of 4 weeks' duration in 420 adults who met DSM-IV-TR criteria for ADHD. After a washout period, patients were randomized to receive 30, 50, or 70 mg of lisdexamfetamine dimesylate daily or placebo. All patients receiving lisdexamfetamine initially received 30 mg daily for the first week, with subsequent dosage titrations occurring in 20-mg increments at weekly intervals for those randomized to receive 50 or 70 mg of the drug daily. The primary measure of efficacy was the ADHD Rating Scale (ADHD-RS) score. At study end point (4 weeks), patients randomized to receive lisdexamfetamine demonstrated significant improvements in ADHD symptoms compared with placebo recipients. Significant improvements in ADHD symptoms were evident within the first week of treatment in all lisdexamfetamine groups. Patients randomized to receive lisdexamfetamine dimesylate 70 mg daily showed a greater reduction in ADHD-RS total score at weeks 3 and 4 compared with patients receiving lisdexamfetamine dimesylate 30 mg daily.

For further information on the management of ADHD, including the use of stimulants such as amphetamines, see Uses: Attention Deficit Hyperactivity Disorder in the Amphetamines General Statement 28:20.04, and also in Methylphenidate 28:20.92.

Dosage and Administration

■ **Administration** ***Oral Administration*** Administer once daily in the morning without regard to meals. Because of potential for insomnia, avoid administering in the afternoon.

Capsule may be swallowed whole or may be opened and the entire contents dissolved in water immediately prior to administration; resulting solution should *not* be stored for use at a later time.

Do *not* subdivide capsule contents; do *not* administer a dose less than the entire contents of one capsule.

■ **Dosage** Available as lisdexamfetamine dimesylate; dosage expressed in terms of the salt.

Adjust dosage according to individual response and tolerance; the smallest dose required to produce the desired response should always be used.

When possible, therapy should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued treatment.

Pediatric Patients **Attention Deficit Hyperactivity Disorder.** *Oral*: Children 6–12 years of age: Initially, 30 mg once daily (as initial treatment for ADHD or in patients being switched to lisdexamfetamine from other drugs); dosage may be adjusted in 10- or 20-mg increments at weekly intervals up to a maximum dosage of 70 mg daily.

If the initial 30-mg daily dosage is not tolerated, dosage can be decreased to 20 mg daily.

Long-term use (i.e., exceeding 4 weeks) has not been studied systematically. If used for long-term therapy, periodically reevaluate the usefulness of the drug.

Adults **Attention Deficit Hyperactivity Disorder.** *Oral*: Initially, 30 mg once daily (as initial treatment for ADHD or in patients being switched to lisdexamfetamine from other drugs); dosage may be adjusted in 10- or 20-mg increments at weekly intervals up to a maximum dosage of 70 mg daily.

If the initial 30-mg daily dosage is not tolerated, dosage can be decreased to 20 mg daily.

Long-term use (i.e., exceeding 4 weeks) has not been studied systematically. If used for long-term therapy, periodically reevaluate the usefulness of the drug.

■ **Special Populations** No special population dosage recommendations at this time.

Cautions

■ **Contraindications** Contraindicated in patients with advanced arteriosclerosis, symptomatic cardiovascular disease, moderate to severe hypertension, hyperthyroidism, known hypersensitivity or idiosyncrasy to sympathomimetic amines, glaucoma, or a history of drug abuse; within 14 days of monoamine oxidase (MAO) inhibitor therapy; and in agitated patients.

Although amphetamines generally should not be used in patients with a history of drug abuse, some experts state that this is not an absolute contraindication, provided the patient can be monitored more carefully than would otherwise be indicated.

■ **Warnings/Precautions** ***Warnings*** **Abuse Potential.** Amphetamines have a high potential for abuse. Administration of amphetamines for prolonged periods of time may lead to drug dependence.

Particular attention should be paid to the possibility of individuals obtaining amphetamines for nontherapeutic use or distribution to others, and the drugs should be prescribed or dispensed sparingly. The possibility that family members may abuse the patient's medication should be considered.

Sudden Death and Serious Cardiovascular Events. Possible sudden death and serious cardiovascular events, particularly in individuals who abuse amphetamines.

Sudden unexplained death, stroke, and myocardial infarction have been reported in adults with ADHD receiving usual dosages of stimulants; sudden death also has been reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of the drugs. A small number of cases of sudden unexplained death also has been reported in children without structural cardiac abnormalities receiving amphetamine combinations; however, confounding factors were present in some of these incidents.

Results of one retrospective, case-control epidemiologic study showed a possible association between use of stimulant medications (amphetamine, dextroamphetamine, methamphetamine, methylphenidate, or their derivatives) and sudden unexplained death in healthy children and adolescents. (See Pediatric Use under Warnings/Precautions: Specific Populations, in Cautions.) Given the study limitations, the US Food and Drug Administration (FDA) is unable to conclude that these data affect the overall risk and benefit profile of stimulant medications used to treat ADHD in children and adolescents. Amphetamines or other stimulants should not be discontinued by parents of children or patients receiving these medications for ADHD before consulting with their clinician. Because of postmarketing reports and results of this and other epidemiologic studies, FDA is conducting an ongoing review of safety of amphetamines and other stimulants to evaluate a possible link between use of these agents and sudden death in children. To determine whether there is a direct causal relationship between use of stimulants and serious adverse cardiovascular events, the Agency for Healthcare Research and Quality (AHRQ) and FDA announced in 2007 that they are collaborating on a large study evaluating clinical data on approximately 500,000 adults and children who received these drugs for management of ADHD during a 7-year period ending in 2005; data collection for the study is expected to be completed in 2009.

Thoroughly review medical history (including evaluation for family history of sudden death or ventricular arrhythmia) *and* perform physical examination in all children, adolescents, and adults being considered for stimulant therapy; if initial findings suggest presence of cardiac disease, perform further cardiac evaluation (e.g., ECG, echocardiogram).

In general, *avoid* use of CNS stimulants in patients with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious cardiac conditions. (See Contraindications under Cautions.)

Patients who develop exertional chest pain, unexplained syncope, or other manifestations suggestive of cardiac disease during stimulant therapy should undergo prompt cardiac evaluation.

For further information on screening for cardiac conditions, selecting appropriate candidates for stimulant therapy, and monitoring for treatment-emergent cardiac conditions, see Cardiovascular Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.

Other Warnings and Precautions Least amount of lisdexamfetamine feasible should be prescribed or dispensed at one time in order to minimize possible overdosage.

Effects on Blood Pressure and Heart Rate. Possible modest increases in average blood pressure (i.e., by about 2–4 mm Hg) and heart rate (i.e., by about 3–6 beats/minute); larger increases may occur. Modest increases not expected to have short-term sequelae; however, monitor all patients for *larger* changes in blood pressure and heart rate.

Caution advised in patients with underlying medical conditions that might be affected by increases in blood pressure or heart rate (e.g., hypertension, heart failure, recent myocardial infarction, ventricular arrhythmia).

Exacerbation or Precipitation of Psychotic Symptoms. May exacerbate symptoms of behavior disturbance and thought disorder in patients with preexisting psychotic disorder.

Psychotic symptoms (e.g., hallucinations, delusional thinking) may occur with usual dosages in children and adolescents without prior history of psychotic illness. If psychotic symptoms occur, consider causal relationship to stimulants, and discontinue therapy as appropriate.

Precipitation of Manic Symptoms. May precipitate mixed or manic episodes in ADHD patients with comorbid bipolar disorder; use with caution in these patients. Prior to initiating therapy, carefully screen patients with ADHD and comorbid depressive symptoms to identify risk for bipolar disorder; screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, or depression).

Manic symptoms may occur with usual dosages in children and adolescents

without prior history of mania. If manic symptoms occur, consider causal relationship to stimulants, and discontinue therapy as appropriate.

Aggression. Aggressive behavior and hostility (frequently observed in children and adolescents with ADHD) reported in patients receiving drug therapy for ADHD. No systematic evidence that stimulants cause these adverse effects; however, monitor patients beginning treatment for ADHD for onset or worsening of aggressive behavior or hostility.

Growth Suppression. Long-term (i.e., exceeding 12 months) administration expected to cause at least a temporary suppression of normal weight and/or height patterns in some children and adolescents. Dose-related weight loss reported in children during 4 weeks of therapy with lisdexamfetamine.

Manufacturer recommends monitoring growth during treatment; patients not growing or gaining weight as expected may require temporary discontinuance of treatment. However, the American Academy of Pediatrics states that studies of stimulants in children found little or no decrease in expected height, with any decrease in growth early in treatment being compensated for later on.

Seizures. Possible lowering of seizure threshold in patients with history of seizures, in those with prior EEG abnormalities but no history of seizures, and, very rarely, in those without history of seizures and with no prior evidence of EEG abnormalities. If seizures occur, discontinue therapy.

Visual Effects. Visual disturbances (e.g., difficulty with accommodation, blurred vision) reported with stimulants.

Tics. Amphetamines reported to exacerbate motor and phonic tics and Tourette's syndrome. However, a history of tics or their development during therapy is *not* an absolute contraindication to continued use. Nevertheless, evaluate for presence of tics and Tourette's syndrome in children and their families prior to initiating stimulant therapy.

Other CNS Effects. Amphetamines may impair the ability to engage in potentially hazardous activities (e.g., operating machinery or vehicles).

Specific Populations **Pregnancy.** Category C.

Risk of prematurity, low birth weight, and withdrawal symptoms (e.g., dysphoria, lassitude, agitation) in infants born to dependent women.

Lactation. Distributed into milk; discontinue nursing or the drug.

Pediatric Use. Safety and efficacy of lisdexamfetamine not established in children 3–5 years of age. Amphetamines not recommended for ADHD in children younger than 3 years of age. Not studied to date in adolescents.

Aggressive behavior, hostility, and psychotic (e.g., hallucinations, delusional thinking) or manic symptoms reported in children and adolescents receiving stimulants for management of ADHD. (See Warnings under Cautions.)

Sudden death reported in children and adolescents with structural cardiac abnormalities or other serious cardiac conditions receiving usual dosages of stimulants. Sudden unexplained death also reported in a small number of children without structural cardiac abnormalities receiving amphetamine combinations. Results of one retrospective, case-control epidemiologic study suggested a possible association between use of stimulant medications and sudden unexplained death in healthy children and adolescents. (See Sudden Death and Serious Cardiovascular Events under Warnings/Precautions, in Cautions.)

Long-term administration expected to cause at least a temporary suppression of normal weight and/or height patterns in some children and adolescents. (See Growth Suppression under Cautions.)

Geriatric Use. Lisdexamfetamine has not been studied in this population.

Hepatic Impairment. Not specifically studied in hepatic impairment.

Renal Impairment. Not specifically studied in renal impairment.

■ **Common Adverse Effects** Children 6–12 years of age: Decreased appetite, insomnia, upper abdominal pain, irritability, vomiting, weight loss, nausea, dry mouth, dizziness, affect lability, rash, tic, pyrexia, somnolence.

Adults: Decreased appetite, insomnia, dry mouth, diarrhea, nausea, anxiety, anorexia, jitteriness, increased blood pressure, agitation, restlessness, hyperhidrosis, increased heart rate, tremor, dyspnea.

Drug Interactions

Active metabolite (dextroamphetamine) inhibits monoamine oxidase (MAO).

Lisdexamfetamine is not metabolized by cytochrome P-450 (CYP) isoenzymes. In vitro studies suggest only minor inhibition of CYP isoenzymes 1A2, 2D6, and 3A4 by amphetamine and/or its metabolites.

■ **Urinary Acidifying Agents** Increased urinary excretion and decreased serum concentrations and efficacy of amphetamines with concomitant use of urinary acidifying agents (ammonium chloride, sodium acid phosphate, cranberry juice).

■ **Adrenergic Blockers** Potential inhibition of adrenergic blockade.

■ **Alkalinizing Agents** Decreased urinary excretion of amphetamines with concomitant use of alkalinizing agents (carbonic anhydrase inhibitors, sodium bicarbonate).

■ **Tricyclic Antidepressants** Enhanced activity of tricyclic antidepressants; desipramine or protriptyline cause striking and sustained increases in the concentration of dextroamphetamine in the brain; cardiovascular effects can be potentiated.

■ **Antihistamines** Amphetamines may counteract the sedative effects of antihistamines.

■ **Antihypertensives** Amphetamines may antagonize the hypotensive effects of antihypertensives.

■ **Chlorpromazine** Chlorpromazine inhibits the central stimulant effects of amphetamines by blocking dopamine and norepinephrine receptors. Can be used to treat amphetamine poisoning.

■ **Ethosuximide** Intestinal absorption of ethosuximide may be delayed.

■ **Haloperidol** Haloperidol inhibits the central stimulant effects of amphetamines by blocking dopamine receptors.

■ **Lithium Carbonate** Lithium may inhibit the anorectic and stimulatory effects of amphetamine.

■ **MAO Inhibitors** MAO inhibitors slow the metabolism of amphetamines, increasing their effect on the release of norepinephrine and other monoamines leading to headaches and other signs of hypertensive crisis. Toxic neurologic effects, hypertensive crisis, and malignant hyperpyrexia can occur, sometimes with fatal results. Amphetamines contraindicated in patients currently or recently (within 14 days) receiving MAO inhibitor.

■ **Meperidine** Amphetamines potentiate the analgesic effect of meperidine.

■ **Methenamine** Acidifying agents used with methenamine increase urinary excretion and decrease efficacy of amphetamines.

■ **Norepinephrine** Amphetamines enhance the adrenergic effects of norepinephrine.

■ **Phenobarbital** Amphetamines may delay absorption of phenobarbital; concomitant use may produce a synergistic anticonvulsant action.

■ **Phenytoin** Amphetamines may delay absorption of phenytoin; concomitant use may produce a synergistic anticonvulsant action.

■ **Propoxyphene** In propoxyphene overdosage, amphetamine-induced CNS stimulation is potentiated and fatal convulsions can occur.

■ **Sympathomimetic Agents** Enhanced activity of sympathomimetic agents. Use with caution.

■ **Tests for Plasma Corticosteroids** Elevated plasma corticosteroid concentrations; this increase is greatest in the evening.

■ **Tests for Urinary Steroids** Possible interference with urinary steroid determinations.

■ **Veratrum Alkaloids** Amphetamines inhibit the hypotensive effect of veratrum.

Description

Lisdexamfetamine, a prodrug of dextroamphetamine, is a CNS stimulant. Lisdexamfetamine is inactive until hydrolyzed in vivo to *l*-lysine, a naturally occurring essential amino acid, and dextroamphetamine, which is responsible for the drug's activity. For information on the pharmacology of amphetamines, see Pharmacology in the Amphetamines General Statement 28:20.04.

Lisdexamfetamine is rapidly absorbed from the GI tract; following oral administration, the onset of action occurs within 2 hours. Conversion of lisdexamfetamine to *l*-lysine and dextroamphetamine is thought to occur by first-pass intestinal and/or hepatic metabolism. Lisdexamfetamine is not metabolized by the cytochrome P-450 (CYP) enzyme system, and the ability of dextroamphetamine to inhibit this enzyme pathway has not been fully elucidated. In vitro studies with human microsomes indicate minor inhibition of CYP isoenzymes 1A2, 2D6, and 3A4 by amphetamine and/or its metabolites. The plasma half-lives of lisdexamfetamine and dextroamphetamine are less than 1 hour and 9.4–9.7 hours, respectively. Approximately 96% of a radiolabeled dose of lisdexamfetamine is excreted in urine, with the parent drug accounting for only about 2% of the recovered radioactivity.

Advice to Patients

Provide patient or caregiver with a copy of the manufacturer's patient information (medication guide); discuss and answer questions about its contents as needed. Instruct patient or caregiver to read and understand contents of medication guide before initiating therapy and each time the prescription is refilled.

Advise parents with concerns about long-term effects (e.g., effects on weight) and the need for continued therapy that drug holidays can be considered in consultation with the patient's clinician. However, the benefits versus risks of such interruptions in therapy have not been established.

Question about possible substance abuse, including in other family members (since they may abuse the patient's medication supply).

Advise to take drug in the morning to minimize insomnia.

Advise that appetite suppression may occur. Giving the morning dose with a meal and providing a high-caloric drink or snack late in the evening when the stimulant effects have subsided may be helpful.

Advise to inform clinician immediately if adverse cardiovascular (e.g., chest pain, shortness of breath, fainting) or psychiatric effects (e.g., hallucinations, delusional thinking, mania) occur.

Instruct about the potential for amphetamines to impair patient's ability to perform potentially hazardous activities, such as driving or operating heavy machinery.

Importance of informing clinicians of existing or contemplated concomitant

therapy, including prescription and OTC drugs, dietary supplements, and herbal products, as well as any concomitant illnesses/conditions (e.g., cardiac/cardiovascular disease, thyroid disease, glaucoma, suicidal ideation or behaviors, mental/psychiatric disorder, seizures).

Importance of women informing clinicians if they are or plan to become pregnant or plan to breast-feed.

Importance of informing patients of other important precautionary information. (See Cautions.)

Overview* (see Users Guide). For additional information on this drug until a more detailed monograph is developed and published, the manufacturer's labeling should be consulted. It is *essential* that the manufacturer's labeling be consulted for more detailed information on usual cautions, precautions, contraindications, potential drug interactions, laboratory test interferences, and acute toxicity.

Preparations

Subject to control under the Federal Controlled Substances Act of 1970 as a schedule II (C-II) drug.

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

	70 mg	Vyvanse® (C-II), Shire

Methamphetamine Hydrochloride

Desoxyephedrine Hydrochloride

■ Methamphetamine hydrochloride, the dextrorotatory isomer of phenylmethylamine, has pharmacologic actions that are qualitatively similar to those of amphetamine and ephedrine.

Uses

Methamphetamine has been used as an adjunct to caloric restriction in the short-term (i.e., a few weeks) treatment of exogenous obesity. However, short-term or intermittent therapy with methamphetamine is unlikely to maintain a long-term benefit, and prolonged administration of methamphetamine for the treatment of obesity is not indicated. Methamphetamine also is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of attention deficit hyperactivity disorder (ADHD). Methamphetamine also has been misused and abused for its CNS stimulatory effects.

■ **Exogenous Obesity** Methamphetamine has been used as an adjunct to caloric restriction in the short-term (i.e., a few weeks) treatment of exogenous obesity. The anorexigenic effect of sympathomimetic compounds used in the treatment of obesity is temporary, seldom lasting more than a few weeks, and tolerance may occur. However, obesity usually is a chronic disease, and short-term or intermittent therapy with these drugs is unlikely to maintain a long-term benefit; therefore, short-term use of anorexigenic agents, including methamphetamine, is not recommended. Furthermore, prolonged administration of methamphetamine in the treatment of obesity is not indicated. (See Cautions: Precautions and Contraindications.) To help bring about and maintain loss of weight, the patient must be taught to curtail overeating and to consume a suitable diet. For further information on the treatment of exogenous obesity, see Uses: Exogenous Obesity, in the Amphetamines General Statement 28:20.04.

■ **Attention Deficit Hyperactivity Disorder** Methamphetamine also is used as an adjunct to psychological, educational, social, and other remedial measures in the treatment of ADHD (hyperkinetic disorder, hyperkinetic syndrome of childhood, minimal brain dysfunction) in children older than 6 years of age.

Methamphetamine should not be used to combat fatigue or exhaustion or to replace sleep in normal persons.

ADHD usually is characterized by developmentally inappropriate symptoms (e.g., moderate to severe distractibility, short attention span, hyperactivity, emotional lability, impulsivity). The final diagnosis of this disorder should not be made if these symptoms are of only comparatively recent origin. Nonlocalizing (soft) neurologic signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of CNS dysfunction may or may not be warranted. Drug therapy is not indicated in all children with ADHD, and such therapy should be considered only after a complete evaluation including medical history has been performed. The decision to use amphetamines should depend on the age of the child and the physician's assessment of the severity and duration of symptoms and should not depend solely on one or more behavioral characteristics. When symptoms of ADHD are associated with acute stress reactions, use of amphetamines usually is not recommended. For a more detailed discussion on the management of ADHD, including the use of stimulants such as methamphetamine, see Uses: Attention Deficit Hyperactivity Disorder, in Methylphenidate 28:20.92.

■ **Misuse and Abuse** Misuse and abuse of amphetamines, especially methamphetamine, for CNS stimulatory effects have experienced a resurgence. In large part, this resurgence has resulted from the relative ease with which methamphetamine can be synthesized clandestinely from readily available chemicals such as ephedrine, phenylpropanolamine (no longer commercially available in the US), or pseudoephedrine. (See Chronic Toxicity, in the Amphetamines General Statement 28:20.04.) Legal restrictions, including enactment of the US Comprehensive Methamphetamine Control Act of 1996 and later the Methamphetamine Anti-Proliferation Act of 2000 and the Combat Methamphetamine Epidemic Act of 2005, on the availability of these compounds have been enacted in an effort to reverse this resurgence in misuse and abuse.

Dosage and Administration

■ **Administration** Methamphetamine hydrochloride is administered orally. Because of the potential for insomnia, administration of methamphetamine in the late evening should be avoided.

■ **Dosage** Dosage and potency of methamphetamine hydrochloride are expressed in terms of the hydrochloride. (See Chemistry and Stability: Chemistry.)

Dosage of methamphetamine hydrochloride should be adjusted according to individual response and tolerance; the smallest dose required to produce the desired response should always be used.

Exogenous Obesity As an adjunct in the treatment of exogenous obesity, the usual adult dosage of methamphetamine hydrochloride is 2.5–5 mg 2 or 3 times daily, given one-half hour before meals. Treatment should not exceed a duration of a few weeks.

Attention Deficit Hyperactivity Disorder As an adjunct in the treatment of attention deficit hyperactivity disorder (ADHD) in children 6 years of age and older, the usual initial dosage of methamphetamine hydrochloride is 5 mg once or twice daily. Daily dosage may be increased by 5 mg at weekly intervals until an optimum clinical response is achieved. The usual effective dosage is 20–25 mg daily. The total daily dose may be given as conventional tablets in 2 divided doses daily.

When possible, therapy should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued treatment.

Cautions

Methamphetamine shares the toxic potentials of amphetamines, and the usual cautions, precautions, and contraindications of amphetamine therapy should be observed. (See Cautions, in the Amphetamines General Statement 28:20.04.)

■ **Cardiovascular Effects** Sudden death, stroke, myocardial infarction, hypertension or hypotension, tachycardia, palpitation, or cardiac arrhythmias may occur in patients receiving stimulants, including methamphetamine. (See Cardiovascular Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.) Fatal cardiorespiratory arrest has been reported following abuse or misuse of methamphetamine.

■ **Nervous System Effects** Adverse nervous system effects of methamphetamine may include nervousness, insomnia, irritability, talkativeness, dizziness, headache, blurred vision, mydriasis, dizziness, dysphoria, euphoria, tremor, restlessness and hyperexcitability. Rarely, psychotic episodes have occurred in patients receiving recommended dosages. The drug may also exacerbate motor and vocal tics and Tourette's disorder. Seizures, aggressive behavior, and hostility also have been reported with stimulants. (See Psychiatric Precautions under Cautions: Precautions and Contraindications, in the Amphetamines General Statement 28:20.04.)

■ **GI Effects** GI disturbances of methamphetamine may include nausea, vomiting, abdominal cramps, diarrhea or constipation, dryness of the mouth, anorexia, and unpleasant taste.

■ **Other Adverse Effects** Urticaria, impotence, and changes in libido may occur in patients receiving methamphetamine. Visual disturbances (difficulty with accommodation, blurred vision) have been reported with stimulants.

■ **Precautions and Contraindications** The manufacturer's patient information (medication guide) should be provided to the patient or caregiver each time methamphetamine is dispensed, and the clinician should discuss and answer questions about its contents (e.g., benefits and risks of stimulant therapy, appropriate use) as needed. The patient or caregiver also should be instructed to read and understand the contents of the medication guide before initiating therapy and each time the prescription is refilled.

Patients should be warned that methamphetamine may impair their ability to perform hazardous activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle).

Methamphetamine should be administered with caution, if at all, to patients with hyperexcitability states or to those receiving drugs that may produce this

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Paroxetine Hydrochloride

Oral		
Suspension	10 mg (of paroxetine) per 5 mL	**Paxil**®, GlaxoSmithKline

†Use is not currently included in the labeling approved by the US Food and Drug Administration

Sertraline Hydrochloride

■ Sertraline, a selective serotonin-reuptake inhibitor (SSRI), is an antidepressant agent.

Uses

■ **Major Depressive Disorder** Sertraline is used in the treatment of major depressive disorder. A major depressive episode implies a prominent and relatively persistent depressed or dysphoric mood that usually interferes with daily functioning (nearly every day for at least 2 weeks). According to DSM-IV criteria, a major depressive episode includes at least 5 of the following 9 symptoms (with at least one of the symptoms being either depressed mood or loss of interest or pleasure): depressed mood most of the day as indicated by subjective report (e.g., feels sad or empty) or observation made by others; markedly diminished interest or pleasure in all, or almost all, activities most of the day; significant weight loss (when not dieting) or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite; insomnia or hypersomnia; psychomotor agitation or retardation (observable by others, not merely subjective feelings of restlessness or being slowed down); fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt (not merely self-reproach or guilt about being sick); diminished ability to think or concentrate or indecisiveness (either by subjective account or as observed by others); and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.

Treatment of major depressive disorder generally consists of an acute phase (to induce remission), a continuation phase (to preserve remission), and a maintenance phase (to prevent recurrence). Various interventions (e.g., psychotherapy, antidepressant drug therapy, electroconvulsive therapy [ECT]) are used alone or in combination to treat major depressive episodes. Treatment should be individualized and the most appropriate strategy for a particular patient is determined by clinical factors such as severity of depression (e.g., mild, moderate, severe), presence or absence of certain psychiatric features (e.g., suicide risk, catatonia, psychotic or atypical features, alcohol or substance abuse or dependence, panic or other anxiety disorder, cognitive dysfunction, dysthymia, personality disorder, seasonal affective disorder), and concurrent illness (e.g., asthma, cardiac disease, dementia, seizure disorder, glaucoma, hypertension). Demographic and psychosocial factors as well as patient preference also are used to determine the most effective treatment strategy.

While use of psychotherapy alone may be considered as an initial treatment strategy for patients with mild to moderate major depressive disorder (based on patient preference and presence of clinical features such as psychosocial stressors), combined use of antidepressant drug therapy and psychotherapy may be useful for initial treatment of patients with moderate to severe major depressive disorder with psychosocial issues, interpersonal problems, or a comorbid axis II disorder. In addition, combined use of antidepressant drug therapy and psychotherapy may be beneficial in patients who have a history of poor compliance or only partial response to adequate trials of either antidepressant drug therapy or psychotherapy alone.

Antidepressant drug therapy can be used alone for initial treatment of patients with mild major depressive disorder (if preferred by the patient) and usually is indicated alone or in combination with psychotherapy for initial treatment of patients with moderate to severe major depressive disorder (unless ECT is planned). ECT is not generally used for initial treatment of uncomplicated major depression, but is recommended as first-line treatment for severe major depressive disorder when it is coupled with psychotic features, catatonic stupor, severe suicidality, food refusal leading to nutritional compromise, or other situations when a rapid antidepressant response is required. ECT also is recommended for patients who have previously shown a positive response or a preference for this treatment modality and can be considered for patients with moderate or severe depression who have not responded to or cannot receive antidepressant drug therapy. In certain situations involving depressed patients unresponsive to adequate trials of several individual antidepressant agents, adjunctive therapy with another agent (e.g., buspirone, lithium) or concomitant use of a second antidepressant agent (e.g., bupropion) has been used; however, such combination therapy is associated with an increased risk of adverse reactions, may require dosage adjustments, and (if not contraindicated) should be undertaken only after careful consideration of the relative risks and benefits. (See Drug Interactions: Serotonergic Drugs, Drug Interactions: Tricyclic and Other Antidepressants, and Drug Interactions: Lithium.)

The efficacy of sertraline for the acute treatment of major depression has been established by 2 placebo-controlled studies in adult outpatients who met DSM-III criteria for major depression. In the first study of 8 weeks' duration, sertraline was administered with flexible dosing in a range of 50–200 mg daily; the mean daily dosage for patients completing the study was 145 mg daily. In the second study of 6 weeks' duration, sertraline was administered in fixed doses of 50, 100, and 200 mg daily. Overall, these 2 studies demonstrated that sertraline was superior to placebo in improving scores on the Hamilton Depression Rating Scale and the Clinical Global Impression Severity and Improvement Scales. However, the second study was not readily interpretable regarding whether there was a dose-response relationship for the drug's efficacy.

In a third study, depressed outpatients who had responded by the end of an initial 8-week open treatment phase to sertraline 50–200 mg daily were randomized to continue sertraline in the same dosage range or placebo for 44 weeks in a double-blind manner. The mean daily dosage of sertraline in those who completed this long-term study was 70 mg daily, and the relapse rate in the sertraline-treated patients was substantially lower than in those who received placebo.

An analysis of these 3 controlled studies for possible gender-related effects on treatment outcome did not suggest any difference in efficacy based on the gender of the patient.

While the optimum duration of sertraline therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). The efficacy of sertraline in maintaining an antidepressant response for up to 1 year without increased toxicity has been demonstrated in a controlled setting. The manufacturers state that the usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically. (See Dosage and Administration: Dosage.)

The manufacturers state that the drug's antidepressant efficacy in hospital settings has not been adequately studied to date.

As with certain other antidepressants, the possibility that sertraline may precipitate hypomanic or manic attacks in patients with bipolar or other major affective disorder should be considered. Sertraline is *not* approved for use in treating bipolar depression in adults.

Considerations in Choosing an Antidepressant A variety of antidepressant drugs is available for the treatment of major depressive disorder, including selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline), selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs; e.g., desvenlafaxine, duloxetine, venlafaxine), tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine), monoamine oxidase (MAO) inhibitors (e.g., phenelzine, tranylcypromine), and other antidepressants (e.g., bupropion, maprotiline, nefazodone, trazodone). Most clinical studies have shown that the antidepressant effect of usual dosages of sertraline in patients with depression is greater than that of placebo and comparable to that of usual dosages of tricyclic antidepressants (e.g., amitriptyline), other SSRIs (e.g., fluoxetine), and other antidepressants (e.g., nefazodone). In geriatric patients with major depression, sertraline appears to be as effective as amitriptyline. The onset of action of sertraline appears to be comparable to that of tricyclic antidepressants.

In general, response rates in patients with major depression are similar for currently available antidepressants, and the choice of antidepressant agent for a given patient depends principally on other factors such as potential adverse effects, safety or tolerability of these adverse effects in the individual patient, psychiatric and medical history, patient or family history of response to specific therapies, patient preference, quantity and quality of available clinical data, cost, and relative acute overdose safety. No single antidepressant can be recommended as optimal for all patients because of substantial heterogeneity in individual responses and in the nature, likelihood, and severity of adverse effects. In addition, patients vary in the degree to which certain adverse effects and other inconveniences of drug therapy (e.g., cost, dietary restrictions) affect their preferences.

In the large-scale Sequenced Treatment Alternatives to Relieve Depression (STAR*D) effectiveness trial, patients with major depressive disorder who did not respond to or could not tolerate therapy with one SSRI (citalopram) were randomized to switch to extended-release ("sustained-release") bupropion, sertraline, or extended-release venlafaxine as a second step of treatment (level 2). Remission rates as assessed by the 17-item Hamilton Rating Scale for Depression (HRSD-17) and the Quick Inventory of Depressive Symptomatology—Self Report (QIDS-SR-16) were approximately 21 and 26% for extended-release bupropion, 18 and 27% for sertraline, and 25 and 25% for extended-release venlafaxine therapy, respectively; response rates as assessed by the QIDS-SR-16 were 26, 27, and 28% for extended-release bupropion, sertraline, and extended-release venlafaxine therapy, respectively. These results suggest that after unsuccessful initial treatment of depressed patients with an SSRI, approximately 25% of patients will achieve remission after therapy is switched to another antidepressant and that either another SSRI (e.g., sertraline) or an agent from another class (e.g., bupropion, venlafaxine) may be reasonable alternative antidepressants in patients not responding to initial SSRI therapy.

Patient Tolerance Considerations. Because of differences in the adverse effect profile between SSRIs and tricyclic antidepressants, particularly less frequent anticholinergic effects, cardiovascular effects, and weight gain with SSRIs, these drugs may be preferred in patients in whom such effects are not tolerated or are of potential concern. The decreased incidence of anticholinergic effects associated with sertraline and other SSRIs compared with tricyclic antidepressants is a potential advantage, since such effects may result in discontinuance of the drug early during therapy in unusually sensitive patients. In addition, some anticholinergic effects may become troublesome during long-term tricyclic antidepressant therapy (e.g., persistent dry mouth may result in tooth decay). Although SSRIs share the same overall tolerability profile, certain patients may tolerate one drug in this class better than another. In an open study, most patients who had discontinued fluoxetine therapy because of adverse effects subsequently tolerated sertraline therapy. Antidepressants other than SSRIs may be preferred in patients in whom certain adverse GI effects (e.g., nausea, anorexia), nervous system effects (e.g., anxiety, nervousness, insomnia), and/or weight loss are not tolerated or are of concern, since such effects appear to occur more frequently with this class of drugs.

Pediatric Considerations. The clinical presentation of depression in children and adolescents can differ from that in adults and generally varies with the age and developmental stages of the child. Younger children may exhibit behavioral problems such as social withdrawal, aggressive behavior, apathy, sleep disruption, and weight loss; adolescents may present with somatic complaints, self esteem problems, rebelliousness, poor performance in school, or a pattern of engaging in risky or aggressive behavior.

Only limited data are available to date from controlled clinical studies evaluating various antidepressant agents in children and adolescents, and many of these studies have methodologic limitations (e.g., nonrandomized or uncontrolled, small sample size, short duration, nonspecific inclusion criteria). However, there is some evidence that the response to antidepressants in pediatric patients may differ from that seen in adults, and caution should be used in extrapolating data from adult studies when making treatment decisions for pediatric patients. Results of several studies evaluating tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline) in preadolescent and adolescent patients with major depression indicate a lack of overall efficacy in this age group. Based on the lack of efficacy data regarding use of tricyclic antidepressants and MAO inhibitors in pediatric patients and because of the potential for life-threatening adverse effects associated with the use of these drugs, many experts consider selective serotonin-reuptake inhibitors, including sertraline, the drugs of choice when antidepressant therapy is indicated for the treatment of major depressive disorder in children and adolescents. However, the US Food and Drug Administration (FDA) states that, while efficacy of fluoxetine has been established in pediatric patients, efficacy of other newer antidepressants (i.e., sertraline, citalopram, desvenlafaxine, duloxetine, escitalopram, fluvoxamine, mirtazapine, nefazodone, paroxetine, venlafaxine) was not conclusively established in clinical trials in pediatric patients with major depressive disorder. In addition, FDA now warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) FDA currently states that anyone considering using an antidepressant in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need. (See Cautions: Precautions and Contraindications.)

Geriatric Considerations. The response to antidepressants in depressed geriatric patients without dementia is similar to that reported in younger adults, but depression in geriatric patients often is not recognized and is not treated. In geriatric patients with major depressive disorder, selective serotonin-reuptake inhibitors (SSRIs) appear to be as effective as tricyclic antidepressants (e.g., amitriptyline) but generally are associated with fewer overall adverse effects than these other agents. Geriatric patients appear to be especially sensitive to anticholinergic (e.g., dry mouth, constipation, vision disturbance), cardiovascular, orthostatic hypotensive, and sedative effects of tricyclic antidepressants. The low incidence of anticholinergic effects associated with sertraline and other SSRIs compared with tricyclic antidepressants also is a potential advantage in geriatric patients, since such effects (e.g., constipation, dry mouth, confusion, memory impairment) may be particularly troublesome in these patients. However, SSRI therapy may be associated with other troublesome adverse effects (e.g., nausea and vomiting, agitation and akathisia, parkinsonian adverse effects, sexual dysfunction, weight loss, hyponatremia). Some clinicians state that SSRIs such as sertraline may be preferred for treating depression in geriatric patients in whom the orthostatic hypotension associated with many antidepressants (e.g., tricyclics) potentially may result in injuries (such as severe falls). However, despite the fewer cardiovascular and anticholinergic effects associated with SSRIs, these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered at increased risk of falls and appropriate measures should be taken. In addition, clinicians prescribing SSRIs in geriatric patients should be aware of the many possible drug interactions associated with these drugs, including those involving metabolism of the drugs through the cytochrome P-450 system. (See Drug Interactions.)

Patients with dementia of the Alzheimer's type (Alzheimer's disease, presenile or senile dementia) often present with depressive symptoms, such as depressed mood, appetite loss, insomnia, fatigue, irritability, and agitation. Most experts recommend that patients with dementia of the Alzheimer's type who present with clinically important and persistent depressive symptoms be considered as candidates for pharmacotherapy even if they fail to meet the criteria for a major depressive syndrome. The goals of such therapy are to improve mood, functional status (e.g., cognition), and quality of life. Treatment of depression also may reduce other neuropsychiatric symptoms associated with depression in patients with dementia, including aggression, anxiety, apathy, and psychosis. Although patients may present with depressed mood alone, the possibility of more extensive depressive symptomatology should be considered. Therefore, patients should be evaluated and monitored carefully for indices of major depression, suicidal ideation, and neurovegetative signs since safety measures (e.g., hospitalization for suicidality) and more vigorous and aggressive therapy (e.g., relatively high dosages, multiple drug trials) may be needed in some patients.

Although placebo-controlled trials of antidepressants in depressed patients with concurrent dementia have shown mixed results, the available evidence and experience with the use of antidepressants in patients with dementia of the Alzheimer's type and associated depressive manifestations indicate that depressive symptoms (including depressed mood alone and with neurovegetative changes) in such patients are responsive to antidepressant therapy. In some patients, cognitive deficits may partially or fully resolve during antidepressant therapy, but the extent of response will be limited to the degree of cognitive impairment that is directly related to depression. SSRIs such as sertraline, citalopram, escitalopram, fluoxetine, or paroxetine are generally considered as first-line agents in the treatment of depressed patients with dementia since they are better tolerated than some other antidepressants (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). Some possible alternative agents to SSRIs include bupropion, mirtazapine, and venlafaxine. Some geriatric patients with dementia and depression may be unable to tolerate the antidepressant dosages needed to achieve full remission. When a rapid antidepressant response is not critical, some experts therefore recommend a very gradual dosage increase to increase the likelihood that a therapeutic dosage of the SSRI or other antidepressant will be reached and tolerated. In a randomized, placebo-controlled study in a limited number of patients with major depression and Alzheimer's disease, sertraline was found to be superior to placebo; depression reduction in this study was accompanied by lessened behavior disturbance and improved activities of daily living but not improved cognition.

Cardiovascular Considerations. The relatively low incidence of adverse cardiovascular effects, including orthostatic hypotension and conduction disturbances, associated with sertraline and other selective serotonin-reuptake inhibitors may be advantageous in patients in whom the cardiovascular effects associated with tricyclic antidepressants may be hazardous. Patients with a recent history of myocardial infarction or unstable cardiovascular disease were excluded from premarketing clinical studies with sertraline. However, the cardiovascular safety of sertraline (50–200 mg daily for 24 weeks; mean dosage of 89 mg daily) was evaluated in a postmarketing, double-blind, placebo-controlled study in adult outpatients with major depressive disorder and a recent history of myocardial infarction or unstable angina pectoris requiring hospitalization but who were otherwise free of life-threatening medical conditions. When therapy was initiated during the acute phase of recovery (within 30 days after a myocardial infarction or hospitalization for unstable angina), sertraline therapy did not differ from placebo on the following cardiovascular end points at week 16: left ventricular ejection fraction and total cardiovascular events (angina, chest pain, edema, palpitations, syncope, postural dizziness, chronic

heart failure, myocardial infarction, tachycardia, bradycardia, blood pressure changes). Although not statistically significant, approximately 20% fewer major cardiovascular events involving death or requiring hospitalization (e.g., for myocardial infarction, chronic heart failure, stroke, angina) occurred in the sertraline-treated patients compared with those receiving placebo. (See Cautions: Cardiovascular Effects and see also Cautions: Precautions and Contraindications.)

Sedative Considerations. Because sertraline and other SSRIs are generally less sedating than some other antidepressants (e.g., tricyclics), some clinicians state that these drugs may be preferable in patients who do not require the sedative effects associated with many antidepressant agents; however, an antidepressant with more prominent sedative effects (e.g., trazodone) may be preferable in certain patients (e.g., those with insomnia).

Suicidal Risk Considerations. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidal thinking and behavior (suicidality) in certain patients during the early phases of treatment. FDA states that antidepressants increased the risk of suicidality in short-term studies in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. (See Cautions: Pediatric Precautions.) An increased suicidality risk was not demonstrated with antidepressants compared with placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older. It currently is unknown whether the suicidality risk extends to longer-term antidepressant use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression. Because the risk of suicidality in depressed patients may persist until substantial remission of depression occurs, appropriate monitoring and close observation of all patients who are receiving antidepressant therapy is recommended. (See Cautions: Precautions and Contraindications.)

Other Considerations. Sertraline has been effective in patients with moderate to severe depression.

In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) level 2 trial, patients with major depressive disorder who did not respond to or could not tolerate therapy with citalopram (another SSRI) were randomized to receive either extended-release ("sustained-release") bupropion or buspirone therapy in addition to citalopram. Although both extended-release bupropion and buspirone were found to produce similar remission rates, extended-release bupropion produced a greater reduction in the number and severity of symptoms and a lower rate of drug discontinuance than buspirone in this large-scale, effectiveness trial. These results suggest that augmentation of SSRI therapy with extended-release bupropion may be useful in some patients with refractory depression.

Sertraline has been effective in patients with depression and concurrent human immunodeficiency virus (HIV) infection and depression with anxiety.

In a double-blind, placebo-controlled study, both sertraline or imipramine were found to be more effective than placebo in reducing the depressive symptoms and improving psychosocial functioning in patients with dysthymia† without concurrent major depression; moreover, fewer patients treated with sertraline than those treated with imipramine or placebo discontinued therapy because of adverse effects. The results of several other studies, both controlled and uncontrolled, also suggest that sertraline may be effective in patients with dysthymia. Because dysthymia is a chronic condition and requires prolonged antidepressant therapy, the good tolerability demonstrated in clinical studies to date may be advantageous. Sertraline also has been used in the treatment of anger attacks associated with atypical depression and dysthymia† in a limited number of patients.

■ **Obsessive-Compulsive Disorder** Sertraline is used in the treatment of obsessive-compulsive disorder when the obsessions or compulsions cause marked distress, are time consuming (take longer than 1 hour daily), or interfere substantially with the patient's normal routine, occupational or academic functioning, or usual social activities or relationships. Obsessions are recurrent and persistent ideas, thoughts, impulses, or images that, at some time during the disturbance, are experienced as intrusive and inappropriate (i.e., "ego dystonic") and that cause marked anxiety or distress but that are not simply excessive worries about real-life problems. Compulsions are repetitive, intentional behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) performed in response to an obsession or according to rules that must be applied rigidly (e.g., in a stereotyped fashion). Although the behaviors or acts are aimed at preventing or reducing distress or preventing some dreaded event or situation, they either are not connected in a realistic manner with what they are designed to neutralize or prevent or are clearly excessive. At some time during the course of the disturbance, the patient, if an adult, recognizes that the obsessions or compulsions are excessive or unreasonable; children may not make such a recognition.

The efficacy of sertraline for the management of obsessive-compulsive disorder has been established in several multicenter, placebo-controlled studies, including one study of 8 weeks' duration and 2 studies of 12 weeks' duration in adults and one study of 12 weeks' duration in children and adolescents 6–17 years of age. Patients in these studies had moderate to severe obsessive-compulsive disorder with mean baseline total scores on the Yale-Brown Obsessive-Compulsive Scale (YBOCS) of 23–25 in adults and 22 in children and adolescents (measured in the Children's Yale-Brown Obsessive-Compulsive Scale [CY-BOCS]). In the 8-week study with flexible dosing, adult patients received sertraline in dosages ranging from 50–200 mg daily; the mean dosage for those completing the study was 186 mg daily. Total scores on the YBOCS decreased by an average of approximately 4 points in sertraline-treated patients and 2 points in patients receiving placebo; this difference was statistically significant.

In a fixed-dose study of 12 weeks' duration involving sertraline dosages of 50, 100, and 200 mg daily, adult patients receiving 50 and 200 mg of the drug daily experienced substantially greater reductions in the YBOCS total score than those receiving placebo (approximately 6 to approximately 3 points, respectively). In a 12-week study with flexible dosing in the range of 50–200 mg daily, the mean sertraline dosage in adult patients completing the study was 185 mg daily. YBOCS total scores in the sertraline-treated patients were reduced by a mean of approximately 7 points, which was better than the mean reduction of approximately 4 points reported in the placebo-treated patients.

In a 12-week study with flexible dosing, sertraline therapy was initiated at dosages of 25 or 50 mg daily in children 6–12 years of age or adolescents 13–17 years of age, respectively. Subsequent dosage was titrated according to individual tolerance over the first 4 weeks to a maximum dosage of 200 mg daily; the mean dosage for those completing the study was 178 mg daily. The drug produced substantially greater reductions in scores in the Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS), the National Institute of Mental Health Global Obsessive-Compulsive Scale (NIMH-OC), and the Clinical Global Impressions (CGI) Improvement Scale; total scores on the CY-BOCS decreased by an average of approximately 7 units in sertraline-treated patients and 3 units in patients receiving placebo. An analysis of these controlled studies for possible age- and gender-related effects on treatment outcome did not suggest any difference in efficacy based on either the age or gender of the patient.

In addition, in an uncontrolled 6-week study with flexible dosing (50–200 mg daily) in children or adolescents 6–17 years of age with obsessive-compulsive disorder or major depression†, those with a diagnosis of obsessive-compulsive disorder had mean baseline total scores on the CY-BOCS, NIMH-OC, and CGI of about 24.9, 10.2, and 5.2, respectively. Sertraline produced substantial reductions in all 3 of the scales; total scores on CY-BOCS, NIMH-OC, and CGI decreased to 12.9, 6.7, and 3.4, respectively. In another uncontrolled, 6-week study employing a sertraline dosage that was escalated from 25 to 200 mg daily over 3 weeks, the drug combined with behavioral therapy was effective in a limited number of adolescents 13–17 years of age with obsessive-compulsive disorder refractory to other therapies; total scores on the CY-BOCS at the end of the study decreased by 11 points (from 25.4 to 14.4).

Results from comparative studies to date suggest sertraline and other selective serotonin-reuptake inhibitors (SSRIs; e.g., fluoxetine, fluvoxamine, paroxetine) are as effective or somewhat less effective than clomipramine and more effective than tricyclic antidepressants (e.g., amitriptyline, desipramine, imipramine, nortriptyline) in the management of obsessive-compulsive disorder. In a pooled analysis of separate short-term (10–13 weeks) studies comparing clomipramine, fluoxetine, fluvoxamine, or sertraline with placebo, clomipramine was calculated as being more effective (as determined by measures on the YBOC scale) than SSRIs, although all drugs were superior to placebo. Like clomipramine, SSRIs reduce but do not completely eliminate obsessions and compulsions.

Many clinicians consider an SSRI (e.g., sertraline, fluoxetine, fluvoxamine, paroxetine) or clomipramine to be the drugs of choice for the pharmacologic treatment of obsessive-compulsive disorder. The decision whether to initiate therapy with an SSRI or clomipramine often is made based on the adverse effect profile of these drugs. For example, some clinicians prefer clomipramine in patients who may not tolerate the adverse effect profile of SSRIs (nausea, headache, overstimulation, sleep disturbances) while SSRIs may be useful alternatives in patients unable to tolerate the adverse effects (anticholinergic effects, cardiovascular effects, sedation) associated with clomipramine therapy. Consideration of individual patient characteristics (age, concurrent medical conditions), pharmacokinetics of the drug, potential drug interactions, and cost of therapy may also influence clinicians when selecting between SSRIs and clomipramine as first-line therapy in patients with obsessive-compulsive disorder. Although not clearly established, it has been suggested that the mechanism of action of sertraline and other potent serotonin-reuptake inhibitors (e.g., clomipramine, fluoxetine, fluvoxamine, paroxetine) used in the management of obsessive-compulsive disorder may be related to their serotonergic activity.

■ **Panic Disorder** Sertraline is used in the treatment of panic disorder with or without agoraphobia. Panic disorder is characterized by the occurrence of unexpected panic attacks and associated concern about having additional attacks, worry about the implications or consequences of the attacks, and/or a clinically important change in behavior related to the attacks.

According to DSM-IV, panic disorder is characterized by recurrent unexpected panic attacks, which consist of a discrete period of intense fear or discomfort in which 4 (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes: palpitations, pounding heart, or accelerated heart rate; sweating; trembling or shaking; sensations of shortness of breath or smothering; feeling of choking; chest pain or discomfort; nausea or abdominal distress; feeling dizzy, unsteady, lightheaded, or faint; derealization (feelings of unreality) or depersonalization (being detached from oneself); fear of losing control; fear of dying; paresthesias (numbness or tingling sensations); and chills or hot flushes.

The efficacy of sertraline for the management of panic disorder has been established by 3 double-blind, placebo-controlled studies in adult outpatients who met DSM-III-R criteria for panic disorder with or without agoraphobia. The first 2 studies were of 10 weeks' duration and used a flexible dosing schedule. Sertraline therapy was initiated in a dosage of 25 mg daily for the first week and then dosage was escalated to 50–200 mg daily depending on clinical response and tolerability. The mean sertraline dosages for completers were 131 and 144 mg daily for the first 2 studies. Overall, these 2 studies demonstrated that sertraline was superior to placebo in decreasing the frequency of panic attacks and in improving scores on the Clinical Global Impression Severity of Illness and Global Improvement Scales. The difference between sertraline and placebo in reduction in the number of full panic attacks per week compared with baseline was approximately 2 in both studies.

The third study was a fixed-dose study of 12 weeks' duration. Sertraline was given in dosages of 50, 100, and 200 mg daily. The patients receiving sertraline demonstrated a substantially greater reduction in panic attack frequency than patients receiving placebo. However, the results of this study were not readily interpretable regarding a dose-response relationship for efficacy in this condition.

An analysis of these 3 controlled studies for possible age-, race-, or gender-related effects on treatment outcome did not suggest any difference in efficacy based on these patient characteristics.

Panic disorder can be treated with cognitive and behavioral psychotherapy and/or pharmacologic therapy. There are several classes of drugs that appear to be effective in the pharmacologic management of panic disorder, including tricyclic antidepressants, MAO inhibitors (e.g., phenelzine), selective serotonin-reuptake inhibitors (SSRIs; e.g., citalopram, fluoxetine, paroxetine, sertraline), and benzodiazepines (e.g., alprazolam, clonazepam). When choosing among the available drugs, clinicians should consider their acceptance and tolerability by patients; their ability to reduce or eliminate panic attacks, reduce clinically important anxiety and disability secondary to phobic avoidance, and ameliorate other common comorbid conditions (such as depression); and their ability to prevent relapse during long-term therapy. Because of their better tolerability when compared with other agents (such as the tricyclic antidepressants and benzodiazepines), the lack of physical dependence problems commonly associated with benzodiazepines, and efficacy in panic disorder with comorbid conditions (e.g., depression, other anxiety disorders such as obsessive-compulsive disorder, alcoholism), many clinicians prefer SSRIs as first-line therapy in the management of panic disorder. If SSRI therapy is ineffective or not tolerated, use of a tricyclic antidepressant or a benzodiazepine is recommended.

Sertraline has improved chronic idiopathic urticaria† associated with panic disorder in at least one patient, but further study is needed to determine whether serotonin is involved in the pathogenesis of urticaria and whether SSRIs are effective in this condition.

■ **Posttraumatic Stress Disorder** Sertraline is used in the treatment of posttraumatic stress disorder (PTSD). PTSD is an anxiety disorder that involves the development of certain characteristic symptoms following personal exposure to an extreme traumatic stressor. According to DSM-IV, PTSD requires exposure to a traumatic event(s) that involved actual or threatened death or serious injury, or threat to the physical integrity of self or others, and the response to the event must involve intense fear, helplessness, or horror (in children the response may be expressed by disorganized or agitated behavior). PTSD is characterized by persistent symptoms of *reexperiencing* the trauma (e.g., intrusive distressing recollections of the event; recurrent distressing dreams of the event; acting or feeling as if the event were recurring including illusions, hallucinations, or flashbacks; intense distress at exposure to internal or external cues that symbolize or resemble an aspect of the event; physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the event), persistent *avoidance* of stimuli associated with the trauma and numbing of general responsiveness (e.g., efforts to avoid thoughts, feelings, or conversations related to the event; efforts to avoid activities, places, or people that arouse recollections of the event; inability to recall an important aspect of the event; markedly diminished interest or participation in significant activities; feeling of detachment or estrangement from others; restricted emotions and/or range of affect not present before the event; sense of a foreshortened future), and persistent symptoms of *increased arousal* (e.g., difficulty sleeping; irritability/outbursts of anger; difficulty concentrating; hypervigilance; exaggerated startle response). According to DSM-IV, a PTSD diagnosis requires the presence of 1 or more symptoms of *reexperiencing*, 3 or more symptoms of *avoidance*, and 2 or more symptoms of *increased arousal*, all of which must be present for at least one month and cause clinically important distress or impairment in social, occupational, or other important areas of functioning. PTSD, like other anxiety disorders, rarely occurs alone, and patients with PTSD often present with comorbid disorders (e.g., major depressive disorder, substance abuse disorders, panic disorder, generalized anxiety disorders, obsessive-compulsive disorder, social phobia); it is unknown whether these comorbid disorders precede or follow the onset of PTSD.

Psychotherapy alone or in combination with pharmacotherapy generally is considered the treatment of choice for PTSD. Pharmacologic therapy may be indicated in addition to psychotherapy for initial treatment of PTSD in patients who have comorbid disorders (e.g., major depressive disorder, bipolar disorder, other anxiety disorders) and also may be indicated in those who do not respond to initial treatment with psychotherapy alone. If pharmacotherapy is indicated in patients with PTSD, selective serotonin-reuptake inhibitors (SSRIs; e.g., sertraline, fluoxetine, paroxetine) usually are considered the drugs of choice (except in patients with bipolar disorder who require treatment with mood stabilizing agents).

The efficacy of sertraline for the management of PTSD has been established in 2 placebo-controlled studies of 12 weeks' duration in adult outpatients (76% women) who met DSM-III-R criteria for chronic PTSD (duration of symptoms 3 months or longer). The mean duration of PTSD for these patients was approximately 12 years and 44% of patients had secondary depressive disorders. Sertraline therapy was initiated at a dosage of 25 mg daily for the first week and then dosage was escalated (using a flexible dosage schedule) to 50–200 mg daily based on clinical response and tolerability. The mean sertraline dosage for patients who completed studies 1 and 2 was 146 mg and 151 mg daily, respectively. Overall, these 2 studies showed that sertraline was superior to placebo in improving scores on the Clinician-Administered PTSD Scale Part 2 total severity scale (a measure of the intensity and frequency of all 3 PTSD diagnostic symptom clusters [reexperiencing/intrusion, avoidance/numbing, and hyperarousal]), Impact of Event Scale (a patient rated measurement of the intrusion and avoidance symptoms), and the Clinical Global Impressions Severity of Illness and Global Improvement Scales.

However, in 2 additional placebo-controlled studies of similar design and duration, the difference in response to treatment on key assessment scales between patients receiving sertraline and those receiving placebo was not statistically significant. In one study of mostly female patients who met the DSM-III-R criteria for PTSD related to sexual/physical trauma, those receiving placebo experienced substantially greater improvement on the Impact of Event Scale than those receiving sertraline therapy. Although this study enrolled a higher proportion of patients with comorbid anxiety disorders and a higher proportion of patients receiving placebo with a successful response to previous psychotropic therapies than the studies demonstrating efficacy of the drug, it is unknown whether these factors alone account for the high placebo response in the study.

Efficacy of sertraline for the management of PTSD related to war or combat was evaluated in a study involving primarily white men in a VA medical center outpatient setting (mean duration of PTSD approximately 18 years). At the end of this study, patients receiving sertraline did not differ from those receiving placebo on any of the key efficacy assessment scales (e.g., Clinician-Administered PTSD scale, Davidson Self-Rating Trauma scale, Impact of Event Scale). In addition, the mean change from baseline for both treatment groups in this study was of a lesser magnitude than those of patients receiving placebo in the other reported studies. The lack of response to sertraline treatment in these combat veterans is consistent with controlled studies evaluating other selective serotonin-reuptake inhibitors (e.g., fluoxetine, brofaromine [not commercially available in the US]) in Vietnam veterans with PTSD. Some experts suggest that patients with combat- or war-related PTSD may be less responsive to treatment than patients with PTSD related to other traumatic events (e.g., sexual assault, accidents, natural disasters) because of some factor inherent in combat- or war-related trauma. However, other experts suggest that the poor treatment response in studies evaluating use in veterans may be the result of sampling error since veterans receiving treatment at VA hospitals may constitute a self-selected group of patients with chronic PTSD who have multiple impairments (comorbid disorders, substance abuse) that make them less responsive to treatment.

Since PTSD is a more common disorder in women than men, the majority (76%) of patients in reported studies were women. A retrospective analysis of pooled data has shown a substantial difference between sertraline and placebo on key efficacy assessment scales (e.g., Clinician-Administered PTSD scale, Impact of Event Scale, Clinical Global Impressions Severity of Illness Scale) in women (regardless of a baseline diagnosis of comorbid depression), but essentially no effect in the limited number of men studied. The clinical importance of this apparent gender effect is unknown; however, only limited data are available to date regarding use of SSRIs in men who have PTSD related to noncombat-related trauma (e.g., sexual assault, accidents, natural disasters). There are insufficient data to date to determine whether race or age has any effect on the efficacy of sertraline in the management of PTSD.

■ **Premenstrual Dysphoric Disorder** Sertraline is used in the treatment of premenstrual dysphoric disorder (previously late luteal phase dysphoric disorder). DSM-IV criteria for premenstrual dysphoric disorder (PMDD) requires that in most menstrual cycles of the previous year at least 5 of the following 11 symptoms must have been present for most of the time during the last week of the luteal phase (with at least one of the symptoms being one of the first 4 listed): marked depressed mood, feelings of hopelessness, or self-deprecating thoughts; marked anxiety, tension, feelings of being "keyed up" or on "edge"; marked affective lability (e.g., feeling suddenly sad or tearful or increased sensitivity to rejection); persistent and marked anger or irritability or increased interpersonal conflicts; decreased interest in usual activities (e.g., work, school, friends, hobbies); a subjective sense of difficulty in concentrating; lethargy, easy fatigability, or marked lack of energy; marked change in appetite, overeating, or specific food cravings; hypersomnia or insomnia; a subjective sense of being overwhelmed or out of control; and other physical symptoms, such as breast tenderness or swelling, headaches, joint or muscle pain, or a sensation of "bloating" or weight gain. Such symptoms should begin to remit within a few days of the onset of menses (follicular phase) and are always absent in the week following menses. The presence of this cyclical pattern of symptoms must be confirmed by at least 2 consecutive months of prospective daily symptom ratings. PMDD should be distinguished from the more common

premenstrual syndrome (PMS) by prospective daily ratings and the strict criteria listed above.

The efficacy of sertraline for the management of PMDD has been established in 2 randomized, placebo-controlled studies over 3 menstrual cycles in adult women who met DSM-III-R or DSM-IV criteria for PMDD. In these studies, flexible dosages (range: 50–150 mg daily) of sertraline administered continuously throughout the menstrual cycle or during the luteal phase only (i.e., for 2 weeks prior to the onset of menses) were shown to be substantially more effective than placebo in improving scores from baseline on the Daily Record of Severity of Problems (DRSP), the Clinical Global Impression of Severity of Illness (CGI-S) and Improvement (CGI-I), and/or the Hamilton Depression Rating Scales (HAMD-17). The mean dosage of sertraline in patients completing these trials was 102 or 74 mg daily for those receiving continuous or luteal-phase dosing of the drug, respectively.

When given in a flexible dosage of 50–150 mg daily in a separate double-blind, placebo-controlled study, sertraline was substantially better than placebo in improving symptoms (depressive symptoms, physical symptoms, anger/irritability) and functional impairment associated with this disorder. The beneficial effect of the drug was apparent by the first treatment cycle. In an open study comparing sertraline and desipramine in the treatment of premenstrual dysphoric disorder, sertraline and possibly desipramine were found to be effective; however, sertraline was better tolerated than desipramine. Additional controlled studies are needed to determine whether the efficacy of the drug is sustained during longer-term, maintenance therapy in women with this condition. In addition, efficacy of sertraline used in conjunction with oral contraceptives for the treatment of PMDD has not been determined since patients receiving oral contraceptives were excluded from most clinical studies to date.

■ **Social Phobia** Sertraline is used in the treatment of social phobia (social anxiety disorder). According to DSM-IV, social phobia is characterized by a marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. Exposure to the feared situation almost invariably provokes anxiety, which may approach the intensity of a panic attack. The feared situations are avoided or endured with intense anxiety or distress. The avoidance, fear, or anxious anticipation of encountering the social or performance situation interferes significantly with the person's daily routine, occupational or academic functioning, or social activities or relationships, or there is marked distress about having the phobias. Lesser degrees of performance anxiety or shyness generally do not require psychotherapy or pharmacologic treatment.

The efficacy of sertraline in the treatment of social phobia has been established in 2 multicenter, placebo-controlled studies in adult outpatients who met DSM-IV criteria for social phobia. In one study of 12 weeks' duration, 47% of patients receiving flexible dosages of sertraline (50–200 mg daily; mean dosage of 144 mg daily) were characterized as responders (defined as a score of 1 or 2 on the Clinical Global Impressions [CGI] Global Improvement Scale) compared with 26% of those receiving placebo (intent-to-treat analysis). Sertraline also was found to be superior to placebo on the Liebowitz Social Anxiety Scale (LSAS), a 24-item clinician administered measure of fear, anxiety, and avoidance of social and performance situation, and on most secondary efficacy measures, including the Duke Brief Social Phobia Scale (BSPS) total score, fear and avoidance subscales of BSPS, and fear/anxiety and avoidance subscales of LSAS. These results were similar to those seen in a flexible-dose study of 20 weeks' duration, in which a score of 1 ("very much improved") or 2 ("much improved") on the CGI Global Improvement Scale was attained by the end of the treatment period by 53 or 29% of patients receiving sertraline (50–200 mg daily; mean dosage of 147 mg daily) or placebo, respectively (intent-to-treat analysis). Sixty-five patients in this study subsequently were enrolled in a separate controlled study, including 50 patients who had responded to sertraline in the initial study and then were randomized to receive either continued treatment with sertraline or placebo in the subsequent study and 15 patients who had responded to placebo in the initial study and continued to receive placebo in the subsequent study. Based on an intent-to-treat analysis, 4% of patients who continued treatment with sertraline, 36% of patients randomized to receive placebo, and 27% of those who continued treatment with placebo relapsed (defined as an increase of 2 or more points from baseline in the CGI Severity of Illness score or discontinuance of the study drug because of lack of efficacy) at the end of the 24-week treatment period. Similar to results of pivotal, short-term clinical studies, sertraline also was shown to be substantially more effective than placebo on the CGI Severity of Illness Scale, Marks Fear Questionnaire (MFQ) Social Phobia subscale, and BSPS total score.

Subgroup analysis of short-term, controlled studies in adult outpatients with social anxiety disorder did not reveal any evidence of gender-related differences in treatment outcome. There was insufficient information to determine the effect of race or age on treatment outcome. Safety and efficacy of sertraline for the treatment of social phobia in children or adolescents have not been established to date.

■ **Premature Ejaculation** Like some other serotonin-reuptake inhibitors, sertraline has been used with some success in the treatment of premature ejaculation†. In a placebo-controlled study, sertraline produced substantial improvements compared with placebo in time to ejaculation, number of successful attempts at intercourse, and incidence of ejaculation during foreplay, as well as overall clinical judgment of improvement. In addition, the drug was well tolerated in most patients. A trial with drug therapy may be particularly useful in patients who fail or refuse behavioral or psychotherapeutic treatment or when partners are unwilling to cooperate with such therapy.

■ **Other Uses** Sertraline has been used in a limited number of patients with various types of headache† with variable results; however, its use in this condition may be limited by frequent adverse effects.

Dosage and Administration

■ **Administration** Sertraline is administered orally. The drug usually is administered once daily in the morning or evening. The extent of GI absorption of sertraline reportedly may be increased slightly, the peak concentration increased by about 25%, and the time to peak concentration after a dose decreased from about 8 to 5.5 hours when the drug is administered with food, but such changes do not appear to be clinically important.

When sertraline hydrochloride concentrate for oral solution (Zoloft®) is used, doses of the drug should be measured carefully using the calibrated dropper provided by the manufacturer. The appropriate dose of the oral solution should be diluted in 120 mL of water, ginger ale, lemon/lime soda, lemonade, or orange juice before administration. The diluted solution containing sertraline hydrochloride should be mixed and administered immediately and should not be allowed to stand before administration. A slight haze may occasionally appear in the diluted oral solution, but the manufacturer states that this is normal.

■ **Dosage** Dosage of sertraline hydrochloride is expressed in terms of sertraline.

Patients receiving sertraline should be monitored for possible worsening of depression, suicidality, or unusual changes in behavior, especially at the beginning of therapy or during periods of dosage adjustment. (See Cautions: Precautions and Contraindications.)

Abrupt discontinuance of sertraline therapy should be avoided because of the potential for withdrawal reactions. (See Chronic Toxicity.) In addition, patients may experience a worsening of psychiatric status when the drug is discontinued abruptly. Therefore, it is recommended that dosage be tapered gradually (e.g., over a period of several weeks) and the patient monitored carefully when sertraline therapy is discontinued.

The manufacturers recommend that an interval of at least 2 weeks elapse when switching a patient from a monoamine oxidase (MAO) inhibitor to sertraline or when switching from sertraline to an MAO inhibitor. For additional information on potentially serious drug interactions that may occur between sertraline and MAO inhibitors or other serotonergic agents, see Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.

Clinical experience regarding the optimal timing of switching from other drugs used in the treatment of major depressive disorder, obsessive-compulsive disorder, panic disorder, posttraumatic stress disorder, premenstrual dysphoric disorder, and social anxiety disorder to sertraline therapy is limited. Therefore, the manufacturers recommend that care and prudent medical judgment be exercised when switching from other drugs to sertraline, particularly from long-acting agents (such as fluoxetine). Because some adverse reactions resembling serotonin syndrome have developed when fluoxetine therapy was discontinued abruptly and sertraline therapy was initiated immediately afterward, a washout period appears to be advisable when transferring a patient from fluoxetine to sertraline therapy. However, the appropriate duration of the washout period when switching from one selective serotonin-reuptake inhibitor to another has not been clearly established. Pending further experience in patients being transferred from therapy with another antidepressant to sertraline, it generally is recommended that the previous antidepressant be discontinued according to the recommended guidelines for the specific antidepressant prior to initiation of sertraline therapy. (See Drug Interactions: Serotonergic Drugs and see Drug Interactions: Tricyclic and Other Antidepressants.)

Major Depressive Disorder For the management of major depressive disorder in adults, the recommended initial dosage of sertraline is 50–100 mg once daily. If no clinical improvement is apparent, dosage may be increased at intervals of not less than 1 week up to a maximum of 200 mg daily. Clinical experience with the drug to date suggests that many patients will respond to 50–100 mg of the drug once daily. While a relationship between dose and antidepressant effect has not been established, efficacy of the drug was demonstrated in clinical trials employing 50–200 mg daily.

While the optimum duration of sertraline therapy has not been established, many experts state that acute depressive episodes require several months or longer of sustained antidepressant therapy. In addition, some clinicians recommend that long-term antidepressant therapy be considered in certain patients at risk for recurrence of depressive episodes (such as those with highly recurrent unipolar depression). Whether the dose of sertraline required to induce remission is identical to the dose needed to maintain and/or sustain euthymia is unknown. Systematic evaluation of sertraline has shown that its antidepressant efficacy is maintained for periods of up to 1 year in patients receiving 50–200 mg daily (mean dose of 70 mg daily). The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Obsessive-Compulsive Disorder For the management of obsessive-compulsive disorder in adults and adolescents 13–17 years of age, the recommended initial dosage of sertraline is 50 mg once daily. In children 6–12 years of age, the recommended initial dosage of sertraline is 25 mg once daily. If no clinical improvement is apparent, dosage may be increased at intervals of not less than 1 week up to a maximum of 200 mg daily. However, it should be considered that children usually have a lower body weight than adults and

particular care should be taken to avoid excessive dosage in children. While a relationship between dose and efficacy in obsessive-compulsive disorder has not been established, efficacy of the drug was demonstrated in clinical trials employing 50–200 mg daily in adults and 25–200 mg daily in children and adolescents.

While the optimum duration of sertraline therapy required to prevent recurrence of obsessive-compulsive symptoms has not been established to date, the manufacturer and many experts state that this disorder is chronic and requires several months or longer of sustained therapy. Whether the dose of sertraline required to induce remission is identical to the dose needed to maintain and/or sustain remission in patients with this disorder is unknown. Systematic evaluation of sertraline has shown that its efficacy in the management of obsessive-compulsive disorder is maintained for periods of up to 28 weeks in patients receiving 50–200 mg daily. The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Panic Disorder For the management of panic disorder in adults, the recommended initial dosage of sertraline is 25 mg once daily. After 1 week, the dosage should be increased to 50 mg once daily. If no clinical improvement is apparent, dosage may then be increased at intervals of not less than 1 week up to a maximum of 200 mg daily.

While the optimum duration of sertraline therapy required to prevent recurrence of panic disorder has not been established to date, the manufacturer and many experts state that this disorder is chronic and requires several months or longer of sustained therapy. Whether the dose of sertraline required to induce remission is identical to the dose needed to maintain and/or sustain remission in patients with this disorder is unknown. Systematic evaluation of sertraline has shown that its efficacy in the management of panic disorder is maintained for periods of up to 28 weeks in patients receiving 50–200 mg daily. The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Posttraumatic Stress Disorder For the management of posttraumatic stress disorder (PTSD) in adults, the recommended initial dosage of sertraline is 25 mg once daily. After 1 week, dosage should be increased to 50 mg once daily. If no clinical improvement is apparent, dosage may then be increased at intervals of not less than 1 week up to a maximum of 200 mg daily.

While the optimum duration of sertraline therapy required to prevent recurrence of PTSD has not been established to date, this disorder is chronic and it is reasonable to continue therapy in responding patients. Whether the dose of sertraline required to induce remission is identical to the dose needed to maintain and/or sustain remission in patients with this disorder is unknown. Systematic evaluation of sertraline has shown that its efficacy in the management of posttraumatic stress disorder is maintained for periods of up to 28 weeks in patients receiving 50–200 mg daily. The usefulness of the drug in patients receiving prolonged therapy should be reevaluated periodically.

Premenstrual Dysphoric Disorder For the treatment of premenstrual dysphoric disorder (previously late luteal-phase dysphoric disorder), the recommended initial dosage of sertraline is 50 mg daily given continuously throughout the menstrual cycle or given during the luteal-phase only (i.e., starting 2 weeks prior to the anticipated onset of menstruation and continuing through the first full day of menses). If no clinical improvement is apparent, dosage may be increased in 50-mg increments at the onset of each new menstrual cycle up to a maximum of 150 mg daily when administered continuously or 100 mg daily when administered during the luteal-phase only. If a dosage of 100 mg daily has been established with luteal phase dosing, dosages should be increased gradually over the first 3 days of each luteal phase dosing period. While a relationship between dose and effect in premenstrual dysphoric disorder (PMDD) has not been established, efficacy of the drug was demonstrated in clinical trials employing 50–150 mg daily.

The optimum duration of sertraline therapy required to treat PMDD has not been established to date. The manufacturer states that the efficacy of sertraline therapy beyond 3 menstrual cycles has not been demonstrated in controlled studies. However, because women commonly report that symptoms of PMDD worsen with age until relieved by the onset of menopause, the manufacturer recommends that long-term sertraline therapy be considered in responding women. Dosage adjustments, which may include transfers between dosing regimens (e.g., continuous versus luteal phase dosing), may be needed to maintain the patient on the lowest effective dosage, and patients should be periodically reassessed to determine the need for continued treatment.

Social Phobia For the management of social phobia in adults, the recommended initial dosage of sertraline is 25 mg once daily. After 1 week, the dosage should be increased to 50 mg once daily. If no clinical improvement is apparent, dosage may then be increased at intervals of not less than 1 week up to a maximum of 200 mg daily.

While the optimum duration of sertraline therapy required to prevent recurrence of social phobia symptoms has not been established to date, the manufacturer states that this disorder is chronic and requires several months or longer of sustained therapy. Whether the dose of sertraline required to induce remission is identical to the dose needed to maintain and/or sustain remission in patients with this disorder is unknown. Systematic evaluation of sertraline has shown that its efficacy in the management of social phobia is maintained for periods of up to 24 weeks following 20 weeks of therapy at dosages of 50–200 mg daily. Dosages should be adjusted so that the patient is maintained on the lowest effective dosage, and patients should be reassessed periodically to determine the need for continued therapy.

Premature Ejaculation For the management of premature ejaculation†, sertraline has been given in a dosage of 25–50 mg daily. Alternatively, patients have taken sertraline on an "as needed" basis using doses of 25–50 mg daily.

■ **Dosage in Geriatric Patients** *Major Depressive Disorder* For the management of depressive symptoms associated with dementia of the Alzheimer's type in geriatric patients, some experts recommend an initial sertraline dosage of 12.5–25 mg once daily. The dosage may then be gradually increased at intervals of 1–2 weeks up to a maximum dosage of 150–200 mg once daily.

■ **Dosage in Renal and Hepatic Impairment** The manufacturers state that, based on the pharmacokinetics of sertraline, there is no need for dosage adjustment in patients with renal impairment. Because sertraline does not appear to be removed substantially by dialysis, supplemental doses of the drug probably are unnecessary after dialysis.

Because sertraline is metabolized extensively by the liver, hepatic impairment can affect the elimination of the drug. (See Pharmacokinetics: Elimination.) Therefore, the manufacturers recommend that sertraline be administered with caution and in a reduced dosage or less frequently in patients with hepatic impairment.

■ **Treatment of Pregnant Women during the Third Trimester** Because some neonates exposed to sertraline and other SSRIs or selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) late in the third trimester of pregnancy have developed severe complications, consideration may be given to cautiously tapering sertraline therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Pregnancy, under Cautions: Pregnancy, Fertility, and Lactation.)

Cautions

The adverse effect profile of sertraline is similar to that of other selective serotonin-reuptake inhibitors (SSRIs) (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine). Because sertraline is a highly selective serotonin-reuptake inhibitor with little or no effect on other neurotransmitters, the incidence of some adverse effects commonly associated with tricyclic antidepressants, such as anticholinergic effects (dry mouth, constipation), adverse cardiovascular effects, drowsiness, and weight gain, is lower in patients receiving sertraline. However, certain adverse GI (e.g., nausea, diarrhea, anorexia) and nervous system (e.g., tremor, insomnia) effects appear to occur more frequently with sertraline and other SSRIs than with tricyclic antidepressants.

Overall, the adverse effect profile of sertraline in adults with depression, obsessive-compulsive disorder, or panic disorder appears to be similar. In controlled studies, the most common adverse effects occurring more frequently in adults receiving sertraline than in those receiving placebo included GI effects such as nausea, diarrhea or loose stools, dyspepsia, and dry mouth; nervous system effects such as somnolence, dizziness, insomnia, and tremor; sexual dysfunction in males (principally ejaculatory delay); and sweating. Discontinuance of sertraline therapy was required in about 15% of adults in clinical trials, principally because of adverse psychiatric (e.g., somnolence, insomnia, agitation, tremor), other nervous system (e.g., dizziness, headache), GI (e.g., nausea, diarrhea or loose stools, anorexia), or male sexual dysfunction (e.g., ejaculatory delay) effects or because of fatigue.

■ **Nervous System Effects** Headache is the most common adverse nervous system effect of sertraline, occurring in approximately 26% of patients receiving the drug in controlled clinical trials; headache occurred in 23% of those receiving placebo in these trials. Somnolence or drowsiness occurred in about 14% of patients receiving sertraline in controlled clinical trials. Headache or somnolence each required discontinuance of therapy in about 2% of patients. Fatigue has been reported in approximately 12% of patients receiving the drug in clinical trials and required discontinuance of therapy in about 1% of patients; this effect was reported in 8% of those receiving placebo in these trials.

Dizziness occurred in about 13% of patients receiving sertraline in controlled clinical trials and required discontinuance of therapy in less than 1% of patients. Insomnia occurred in about 22% of patients receiving the drug in controlled clinical trials. However, because insomnia is a symptom also associated with depression, relief of insomnia and improvement in sleep patterns may occur when clinical improvement in depression becomes apparent during antidepressant therapy. In clinical trials, about 2% of patients discontinued sertraline because of insomnia.

Tremor occurred in about 9%, nervousness in about 6%, anxiety (which occasionally may be severe [e.g., panic]) in about 4%, paresthesia in about 3%, and agitation in about 6% of patients receiving sertraline in controlled clinical trials. Tremor, agitation, and nervousness resulted in discontinuance of sertraline in about 1% of patients while anxiety resulted in discontinuance in less than 1% of patients in clinical trials. Agitation and anxiety may subside with continued therapy. Hypoesthesia, hypertonia, or malaise occurred in at least 1% of patients receiving sertraline in clinical trials. Impaired concentration, dystonia, or twitching occurred in approximately 0.1–1% of patients receiving sertraline, although these adverse effects have not been definitely attributed to the drug.

The incidence of seizures during sertraline therapy appears to be similar to or less than that observed during therapy with most other currently available antidepressants. Seizures occurred in less than 0.1% of patients receiving sertraline in clinical trials. (See Cautions: Precautions and Contraindications.)

Hypomania and mania have been reported in approximately 0.4% of patients receiving sertraline in controlled clinical trials, which is similar to the incidence reported in patients receiving active control agents (i.e., other antidepressants). In at least 2 patients, hypomanic symptoms occurred after they were receiving sertraline 200 mg daily for approximately 9 weeks. In both patients, the adverse reaction was obviated by a reduction in sertraline dosage. (See Cautions: Precautions and Contraindications.) Such reactions have occurred in patients receiving other antidepressant agents and may be caused by antidepressant-induced functional increases in catecholamine activity within the CNS, resulting in a "switch" from depressive to manic behavior. There is some evidence that patients with bipolar disorder may be more likely to experience antidepressant-induced hypomanic or manic reactions than patients without evidence of this disorder. In addition, limited evidence suggests that such reactions may occur more frequently in bipolar depressed patients receiving tricyclics and tetracyclics (e.g., maprotiline, mianserin [not commercially available in the US]) than in those receiving SSRIs (e.g., citalopram, escitalopram, fluoxetine, paroxetine, sertraline). However, further studies are needed to confirm these findings.

Asthenia has been reported in at least 1% of patients receiving sertraline; however, a causal relationship to the drug has not been established. Confusion, migraine, abnormal coordination, abnormal gait, hyperesthesia, ataxia, depersonalization, hallucinations, hyperkinesia, hypokinesia, nystagmus, vertigo, abnormal dreams, aggressive reaction, amnesia, apathy, paroniria, delusion, depression or aggravated depression, emotional lability, euphoria, abnormal thinking, or paranoid reaction have been reported in 0.1–1% of patients receiving the drug; although these adverse effects have not been definitely attributed to sertraline.

Adverse nervous system effects reported in less than 0.1% of patients receiving sertraline include dysphoria, choreoathetosis, dyskinesia, coma, dysphonia, hyporeflexia, hypotonia, ptosis, somnambulism, and illusion; these effects have not been definitely attributed to the drug. Although a causal relationship has not been established, psychosis, extrapyramidal symptoms, and oculogyric crisis have been reported during postmarketing surveillance. Serotonin syndrome and neuroleptic malignant syndrome (NMS)-like reactions also have been reported in patients receiving sertraline, other SSRIs, and selective serotonin- and norepinephrine-reuptake inhibitors. (See Cautions: Precautions and Contraindications, Drug Interactions: Serotonergic Drugs, and Acute Toxicity.)

A withdrawal syndrome, which also has not been definitely attributed to the drug, has been reported in less than 0.1% of sertraline-treated patients. Fatigue, severe abdominal cramping, memory impairment, and influenza-like symptoms were reported 2 days following the abrupt discontinuance of sertraline in one patient; when sertraline was restarted, the symptoms remitted. Electric shock-like sensations occurred in another patient 1 day after the last administered dose of sertraline; these sensations became less intense and eventually disappeared 13 weeks after sertraline therapy was discontinued. (See Chronic Toxicity.) Forgetfulness, panic attacks, and unspecified pain also have been reported rarely, although a causal relationship to sertraline has not been established. Sertraline also has been reported to precipitate or exacerbate "flashbacks" in patients who previously had used lysergic acid diethylamide (LSD).

Extrapyramidal reactions, including akathisia, stuttering (which may be a speech manifestation of akathisia), bilateral jaw stiffness, and torticollis, have been reported rarely with sertraline use, and such reactions appear to be a class effect of SSRIs and dose related. Reactions occurring *early* during therapy with these drugs may be secondary to preexisting parkinsonian syndrome and/or concomitant therapy.

Suicidality Suicidal ideation has been reported in less than 0.1% of adults receiving sertraline. The US Food and Drug Administration (FDA) has determined that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. (See Suicidality, under Cautions: Nervous System Effects, in Paroxetine 28:16.04.20.) Patients, therefore, should be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of sertraline therapy (i.e., the first few months) and during periods of dosage adjustments. (See Cautions: Precautions and Contraindications and Cautions: Pediatric Precautions.)

■ **GI Effects** Like other selective serotonin-reuptake inhibitors (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine), sertraline therapy is associated with a relatively high incidence of GI disturbances, principally nausea, dry mouth, and diarrhea/loose stools. The most frequent adverse effect associated with sertraline therapy is nausea, which occurred in about 28% of patients receiving the drug in controlled clinical trials. In clinical trials, nausea required discontinuance of sertraline in about 4% of patients. In general, the incidence of nausea associated with selective serotonin-reuptake inhibitors appears to be higher when therapy is initiated with high doses but decreases as therapy with these drugs is continued. While the mechanism(s) of sertraline-induced GI effects has not been fully elucidated, they appear to arise at least in part because of increased serotonergic activity in the GI tract (which may result in stimulation of small intestine motility and inhibition of gastric and large intestine motility) and possibly because of the drug's effect on central serotonergic type 3 (5-HT_3) receptors.

Diarrhea or loose stools occurred in about 20%, dry mouth in about 15%, constipation in about 7%, dyspepsia in about 8%, or anorexia in about 6% of patients receiving sertraline in controlled clinical trials. Other adverse GI effects associated with sertraline therapy include vomiting which occurred in about 4% and flatulence which occurred in about 3% of patients receiving the drug in controlled clinical trials. Abdominal pain was reported in approximately 2% and taste perversion in about 1% of patients receiving sertraline. In clinical trials, diarrhea or loose stools required discontinuance of sertraline in about 3% of patients and dry mouth required discontinuance of therapy in about 1% of patients.

Epidemiologic case-control and cohort design studies have suggested that selective serotonin-reuptake inhibitors may increase the risk of upper GI bleeding. Although the precise mechanism for this increased risk remains to be clearly established, serotonin release by platelets is known to play an important role in hemostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets thereby decreasing the amount of serotonin in platelets. In addition, concurrent use of aspirin or other nonsteroidal anti-inflammatory drugs was found to substantially increase the risk of GI bleeding in patients receiving selective serotonin-reuptake inhibitors in 2 of these studies. Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated. Further clinical studies are needed to determine the clinical importance of these findings. (See Cautions: Hematologic Effects, and see also Drug Interactions: Drugs Affecting Hemostasis.)

Although a causal relationship to sertraline has not been established, dysphagia, esophagitis, aggravation of dental caries, gastroenteritis, eructation, and increased salivation have been reported in 0.1–1% of patients receiving the drug. Aphthous stomatitis, ulcerative stomatitis, stomatitis, tongue ulceration or edema, glossitis, diverticulitis, gastritis, hemorrhagic peptic ulcer, rectal hemorrhage, colitis, proctitis, fecal incontinence, melena, or tenesmus has been reported in less than 0.1% of patients receiving sertraline; however, these adverse effects have not been definitely attributed to the drug. Pancreatitis also has been reported rarely in association with sertraline; however, a causal relationship to the drug has not been clearly established.

Although a causal relationship has not been established, nocturnal bruxism (clenching and/or grinding of the teeth during sleep) has developed within 2–4 weeks following initiation of sertraline or fluoxetine therapy in several patients. The bruxism remitted upon reduction in dosage of the serotonin-reuptake inhibitor and/or the addition of buspirone therapy.

Speech blockage also has been reported in at least one sertraline-treated patient.

■ **Dermatologic and Sensitivity Reactions** Sweating occurred in about 7% of patients receiving sertraline in controlled clinical trials.

Rash, which may be erythematous, follicular, maculopapular, or pustular, has been reported in about 3% of patients receiving sertraline in controlled clinical trials. Adverse dermatologic effects reported in 0.1–1% of patients receiving sertraline in controlled clinical trials include acne, alopecia, dry skin, urticaria, pruritus, and photosensitivity reaction (which may be severe); however, these adverse effects have not been definitely attributed to sertraline. Bullous eruption, eczema, contact dermatitis, skin discoloration, and hypertrichosis have been reported in less than 0.1% of patients receiving the drug, although a causal relationship to sertraline has not been established. Allergy, allergic reaction, and angioedema also have been reported rarely.

Other dermatologic and sensitivity events, which can be severe and potentially may be fatal, reported during the postmarketing surveillance of sertraline have included anaphylactoid reaction, angioedema, Stevens-Johnson syndrome, erythema multiforme, and vasculitis.

■ **Metabolic Effects** Thirst has been reported in 0.1–1% of patients receiving sertraline in controlled clinical trials.

Weight loss occurred in 0.1–1% of patients receiving sertraline. In controlled clinical trials, patients lost an average of about 0.45–0.9 kg while receiving sertraline. Rarely, weight loss has required discontinuance of therapy. Like fluoxetine, sertraline exhibits anorexigenic activity and can cause anorexia, which may be more pronounced in overweight patients and those with carbohydrate craving. Anorexia occurred in about 3% of patients receiving sertraline in controlled clinical trials and required discontinuance in at least 1% of patients. Increased appetite and weight gain have been reported in at least 1% of patients receiving sertraline in controlled clinical trials, although a causal relationship to the drug has not been established. (See Cautions: Pediatric Precautions.)

Sertraline use has been associated with small mean decreases (approximately 7%) in serum uric acid concentration as a result of a weak uricosuric effect; the clinical importance is not known and there have been no cases of acute renal failure associated with the drug. Small mean increases in serum total cholesterol (about 3%) and triglyceride (about 5%) concentrations also have been reported in patients receiving sertraline. Hypercholesterolemia has been reported in less than 0.1% of patients. Other adverse effects reported in less than 0.1% of patients receiving the drug include dehydration and hypoglycemia. These adverse effects have not been definitely attributed to sertraline.

■ **Ocular and Otic Effects** Abnormal vision (including blurred vision) occurred in about 4% of patients receiving sertraline in controlled clinical trials. Adverse ocular effects reported in 0.1–1% of patients receiving sertraline include abnormality of accommodation, conjunctivitis, mydriasis, and ocular pain. Although a causal relationship to sertraline has not been established, anisocoria, abnormal lacrimation, xerophthalmia, diplopia, scotoma, visual field defect, exophthalmos, hemorrhage of the anterior chamber of the eye,

glaucoma, or photophobia has been reported in less than 0.1% of patients receiving the drug. Other adverse ocular effects reported during postmarketing surveillance of sertraline have included blindness, optic neuritis, and cataract; however, a causal relationship to the drug has not been established.

Tinnitus occurred in at least 1% of patients receiving sertraline in controlled clinical trials. Earache has been reported in 0.1–1% of patients, and hyperacusis and labyrinthine disorder have been reported in less than 0.1% of patients.

■ **Cardiovascular Effects** Sertraline does not exhibit clinically important anticholinergic activity, and current evidence suggests that sertraline is less cardiotoxic than many antidepressant agents (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). (See Cardiovascular Considerations in Uses: Major Depressive Disorder and see also Pharmacology: Cardiovascular Effects.) However, bradycardia, AV block, atrial arrhythmias, QT-interval prolongation, and ventricular tachycardia (including torsades de pointes-type arrhythmias) have been reported during postmarketing surveillance evaluations of the drug.

Hot flushes occurred in about 2% of patients receiving sertraline in controlled clinical trials. Palpitation and chest pain have been reported in at least 1% of patients receiving sertraline in controlled clinical trials. In one patient with underlying coronary artery disease, chest pain developed suddenly and was relieved with sublingual nitroglycerin but was not associated with ECG changes; the mechanism of this effect, particularly regarding any potential cardiovascular effect, is unclear and alternative mechanisms (e.g., GI) for the chest pain have been proposed.

Unlike tricyclic antidepressants, sertraline has been associated with hypotension (e.g., orthostatic) infrequently; in controlled clinical trials, postural effects (e.g., dizziness, hypotension [which can also be nonpostural]) occurred in 0.1–1% of patients receiving sertraline. Syncope also occurred in at least 0.1% of patients.

Hypertension, peripheral ischemia, and tachycardia have been reported in 0.1–1% of patients receiving the drug, although a definite causal relationship to sertraline has not been established. Precordial or substernal chest pain, aggravated hypertension, myocardial infarction, pallor, vasodilation, and cerebrovascular disorder have been reported in less than 0.1% of patients receiving sertraline; these adverse effects have not been definitely attributed to the drug.

Generalized, dependent, periorbital, or peripheral edema has been reported in at least 0.1% of patients receiving sertraline, and facial edema has been reported rarely. However, a causal relationship to the drug has not been established.

■ **Musculoskeletal Effects** Myalgia or back pain occurred in at least 1% of patients receiving sertraline in controlled clinical trials. Arthralgia, arthrosis, leg or other muscle cramps, or muscle weakness has been reported in 0.1–1% of patients receiving sertraline; these adverse effects have not been definitely attributed to the drug.

■ **Hematologic Effects** Purpura, aplastic anemia, pancytopenia, leukopenia, thrombocytopenia, and abnormal bleeding have been reported occasionally in patients receiving sertraline; however, these adverse effects have not been definitely attributed to the drug.

Altered platelet function and/or abnormal platelet laboratory results have been reported rarely, but a causal relationship to sertraline remains to be established. In addition, in at least one patient with idiopathic thrombocytopenic purpura, sertraline therapy was associated with an increase in platelet counts. Anemia has been reported in less than 0.1% of patients receiving sertraline, although a causal relationship to the drug has not been established. Neutropenia also has been reported rarely with sertraline use and has been a reason for drug discontinuance. Agranulocytosis and septic shock developed in a geriatric woman who had been receiving sertraline for about 1 month in addition to atenolol, bendroflumethiazide, and thioridazine; the patient responded to anti-infective and granulocyte colony-stimulating factor therapy and made a full recovery within 10 days.

Bleeding complications (e.g., ecchymosis, purpura, menorrhagia, rectal bleeding) have been reported infrequently in patients receiving selective serotonin-reuptake inhibitors. Although the precise mechanism for these reactions has not been established, it has been suggested that impaired platelet aggregation and prolonged bleeding time may be due at least in part to inhibition of serotonin reuptake into platelets and/or that increased capillary fragility and vascular tone may contribute to these cases. (See Cautions: GI Effects and see also Drug Interactions: Drugs Affecting Hemostasis.)

■ **Respiratory Effects** Rhinitis or yawning has been reported in at least 1% of patients receiving sertraline in controlled clinical trials. Adverse respiratory effects reported in 0.1–1% of patients receiving the drug include bronchospasm, dyspnea, epistaxis, upper respiratory tract infection, sinusitis, and coughing; however, a definite causal relationship to sertraline has not been established. Adverse respiratory effects reported in less than 0.1% of patients receiving sertraline include bradypnea, hypoventilation, hyperventilation, apnea, stridor, hiccups, hemoptysis, bronchitis, laryngismus, and laryngitis. Pulmonary hypertension also has been reported during postmarketing surveillance evaluations of the drug. However, these adverse effects have not been definitely attributed to the drug.

■ **Renal, Electrolyte, and Genitourinary Effects** ***Sexual Dysfunction*** Like other selective serotonin-reuptake inhibitors, adverse effects on sexual function have been reported in both men and women receiving sertraline. Although changes in sexual desire, sexual performance, and sexual satisfaction often occur as manifestations of a psychiatric disorder, they also may occur as the result of pharmacologic therapy. It is difficult to determine the true incidence and severity of adverse effects on sexual function during sertraline therapy, in part because patients and clinicians may be reluctant to discuss these effects. Therefore, incidence data reported in product labeling and earlier studies are most likely underestimates of the true incidence of adverse sexual effects. Recent reports indicate that up to 50% of patients receiving selective serotonin-reuptake inhibitors describe some form of sexual dysfunction during treatment and the actual incidence may be even higher.

Sexual dysfunction (principally ejaculatory delay) is the most common adverse urogenital effect of sertraline in males, occurring in about 14% of male patients receiving the drug in controlled clinical trials. In some cases, this effect has been used for therapeutic benefit in the treatment of premature ejaculation. (See Uses: Premature Ejaculation.) Impotence has occurred in at least 1% of male patients receiving sertraline in controlled trials, and priapism has been reported rarely. Female sexual dysfunction (e.g., anorgasmia) has been reported in at least 1% of female patients receiving the drug in controlled clinical trials. Decreased libido has been reported in males and females, occurring in 6% of patients in controlled clinical studies. Sexual dysfunction (principally ejaculatory delay) required discontinuance of therapy in at least 1% of patients in controlled clinical trials. Increased libido has been reported in less than 1% of patients receiving the drug.

Results of some (but not all) studies in men and women suggest that paroxetine may be associated with a higher incidence of sexual dysfunction than some other currently available selective serotonin-reuptake inhibitors, including sertraline and citalopram. Since it is difficult to know the precise risk of sexual dysfunction associated with serotonin-reuptake inhibitors, clinicians should routinely inquire about such possible adverse effects in patients receiving these drugs.

The long-term effects of selective serotonin-reuptake inhibitors on sexual function have not been fully determined to date. In a double-blind study evaluating 6 months of sertraline or citalopram therapy in depressed patients, sexual desire and overall sexual functioning (as mensured on the UKU Side Effect Scale) substantially improved in women and sexual desire improved in men. In men, no change in orgasmic dysfunction, erectile dysfunction, or overall sexual functioning was reported after 6 months of therapy with sertraline or citalopram, although there was a trend toward worsening of ejaculatory dysfunction. However, in the subgroups of women and men reporting no sexual problems at baseline, approximately 12% of women reported decreased sexual desire and 14% reported orgasmic dysfunction after 6 months of citalopram therapy; the corresponding figures in the same subgroup of men were approximately 17 and 19%, respectively, and as many as 25% experienced ejaculatory dysfunction after 6 months. No substantial differences between sertraline and citalopram were reported in this study.

Management of sexual dysfunction caused by selective serotonin-reuptake inhibitor therapy includes waiting for tolerance to develop; using a lower dosage of the drug; using drug holidays; delaying administration of the drug until after coitus; or changing to another antidepressant. Although further study is needed, there is some evidence that adverse sexual effects of the selective serotonin-reuptake inhibitors may be reversed by concomitant use of certain drugs, including buspirone, 5-hydroxytryptamine-2 (5-HT_2) receptor antagonists (e.g., nefazodone), 5-HT_3 receptor inhibitors (e.g., granisetron), or α_2-adrenergic receptor antagonists (e.g., yohimbine), selective phosphodiesterase (PDE) inhibitors (e.g., sildenafil), or dopamine receptor agonists (e.g., amantadine, dextroamphetamine, pemoline [no longer commercially available in the US], methylphenidate). In most patients, sexual dysfunction is fully reversed 1–3 days after discontinuance of the antidepressant.

Other Renal, Electrolyte, and Genitourinary Effects Although a definite causal relationship to sertraline has not been established, menstrual disorders, dysmenorrhea, intermenstrual bleeding, amenorrhea, vaginal hemorrhage, and leukorrhea have been reported in 0.1–1% of patients receiving sertraline. In addition, menorrhagia, breast enlargement, female breast pain or tenderness, acute mastitis in females, gynecomastia, and atrophic vaginitis have been reported in less than 0.1% of patients receiving sertraline; however, a causal relationship to the drug has not been clearly established.

Treatment with SSRIs, including sertraline, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when the SSRI or SNRI was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Hyponatremia and SIADH in patients receiving SSRIs usually develop an average of 2 weeks after initiating therapy (range: 3–120 days). Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Discontinuance of sertraline should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. Because geriatric patients may be at increased risk for hyponatremia associated with these drugs, clinicians prescribing sertraline in such patients should be aware of the possibility that such reactions may occur. In addition, periodic monitoring of serum sodium concentrations (particularly during the first several months) in geriatric patients receiving SSRIs has been recommended by some clinicians.

A variety of urinary disorders, including urinary frequency, polyuria, urinary hesitancy and/or retention, dysuria, nocturia, and urinary incontinence, has been reported in 0.1–1% of patients receiving sertraline; however, these

effects have not been definitely attributed to the drug. In addition, cystitis, oliguria, pyelonephritis, hematuria, renal pain, strangury, and balanoposthitis have been reported in less than 0.1% of patients receiving sertraline, although a causal relationship to the drug has not been clearly established.

■ **Hepatic Effects** Impaired hepatic function has been reported in less than 1% of patients receiving sertraline in controlled clinical trials; in most cases, such reactions appeared to be reversible upon discontinuance of sertraline therapy. Asymptomatic elevations in serum AST (SGOT) and ALT (SGPT) concentrations have been reported in approximately 0.8% of patients receiving the drug and occasionally have been a reason for drug discontinuance. Elevations in aminotransferase concentrations usually occurred within the first 1–9 weeks of sertraline therapy and were rapidly reversible following discontinuance of the drug. In addition, in at least 2 patients, elevated liver enzymes returned to normal levels with continued therapy.

Increased serum alkaline phosphatase and bilirubin concentrations occurred rarely in patients receiving sertraline in clinical trials and required discontinuance of therapy in some cases. Other clinical features associated with adverse hepatic reactions that have been reported in at least one patient include hepatitis, hepatomegaly, jaundice, abdominal pain, vomiting, hepatic failure, and death. However, these effects have not been definitely attributed to the drug.

■ **Endocrine Effects** Low levels of total thyroxine developed in a depressed adolescent who had been receiving sertraline therapy; however, it appears that sertraline only displaced the bound fraction of total thyroxine but was not associated with true hypothyroidism. In a limited number of hypothyroid patients receiving thyroxine therapy, elevated serum thyrotropin and reduced serum thyroxine concentrations have been observed following the initiation of sertraline therapy. Hypothyroidism also has been reported. (See Cautions: Precautions and Contraindications.)

Hyperprolactinemia and galactorrhea also have been reported rarely; however, a causal relationship to the drug has not been established.

■ **Other Adverse Effects** Cold clammy skin, flushing, fever, or rigors has been reported in 0.1–1% of patients receiving the drug, although a causal relationship to sertraline has not been established. In addition, lupus-like syndrome and serum sickness have been reported during postmarketing surveillance evaluations of the drug; however, a causal relationship has not been definitively established.

■ **Precautions and Contraindications** Worsening of depression and/or the emergence of suicidal ideation and behavior (suicidality) or unusual changes in behavior may occur in both adult and pediatric (see Cautions: Pediatric Precautions) patients with major depressive disorder or other psychiatric disorders, whether or not they are taking antidepressants. This risk may persist until clinically important remission occurs. Suicide is a known risk of depression and certain other psychiatric disorders, and these disorders themselves are the strongest predictors of suicide. However, there has been a long-standing concern that antidepressants may have a role in inducing worsening of depression and the emergence of suicidality in certain patients during the early phases of treatment. Pooled analyses of short-term, placebo-controlled studies of antidepressants (i.e., selective serotonin-reuptake inhibitors [SSRIs] and other antidepressants) have shown an increased risk of suicidality in children, adolescents, and young adults (18–24 years of age) with major depressive disorder and other psychiatric disorders. An increased suicidality risk was not demonstrated with antidepressants compared to placebo in adults older than 24 years of age and a reduced risk was observed in adults 65 years of age or older. It currently is unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months); however, there is substantial evidence from placebo-controlled maintenance trials in adults with major depressive disorder that antidepressants can delay the recurrence of depression.

The US Food and Drug Administration (FDA) recommends that all patients being treated with antidepressants for any indication be appropriately monitored and closely observed for clinical worsening, suicidality, and unusual changes in behavior, particularly during initiation of therapy (i.e., the first few months) and during periods of dosage adjustments. Families and caregivers of patients being treated with antidepressants for major depressive disorder or other indications, both psychiatric and nonpsychiatric, also should be advised to monitor patients on a daily basis for the emergence of agitation, irritability, or unusual changes in behavior as well as the emergence of suicidality, and to report such symptoms immediately to a health-care provider. (See Suicidality under Cautions: Nervous System Effects, in Paroxetine 28:16.04.20.)

Although a causal relationship between the emergence of symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and/or mania and either the worsening of depression and/or the emergence of suicidal impulses has not been established, there is concern that such symptoms may represent precursors to emerging suicidality. Consequently, consideration should be given to changing the therapeutic regimen, or discontinuing therapy in patients whose depression is persistently worse or in patients experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality, particularly if such manifestations are severe, abrupt in onset, or were not part of the patient's presenting symptoms. If a decision is made to discontinue therapy, sertraline dosage should be tapered as rapidly as is feasible but with recognition of the risks of abrupt discontinuance. (See Dosage and Administration: Dosage.) FDA also recommends that the drugs be prescribed in the smallest quantity consistent with good patient management, in order to reduce the risk of overdosage.

It is generally believed (though not established in controlled trials) that treating a major depressive episode with an antidepressant alone may increase the likelihood of precipitating a mixed or manic episode in patients at risk for bipolar disorder. Therefore, patients should be adequately screened for bipolar disorder prior to initiating treatment with an antidepressant; such screening should include a detailed psychiatric history (e.g., family history of suicide, bipolar disorder, and depression).

Potentially life-threatening serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions have been reported with SSRIs, including sertraline, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) alone, but particularly with concurrent administration of other serotonergic drugs (including serotonin [5-hydroxytryptamine; 5-HT] type 1 receptor agonists ["triptans"]), drugs that impair the metabolism of serotonin (e.g., monoamine oxidase [MAO] inhibitors), or antipsychotic agents or other dopamine antagonists. Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. Patients receiving sertraline should be monitored for the development of serotonin syndrome or NMS-like signs and symptoms.

Concurrent or recent (i.e., within 2 weeks) therapy with MAO inhibitors used for treatment of depression is contraindicated in patients receiving sertraline and vice versa. If concurrent therapy with sertraline and a 5-HT_1 receptor agonist (triptan) is clinically warranted, the patient should be observed carefully, particularly during initiation of therapy, when dosage is increased, or when another serotonergic agent is initiated. Concomitant use of sertraline and serotonin precursors (e.g., tryptophan) is not recommended. If signs and symptoms of serotonin syndrome or NMS develop during sertraline therapy, treatment with sertraline and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated. (See Drug Interactions: Serotonergic Drugs.)

The dropper dispenser provided with Zoloft® oral solution contains natural latex proteins in the form of dry natural rubber which may cause sensitivity reactions in susceptible individuals.

Because clinical experience with sertraline in patients with certain concurrent systemic disease, including cardiovascular disease and renal impairment, is limited, caution should be exercised when sertraline is administered to patients with any systemic disease or condition that may alter metabolism of the drug or adversely affect hemodynamic function. (See Dosage and Administration: Dosage.)

Sertraline should be used with caution in patients with hepatic impairment, since prolonged elimination of the drug has been reported to occur in patients with liver cirrhosis. (See Pharmacokinetics: Elimination and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

The manufacturers recommend that patients receiving sertraline be advised to notify their clinician if they are taking or plan to take nonprescription (over-the-counter) or prescription medications or alcohol-containing beverages or preparations. Although no interactions with nonprescription medications have been reported to date, the potential for such adverse drug interactions exists. Therefore, the use of any nonprescription medication should be initiated cautiously according to the directions of use provided on the nonprescription medication. Although sertraline has not been shown to potentiate the impairment of mental and motor skills caused by alcohol, the manufacturers recommend that patients be advised to avoid alcohol while receiving the drug.

Sertraline generally is less sedating than most other currently available antidepressants and does not appear to produce substantial impairment of cognitive or psychomotor function. However, patients should be cautioned that sertraline may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle) and to avoid such activities until they experience how the drug affects them. Because the risk of using sertraline concomitantly with other CNS active drugs has not been evaluated systematically to date, the manufacturers recommend that such therapy be employed cautiously.

Seizures have been reported in patients receiving therapeutic dosages of sertraline. Because of limited experience with sertraline in patients with a history of seizures, the drug should be used with caution in such patients.

Activation of mania and hypomania has occurred in patients receiving therapeutic dosages of sertraline. The drug should be used with caution in patients with a history of mania or hypomania.

Treatment with SSRIs, including sertraline, and selective serotonin- and norepinephrine-reuptake inhibitors (SNRIs) may result in hyponatremia. In many cases, this hyponatremia appears to be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and was reversible when sertraline was discontinued. Cases with serum sodium concentrations lower than 110 mEq/L have been reported. Geriatric individuals and patients receiving diuretics or who are otherwise volume depleted may be at greater risk of developing hyponatremia during therapy with SSRIs or SNRIs. Signs and symptoms of hyponatremia include headache, difficulty concentrating, memory impairment, confusion, weakness, and unsteadiness, which may lead to falls; more severe and/or acute cases have been associated with hallucinations, syncope, seizures, coma, respiratory arrest, and death. Discontinuance of sertraline

should be considered in patients with symptomatic hyponatremia and appropriate medical intervention should be instituted. (See Cautions: Renal, Electrolyte, and Genitourinary Effects and see also Cautions: Geriatric Precautions.)

Altered platelet function has been reported rarely in patients receiving sertraline. In addition, use of the drug has been associated with several reports of abnormal bleeding or purpura. While a causal relationship to sertraline remains to be established, pending such establishment, the drug should be used with caution in patients with an underlying coagulation defect since the possible effects on hemostasis may be exaggerated in such patients. (See Cautions: Hematologic Effects.)

Sertraline has a weak uricosuric effect. (See Cautions: Metabolic Effects.) Pending further elucidation of the clinical importance, if any, of this effect, the drug should be used with caution in patients who may be adversely affected (e.g., those at risk for acute renal failure).

Because sertraline therapy has been associated with anorexia and weight loss (see Cautions: Metabolic Effects), the drug should be used with caution in patients who may be adversely affected by these effects (e.g., underweight patients).

Like many other antidepressant drugs, sertraline has been associated with hypothyroidism, elevated serum thyrotropin, and/or reduced serum thyroxine concentrations in a limited number of patients. Because of reports with other antidepressant agents and the complex interrelationship between the hypothalamic-pituitary-thyroid axis and affective (mood) disorders, at least one manufacturer recommends that thyroid function be reassessed periodically in patients with thyroid disease who are receiving sertraline.

Commercially available sertraline hydrochloride oral solution (Zoloft®) contains alcohol. Therefore, concomitant use of sertraline hydrochloride oral solution and disulfiram is contraindicated.

Sertraline is contraindicated in patients concurrently receiving pimozide. (See Drug Interactions: Pimozide.)

Sertraline also is contraindicated in patients who are hypersensitive to the drug or any ingredient in the formulation.

■ **Pediatric Precautions** Safety and efficacy of sertraline in children with obsessive-compulsive disorder (OCD) younger than 6 years of age have not been established. Safety and efficacy of sertraline in children with other disorders (e.g., major depressive disorder, panic disorder, posttraumatic stress disorder, premenstrual dysphoric disorder, social phobia) have not been established. The overall adverse effect profile of sertraline in over 600 pediatric patients who received sertraline in controlled clinical trials was generally similar to that seen in the adult clinical studies. However, adverse effects reported in at least 2% of the sertraline-treated pediatric patients in these trials and that occurred at least twice as frequently as in pediatric patients receiving placebo included fever, hyperkinesia, urinary incontinence, aggressive reaction, sinusitis, epistaxis, and purpura.

Efficacy of sertraline in pediatric patients with major depressive disorder was evaluated in 2 randomized, 10-week, double-blind, placebo-controlled, flexible-dose (50–200 mg daily) trials in 373 children and adolescents with major depressive disorder, but data from these studies were not sufficient to establish efficacy in pediatric patients. In a safety analysis of the pooled data from these 2 studies, a difference in weight change between the sertraline and placebo groups was noted of approximately 1 kg for both pediatric patients (6–11 years of age) and adolescents (12–17 years of age) representing a slight weight loss for those receiving sertraline and a slight weight gain for those receiving placebo. In addition, a larger difference was noted in children than in adolescents between the sertraline and placebo groups in the proportion of outliers for clinically important weight loss; about 7% of the children and about 2% of the adolescents receiving sertraline in these studies experienced a weight loss of more than 7% of their body weight compared with none of those receiving placebo.

A subset of patients who completed these controlled trials was continued into a 24-week, flexible-dose, open-label, extension study. A mean weight loss of approximately 0.5 kg was observed during the initial 8 weeks of treatment for those pediatric patients first exposed to sertraline during the extension study, which was similar to the weight loss observed among sertraline-treated patients during the first 8 weeks of the randomized controlled trials. The patients continuing in the extension study began gaining weight relative to their baseline weight by week 12 of sertraline therapy, and patients who completed the entire 34 weeks of therapy with the drug had a weight gain that was similar to that expected using data from age-adjusted peers. The manufacturers state that periodic monitoring of weight and growth is recommended in pediatric patients receiving long-term therapy with sertraline or other selective serotonin-reuptake inhibitors (SSRIs).

FDA warns that antidepressants increase the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder and other psychiatric disorders. The risk of suicidality for these drugs was identified in a pooled analysis of data from a total of 24 short-term (4–16 weeks), placebo-controlled studies of 9 antidepressants (i.e., sertraline, bupropion, citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, paroxetine, venlafaxine) in over 4400 children and adolescents with major depressive disorder, OCD, or other psychiatric disorders. The analysis revealed a greater risk of adverse events representing suicidal behavior or thinking (suicidality) during the first few months of treatment in pediatric patients receiving antidepressants than in those receiving placebo. However, a more recent meta-analysis of 27 placebo-controlled trials of 9 antidepressants (SSRIs and others) in patients younger than 19 years of age with major depressive disorder, OCD, or non-OCD anxiety disorders suggests that the benefits of antidepressant therapy in treating these conditions may outweigh the risks of suicidal behavior or suicidal ideation. No suicides occurred in these pediatric trials.

The risk of suicidality in FDA's pooled analysis differed across the different psychiatric indications, with the highest incidence observed in the major depressive disorder studies. In addition, although there was considerable variation in risk among the antidepressants, a tendency toward an increase in suicidality risk in younger patients was found for almost all drugs studied. It is currently unknown whether the suicidality risk in pediatric patients extends to longer-term use (i.e., beyond several months). (See Suicidality, under Cautions: Nervous System Effects, in Paroxetine 28:16.04.20.)

As a result of this analysis and public discussion of the issue, FDA has directed manufacturers of all antidepressants to add a boxed warning to the labeling of their products to alert clinicians of this suicidality risk in children and adolescents and to recommend appropriate monitoring and close observation of patients receiving these agents. (See Cautions: Precautions and Contraindications.) The drugs that are the focus of the revised labeling are all drugs included in the general class of antidepressants, including those that have not been studied in controlled clinical trials in pediatric patients, since the available data are not adequate to exclude any single antidepressant from an increased risk. In addition to the boxed warning and other information in professional labeling on antidepressants, FDA currently recommends that a patient medication guide explaining the risks associated with the drugs be provided to the patient each time the drugs are dispensed. Caregivers of pediatric patients whose depression is persistently worse or who are experiencing emergent suicidality or symptoms that might be precursors to worsening depression or suicidality during antidepressant therapy should consult their clinician regarding the best course of action (e.g., whether the therapeutic regimen should be changed or the drugs discontinued). *Patients should not discontinue use of selective serotonin-reuptake inhibitors without first consulting their clinician; it is very important that the drugs not be abruptly discontinued (see Dosage and Administration: Dosage), as withdrawal effects may occur.*

Anyone considering the use of sertraline in a child or adolescent for any clinical use must balance the potential risk of therapy with the clinical need.

■ **Geriatric Precautions** In clinical studies in geriatric patients, 660 patients receiving sertraline for the treatment of depression were 65 years of age or older, and 180 were 75 years of age or older. No overall differences in efficacy or adverse effects were observed for geriatric patients in these studies relative to younger patients, and other clinical experience has revealed no evidence of age-related differences in safety. In addition, no adverse effects on psychomotor performance were observed in geriatric individuals who received the drug in one controlled study. However, the possibility that older patients may exhibit increased sensitivity to the drug cannot be excluded. (See Dosage in Geriatric Patients under Dosage and Administration.)

Limited evidence suggests that geriatric patients may be more likely than younger patients to develop sertraline-induced hyponatremia and transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Therefore, clinicians prescribing sertraline in geriatric patients should be aware of the possibility that such reactions may occur. Periodic monitoring (especially during the first several months) of serum sodium concentrations in geriatric patients receiving the drug has been recommended by some clinicians. (See Cautions: Precautions and Contraindications.)

As with other psychotropic drugs, geriatric patients receiving antidepressants appear to have an increased risk of hip fracture. Despite the fewer cardiovascular and anticholinergic effects associated with selective serotonin-reuptake inhibitors (SSRIs), these drugs did not show any advantage over tricyclic antidepressants with regard to hip fracture in a case-control study. In addition, there was little difference in the rates of falls between nursing home residents receiving SSRIs and those receiving tricyclic antidepressants in a retrospective study. Therefore, all geriatric individuals receiving either type of antidepressant should be considered to be at increased risk of falls and appropriate measures should be taken.

In pooled data analyses, a *reduced* risk of suicidality was observed in adults 65 years of age or older with antidepressant therapy compared with placebo. (See Cautions: Precautions and Contraindications.)

Plasma clearance of sertraline may be decreased in geriatric patients; plasma clearance of the less active metabolite, *N*-desmethylsertraline, also may be decreased in older males.

■ **Mutagenicity and Carcinogenicity** Sertraline was not mutagenic, with or without metabolic activation, in several in vitro tests including the bacterial mutation assay and the mouse lymphoma mutation assay. Sertraline also was not mutagenic in tests for cytogenetic aberrations in vivo in mouse bone marrow and in vitro in human lymphocytes.

Lifetime studies to determine the carcinogenic potential of sertraline were performed in CD-1 mice and Long-Evans rats receiving dosages up to 40 mg/kg daily. This dosage corresponded to 1 and 2 times the maximum recommended human dose on a mg/m² basis in mice and rats, respectively. There was a dose-related increase in the incidence of hepatic adenomas in male mice receiving sertraline dosages of 10–40 mg/kg (0.25–1 times the maximum recommended human dose on a mg/m² basis). No increase was seen in female mice or in rats of either gender receiving the same dosages, nor was there an increase in hepatocellular carcinomas. Hepatic adenomas have a variable rate of spontaneous occurrence in this strain of mice, and the relevance of this finding to humans is not known. There was an increase in follicular adenomas

of the thyroid, not accompanied by thyroid hyperplasia, in female rats receiving a sertraline dosage of 40 mg/kg (2 times the maximum recommended human dose on a mg/m² basis). There also was an increase in uterine adenocarcinomas in rats receiving sertraline dosages of 10–40 mg/kg (0.5–2 times the maximum recommended human dose on a mg/m² basis); however, this effect could not be directly attributed to the drug.

■ **Pregnancy, Fertility, and Lactation** ***Pregnancy*** Some neonates exposed to sertraline and other SSRIs or SNRIs late in the third trimester of pregnancy have developed complications that have sometimes been severe and required prolonged hospitalization, respiratory support, enteral nutrition, and other forms of supportive care in special-care nurseries. Such complications can arise immediately upon delivery and usually last several days or up to 2–4 weeks. Clinical findings reported to date in the neonates have included respiratory distress, cyanosis, apnea, seizures, temperature instability or fever, feeding difficulty, dehydration, excessive weight loss, vomiting, hypoglycemia, hypotonia, hypertonia, hyperreflexia, tremor, jitteriness, irritability, lethargy, reduced or lack of reaction to pain stimuli, and constant crying. These clinical features appear to be consistent with either a direct toxic effect of the SSRI or SNRI or, possibly, a drug withdrawal syndrome. It should be noted that in some cases the clinical picture was consistent with serotonin syndrome (see Drug Interactions: Serotonergic Drugs). When treating a pregnant woman with sertraline during the third trimester of pregnancy, the clinician should carefully consider the potential risks and benefits of such therapy. Consideration may be given to cautiously tapering sertraline therapy in the third trimester prior to delivery if the drug is administered during pregnancy. (See Treatment of Pregnant Women during the Third Trimester under Dosage and Administration: Dosage.)

FDA states that decisions about management of depression in pregnant women are challenging and that the patient and her clinician must carefully consider and discuss the potential benefits and risks of SSRI therapy during pregnancy for the individual woman. Two recent studies provide important information on risks associated with discontinuing or continuing antidepressant therapy during pregnancy.

The first study, which was prospective, naturalistic, and longitudinal in design, evaluated the potential risk of relapsed depression in pregnant women with a history of major depressive disorder who discontinued or attempted to discontinue antidepressant (SSRIs, tricyclic antidepressants, or others) therapy during pregnancy compared with that in women who continued antidepressant therapy throughout their pregnancy; all women were euthymic while receiving antidepressant therapy at the beginning of pregnancy. In this study, women who discontinued antidepressant therapy were found to be 5 times more likely to have a relapse of depression during their pregnancy than were women who continued to receive their antidepressant while pregnant, suggesting that pregnancy does not protect against a relapse of depression.

The second study suggests that infants exposed to SSRIs in late pregnancy may have an increased risk of persistent pulmonary hypertension of the newborn (PPHN), which is associated with substantial neonatal morbidity and mortality. PPHN occurs at a rate of 1–2 neonates per 1000 live births in the general population in the US. In this retrospective case-control study of 377 women whose infants were born with PPHN and 836 women whose infants were born healthy, the risk for developing persistent pulmonary hypertension of the newborn was approximately sixfold higher for infants exposed to SSRIs after the twentieth week of gestation compared with infants who had not been exposed to SSRIs during this period. The study was too small to compare the risk of PPHN associated with individual SSRIs, and the findings have not been confirmed. Although the risk of PPHN identified in this study still is low (6–12 cases per 1000) and further study is needed, the findings add to concerns from previous reports that infants exposed to SSRIs late in pregnancy may experience adverse effects.

Most epidemiologic studies of pregnancy outcome following first-trimester exposure to SSRIs, including sertraline, conducted to date have not revealed evidence of an increased risk of major congenital malformations. In a prospective, controlled, multicenter study, maternal use of several SSRIs (sertraline, fluvoxamine, paroxetine) in a limited number of pregnant women did not appear to increase the risk of congenital malformation, miscarriage, stillbirth, or premature delivery when used during pregnancy at recommended dosages. Birth weight and gestational age in neonates exposed to the drugs were similar to those in the control group. In another small study based on medical records review, the incidence of congenital anomalies reported in infants born to women who were treated with sertraline and other SSRIs during pregnancy was comparable to that observed in the general population. However, the results of epidemiologic studies indicate that exposure to paroxetine during the first trimester of pregnancy may increase the risk for congenital malformations, particularly cardiovascular malformations. (See Cautions: Pregnancy, Fertility, and Lactation, in Paroxetine 28:16.04.20.) Additional epidemiologic studies are needed to more thoroughly evaluate the relative safety of sertraline and other SSRIs during pregnancy, including their potential teratogenic risks and possible effects on neurobehavioral development.

The manufacturers state that there are no adequate and controlled studies to date using sertraline in pregnant women, and the drug should be used during pregnancy only when the potential benefits justify the possible risks to the fetus. Women should be advised to notify their physician if they become pregnant or plan to become pregnant during therapy with the drug. FDA states that women who are pregnant or thinking about becoming pregnant should not discontinue any antidepressant, including sertraline, without first consulting their clinician. The decision whether or not to continue antidepressant therapy should be made only after careful consideration of the potential benefits and risks of antidepressant therapy for each individual pregnant patient. If a decision is made to discontinue treatment with sertraline or other SSRIs before or during pregnancy, discontinuance of therapy should be done in consultation with the clinician in accordance with the prescribing information for the antidepressant and the patient should be closely monitored for possible relapse of depression.

Reproduction studies in rats using sertraline dosages up to 80 mg/kg daily and in rabbits using dosages up to 40 mg/kg daily have not revealed evidence of teratogenicity; these dosages correspond to approximately 4 times the maximum recommended human dosage on a mg/m² basis. No evidence of teratogenicity was observed at any dosage studied. When pregnant rats and rabbits were given sertraline during the period of organogenesis, delayed ossification was observed in fetuses at doses of 10 mg/kg (0.5 times the maximum recommended human dose on a mg/m² basis) in rats and 40 mg/kg (4 times the maximum recommended human dose on a mg/m² basis) in rabbits. When female rats received sertraline during the last third of gestation and throughout lactation, there was an increase in the number of stillborn pups and in the number of pups dying during the first 4 days after birth. The body weights of the pups also were decreased during the first 4 days after birth. These effects occurred at a dose of 20 mg/kg (approximately the same as the maximum recommended human dose on a mg/m² basis). At 10 mg/kg (0.5 times the maximum recommended human dose on a mg/m² basis), no effect on rat pup mortality was observed. The decrease in pup survival was shown to result from in utero exposure to the drug. The clinical importance of these effects is not known.

The effect of sertraline on labor and delivery is not known.

Fertility A decrease in fertility was observed in 1 of 2 reproduction studies in rats using sertraline dosages of 80 mg/kg (4 times the maximum recommended human dose on a mg/m² basis).

Lactation Sertraline and its principal metabolite, *N*-desmethylsertraline, are distributed into milk. Sertraline should be used with caution in nursing women, and women should be advised to notify their physician if they plan to breast-feed.

Drug Interactions

■ **Serotonergic Drugs** Use of selective serotonin-reuptake inhibitors (SSRIs) such as sertraline concurrently or in close succession with other drugs that affect serotonergic neurotransmission may result in serotonin syndrome or neuroleptic malignant syndrome (NMS)-like reactions. Symptoms of serotonin syndrome may include mental status changes (e.g., agitation, hallucinations, coma), autonomic instability (e.g., tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g., hyperreflexia, incoordination), and/or GI symptoms (e.g., nausea, vomiting, diarrhea). Although the syndrome appears to be relatively uncommon and usually mild in severity, serious and potentially life-threatening complications, including seizures, disseminated intravascular coagulation, respiratory failure, and severe hyperthermia as well as death occasionally have been reported. In its most severe form, serotonin syndrome may resemble NMS, which is characterized by hyperthermia, muscle rigidity, autonomic instability with possible rapid fluctuation in vital signs, and mental status changes. The precise mechanism of these reactions is not fully understood; however, they appear to result from excessive serotonergic activity in the CNS, probably mediated by activation of serotonin 5-HT_{1A} receptors. The possible involvement of dopamine and 5-HT_2 receptors also has been suggested, although their roles remain unclear.

Serotonin syndrome most commonly occurs when 2 or more drugs that affect serotonergic neurotransmission are administered either concurrently or in close succession. Serotonergic agents include those that increase serotonin synthesis (e.g., the serotonin precursor tryptophan), stimulate synaptic serotonin release (e.g., some amphetamines, dexfenfluramine [no longer commercially available in the US], fenfluramine [no longer commercially available in the US]), inhibit the reuptake of serotonin after release (e.g., SSRIs, selective serotonin- and norepinephrine-reuptake inhibitors [SNRIs], tricyclic antidepressants, trazodone, dextromethorphan, meperidine, tramadol), decrease the metabolism of serotonin (e.g., MAO inhibitors), have direct serotonin postsynaptic receptor activity (e.g., buspirone), or nonspecifically induce increases in serotonergic neuronal activity (e.g., lithium salts). Selective agonists of serotonin (5-hydroxytryptamine; 5-HT) type 1 receptors ("triptans") and dihydroergotamine, agents with serotonergic activity used in the management of migraine headache, and St. John's wort (*Hypericum perforatum*) also have been implicated in serotonin syndrome.

The combination of SSRIs and MAO inhibitors may result in serotonin syndrome or NMS-like reactions. Such reactions have also been reported in patients receiving SSRIs concomitantly with tryptophan, lithium, dextromethorphan, sumatriptan, dihydroergotamine, or antipsychotics or other dopamine antagonists. In rare cases, serotonin syndrome reportedly has occurred in patients receiving the recommended dosage of a single serotonergic agent (e.g., clomipramine) or during accidental overdosage (e.g., sertraline intoxication in a child). Some other drugs that have been implicated in precipitating symptoms suggestive of serotonin syndrome or NMS-like reactions include buspirone, bromocriptine, dextropropoxyphene, linezolid, methylenedioxymethamphetamine (MDMA; "ecstasy"), selegiline (a selective MAO-B inhibitor), and sibutramine (an SNRI used for the management of obesity). Other drugs that

have been associated with the syndrome but for which less convincing data are available include carbamazepine, fentanyl, and pentazocine.

Clinicians should be aware of the potential for serious, possibly fatal reactions associated with serotonin syndrome or NMS-like reactions in patients receiving 2 or more drugs that affect serotonergic neurotransmission, even if no such interactions with the specific drugs have been reported to date in the medical literature. Pending further accumulation of data, serotonergic drugs should be used cautiously in combination and such combinations avoided whenever clinically possible. Serotonin syndrome may be more likely to occur when initiating therapy, increasing the dosage, or following the addition of another serotonergic drug. Some clinicians state that patients who have experienced serotonin syndrome may be at higher risk for recurrence of the syndrome upon reinitiation of serotonergic drugs. Pending further experience in such cases, some clinicians recommend that therapy with serotonergic agents be limited following recovery. In cases in which the potential benefit of the drug is thought to outweigh the risk of serotonin syndrome, lower potency agents and reduced dosages should be used, combination serotonergic therapy should be avoided, and patients should be monitored carefully for manifestations of serotonin syndrome. If signs and symptoms of serotonin syndrome or NMS develop during therapy, treatment with sertraline and any concurrently administered serotonergic or antidopaminergic agents, including antipsychotic agents, should be discontinued immediately and supportive and symptomatic treatment should be initiated.

For further information on serotonin syndrome, including manifestations and treatment, see Drug Interactions: Serotonergic Drugs, in Fluoxetine Hydrochloride 28:16.04.20.

Monoamine Oxidase Inhibitors Potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions have been reported in patients receiving SSRIs, including sertraline, in combination with an MAO inhibitor. Severe serotonin syndrome reaction developed several hours after initiating sertraline in a woman already receiving phenelzine, lithium, thioridazine, and doxepin. Such reactions also have been reported in patients who recently have discontinued an SSRI and have been started on an MAO inhibitor.

Because of the potential risk of serotonin syndrome or NMS-like reactions, concomitant use of sertraline and MAO inhibitors is contraindicated. At least 2 weeks should elapse between discontinuance of MAO inhibitor therapy and initiation of sertraline therapy and vice versa.

Linezolid. Linezolid, an anti-infective agent that is a nonselective and reversible MAO inhibitor, has been associated with drug interactions resulting in serotonin syndrome, including some associated with SSRIs, and potentially may also cause NMS-like reactions. Therefore, some manufacturers of sertraline state that linezolid should be used with caution in patients receiving sertraline. The manufacturer of linezolid states that, unless patients are carefully observed for signs and/or symptoms of serotonin syndrome, the drug should not be used in patients receiving SSRIs. Some clinicians suggest that linezolid only be used with caution and close monitoring in patients concurrently receiving SSRIs, and some suggest that SSRI therapy should be discontinued before linezolid is initiated and not reinitiated until 2 weeks after linezolid therapy is completed.

Moclobemide. Moclobemide (not commercially available in the US), a selective and reversible MAO-A inhibitor, has been associated with serotonin syndrome, and such reactions have been fatal in several cases in which the drug was given in combination with the SSRI citalopram or with clomipramine. Pending further experience with such combinations, some clinicians recommend that concurrent therapy with moclobemide and SSRIs be used only with extreme caution and that SSRIs should have been discontinued for some time (depending on the elimination half-lives of the drug and its active metabolites) before initiating moclobemide therapy.

Selegiline. Selegiline, a selective MAO-B inhibitor used in the management of parkinsonian syndrome, has been reported to cause serotonin syndrome when given concurrently with SSRIs (e.g., fluoxetine, paroxetine, sertraline). Although selegiline is a selective MAO-B inhibitor at therapeutic dosages, the drug appears to lose its selectivity for the MAO-B enzyme at higher dosages (e.g., those exceeding 10 mg/kg), thereby increasing the risk of serotonin syndrome in patients receiving higher dosages of the drug either alone or in combination with other serotonergic agents. The manufacturer of selegiline recommends avoiding concurrent selegiline and SSRI therapy. In addition, the manufacturer of selegiline recommends that at least 2 weeks elapse between discontinuance of selegiline and initiation of SSRI therapy.

Isoniazid. Isoniazid, an antituberculosis agent, appears to have some MAO-inhibiting activity. In addition, iproniazid (not commercially available in the US), another antituberculosis agent structurally related to isoniazid that also possesses MAO-inhibiting activity, reportedly has resulted in serotonin syndrome in at least 2 patients when given in combination with meperidine. Pending further experience, clinicians should be aware of the potential for serotonin syndrome when isoniazid is given in combination with SSRI therapy (such as sertraline) or other serotonergic agents.

Tryptophan and Other Serotonin Precursors Because of the potential risk of serotonin syndrome or NMS-like reactions, concurrent use of tryptophan or other serotonin precursors should be avoided in patients receiving sertraline.

5-HT$_1$ Receptor Agonists ("Triptans") Weakness, hyperreflexia, and incoordination have been reported rarely during postmarketing surveillance in patients receiving sumatriptan concomitantly with an SSRI (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline); these reactions resembled serotonin syndrome. Oral or subcutaneous sumatriptan and SSRIs were used concomitantly in some clinical studies without unusual adverse effects. However, an increase in the frequency of migraine attacks and a decrease in the effectiveness of sumatriptan in relieving migraine headache have been reported in a patient receiving subcutaneous injections of sumatriptan intermittently while undergoing fluoxetine therapy.

Clinicians prescribing 5-HT$_1$ receptor agonists, SSRIs, and SNRIs should consider that 5-HT$_1$ receptor agonists often are used intermittently and that either the 5-HT$_1$ receptor agonist, SSRI, or SNRI may be prescribed by a different clinician. Clinicians also should weigh the potential risk of serotonin syndrome or NMS-like reactions with the expected benefit of using a 5-HT$_1$ receptor agonist concurrently with SSRI or SNRI therapy. If concomitant treatment with sumatriptan or another 5-HT$_1$ receptor agonist and sertraline is clinically warranted, the patient should be observed carefully, particularly during treatment initiation, dosage increases, and following the addition of other serotonergic agents. Patients receiving concomitant 5-HT$_1$ receptor agonist and SSRI or SNRI therapy should be informed of the possibility of serotonin syndrome or NMS-like reactions and advised to immediately seek medical attention if they experience signs or symptoms of these syndromes.

Sibutramine Because of the possibility of developing potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions, sibutramine should be used with caution in patients receiving sertraline.

Other Selective Serotonin-reuptake Inhibitors and Selective Serotonin- and Norepinephrine-reuptake Inhibitors Concomitant administration of sertraline with other SSRIs or SNRIs potentially may result in serotonin syndrome or NMS-like reactions and is therefore not recommended. (See Dosage and Administration: Dosage.)

Antipsychotic Agents and Other Dopamine Antagonists Concomitant use of antipsychotic agents and other dopamine antagonists with sertraline rarely may result in potentially serious, sometimes fatal serotonin syndrome or NMS-like reactions. If signs and symptoms of serotonin syndrome or NMS occur, treatment with sertraline and any concurrently administered antidopaminergic or serotonergic agents should be immediately discontinued and supportive and symptomatic treatment initiated. (See Drug Interactions: Clozapine and see also Drug Interactions: Pimozide.)

Tramadol and Other Serotonergic Drugs Because of the potential risk of serotonin syndrome or NMS-like reactions, caution is advised whenever SSRIs, including sertraline, and SNRIs are concurrently administered with other drugs that may affect serotonergic neurotransmitter systems, including tramadol and St. John's wort (*Hypericum perforatum*).

■ **Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes** Animal studies have demonstrated that sertraline induces hepatic microsomal enzymes. In humans, microsomal enzyme induction by sertraline was minimal as determined by a small (5%) but statistically significant decrease in antipyrine half-life following sertraline administration (200 mg daily) for 21 days. The manufacturers state that this small change in antipyrine half-life reflects a clinically unimportant change in hepatic metabolism. Nonetheless, caution should be exercised when sertraline is given to patients receiving drugs that are hepatically metabolized and that have a low therapeutic ratio, such as warfarin. (See Drug Interactions: Protein-bound Drugs and see also Anticoagulants under Drug Interactions: Drugs Affecting Hemostasis.)

Drugs Metabolized by Cytochrome P-450 (CYP) 2D6 Sertraline, like many other antidepressants (e.g., other SSRIs, many tricyclic antidepressants) is metabolized by the drug-metabolizing cytochrome P-450 (CYP) 2D6 isoenzyme (debrisoquine hydroxylase). In addition, like many other drugs metabolized by CYP2D6, sertraline inhibits the activity of CYP2D6 and potentially may increase plasma concentrations of concomitantly administered drugs that also are metabolized by this isoenzyme. Although similar interactions are possible with other SSRIs, there is considerable variability among the drugs in the extent to which they inhibit CYP2D6. At lower doses, sertraline has demonstrated a less prominent inhibitory effect on CYP2D6 than some other SSRIs. Nevertheless, even sertraline has the potential for clinically important CYP2D6 inhibition.

Concomitant use of sertraline with other drugs metabolized by CYP2D6 has not been systematically studied. The extent to which this potential interaction may become clinically important depends on the extent of inhibition of CYP2D6 by the antidepressant and the therapeutic index of the concomitantly administered drug. The drugs for which this potential interaction is of greatest concern are those that are metabolized principally by CYP2D6 and have a narrow therapeutic index, such as tricyclic antidepressants, class IC antiarrhythmics (e.g., propafenone, flecainide, encainide), and some phenothiazines (e.g., thioridazine).

Caution should be used whenever concurrent therapy with sertraline and other drugs metabolized by CYP2D6 is considered. Because concomitant use of sertraline and thioridazine may result in increased plasma concentrations of the phenothiazine and increase the risk of serious, potentially fatal, adverse cardiac effects (e.g., cardiac arrhythmias), the manufacturer of thioridazine states that the drug should not be used concomitantly with any drug that inhibits the CYP2D6 isozyme. The manufacturers of sertraline state that concurrent use of a drug metabolized by CYP2D6 may necessitate the administration of dos-

ages of the other drug that are lower than those usually prescribed. Furthermore, whenever sertraline therapy is discontinued (and plasma concentrations of sertraline are decreased) during concurrent therapy with another drug metabolized by CYP2D6, an increased dosage of the concurrently administered drug may be necessary.

Drugs Metabolized by Cytochrome P-450 (CYP) 3A4 Although sertraline can inhibit the cytochrome P-450 (CYP) 3A4 isoenzyme, results of in vitro and in vivo studies indicate that the drug is a much less potent inhibitor of this enzyme than many other drugs. In an in vivo drug interaction study, concomitant use of sertraline and the CYP3A4 substrate, carbamazepine, under steady-state conditions had no effect on plasma concentrations of carbamazepine. The manufacturers of sertraline state that these data suggest that the extent of sertraline's inhibition of CYP3A4 activity is unlikely to be of clinical importance. However, a marked increase in plasma concentrations (ranging from 80–250%) and bone marrow suppression developed within 1–2 months of initiating sertraline in a patient previously stabilized on carbamazepine and flecainide therapy. Although the precise mechanism for this possible interaction and the role of the cytochrome P-450 enzyme system are unclear, some clinicians recommend that carbamazepine concentrations be monitored during concomitant sertraline therapy.

Results of an in vivo drug interaction study with cisapride indicate that concomitant use of sertraline (200 mg daily) induces the metabolism of cisapride; peak plasma concentrations and area under the plasma concentration-time curve (AUC) of cisapride were decreased by about 35% in the study. However, the manufacturers of sertraline state that the extent of sertraline's inhibition of CYP3A4 activity is unlikely to be of clinical importance.

Results of another drug interaction study in which sertraline was used concomitantly with terfenadine (no longer commercially available in the US), a drug metabolized principally by the cytochrome P-450 microsomal enzyme system (mainly by the CYP3A4 isoenzyme), indicate that concurrent use of sertraline did not increase plasma concentrations of terfenadine and, therefore, the manufacturers state that these data suggest that the extent of sertraline's inhibition of CYP3A4 activity is unlikely to be of clinical importance. However, the manufacturer of astemizole (no longer commercially available in the US) and some clinicians state that until the clinical importance of these findings is established, concomitant use of sertraline with astemizole or terfenadine is not recommended since substantially increased plasma concentrations of unchanged astemizole or terfenadine could occur resulting in an increased risk of serious adverse cardiac effects.

■ **Tricyclic and Other Antidepressants** The extent to which SSRI interactions with tricyclic antidepressants may pose clinical problems depends on the degree of inhibition and the pharmacokinetics of the serotonin-reuptake inhibitor involved. In healthy individuals, sertraline has been shown to substantially reduce the clearance of two tricyclic antidepressants, desipramine and imipramine. This interaction appears to result from sertraline-induced inhibition of CYP2D6. Thus, the manufacturers and some clinicians recommend that caution be exercised during concurrent use of tricyclics with sertraline since sertraline may inhibit the metabolism of the tricyclic antidepressant. In addition, plasma tricyclic concentrations may need to be monitored and the dosage of the tricyclic reduced during concomitant administration. (See Dosage and Administration: Dosage and see also Drugs Metabolized by Cytochrome P-450 [CYP] 2D6 under Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes.)

Clinical experience regarding the optimal timing of switching from other antidepressants to sertraline therapy is limited. Therefore, the manufacturers recommend that care and prudent medical judgment be exercised when switching from other antidepressants to sertraline, particularly from long-acting agents (e.g., fluoxetine). Pending further experience in patients being transferred from therapy with another antidepressant to sertraline and as the clinical situation permits, it generally is recommended that the previous antidepressant be discontinued according to the recommended guidelines for the specific antidepressant prior to initiation of sertraline therapy. (See Drug Interactions: Serotonergic Drugs.)

■ **Protein-bound Drugs** Because sertraline is highly protein bound, the drug theoretically could be displaced from binding sites by, or it could displace from binding sites, other protein-bound drugs such as oral anticoagulants or digitoxin. In vitro studies to date have shown that sertraline has no effect on the protein binding of 2 other highly protein-bound drugs, propranolol or warfarin; these findings also have been confirmed in clinical studies. However, pending further accumulation of data, patients receiving sertraline concomitantly with any highly protein-bound drug should be observed for potential adverse effects associated with combined therapy. (See Anticoagulants under Drug Interactions: Drugs Affecting Hemostasis.)

■ **Drugs Affecting Hemostasis** *Anticoagulants* In a study comparing prothrombin time AUC (0–120 hour) following a dose of warfarin (0.75 mg/kg) or placebo prior to and after 21 days of either sertraline (50–200 mg daily) or placebo, prothrombin time increased by an average of 8% compared with baseline in the sertraline group and decreased by an average of 1% in those receiving placebo. In addition, the normalization of prothrombin time was slightly delayed in those receiving sertraline when compared with those receiving placebo. Because the clinical importance of these findings is not known, prothrombin time should be monitored carefully whenever sertraline therapy is initiated or discontinued in patients receiving anticoagulants. (See Drug Interactions: Protein-bound Drugs.)

Other Drugs That Interfere with Hemostasis Epidemiologic case-control and cohort design studies that have demonstrated an association between selective serotonin-reuptake inhibitor therapy and an increased risk of upper GI bleeding also have shown that concurrent use of aspirin or other nonsteroidal anti-inflammatory agents substantially increases the risk of GI bleeding. Although these studies focused on upper GI bleeding, there is some evidence suggesting that bleeding at other sites may be similarly potentiated. The precise mechanism for this increased risk remains to be clearly established; however, serotonin release by platelets is known to play an important role in hemostasis, and selective serotonin-reuptake inhibitors decrease serotonin uptake from the blood by platelets, thereby decreasing the amount of serotonin in platelets. Patients receiving sertraline should be cautioned about the concomitant use of drugs that interfere with hemostasis, including aspirin and other nonsteroidal anti-inflammatory agents.

■ **Alcohol** Sertraline administration did not potentiate the cognitive and psychomotor effects induced by alcohol in healthy individuals. In addition, no apparent additive CNS depressant effects were observed in geriatric patients receiving sertraline together with moderate amounts of alcohol. Nonetheless, the manufacturers state that concurrent use of sertraline and alcohol is not recommended.

■ **Electroconvulsive Therapy** The effects of sertraline in conjunction with electroconvulsive therapy (ECT) have not been evaluated to date in clinical studies.

■ **Cimetidine** In a study evaluating the effect of the addition of a single dose of sertraline (100 mg) on the second of 8 days of cimetidine administration (800 mg daily), the mean AUC, peak concentration, and elimination half-life of sertraline increased substantially (by 50, 24, and 26%, respectively) compared with the placebo group. The clinical importance of these changes is unknown.

■ **Benzodiazepines** In a study comparing the disposition of diazepam administered IV before and after 21 days of sertraline therapy (dosage titrated from 50–200 mg daily) or placebo, there was a 32% decrease in diazepam clearance in the sertraline recipients and a 19% decrease in those receiving placebo when compared with baseline. There was a 23% increase in the time to maximal plasma concentration for desmethyldiazepam in the sertraline group compared with a 20% decrease in the placebo group. The clinical importance of these findings is unknown; however, they suggest that sertraline and *N*-desmethylsertraline are not likely to substantially inhibit the CYP2C19 and CYP3A3/4 hepatic isoenzymes involved in the metabolism of diazepam.

■ **Clozapine** Concomitant use of SSRIs such as sertraline in patients receiving clozapine can increase plasma concentrations of the antipsychotic agent. In a study in schizophrenic patients receiving clozapine under steady-state conditions, initiation of paroxetine therapy resulted in only minor changes in plasma concentrations of clozapine and its metabolites; however, initiation of fluvoxamine therapy resulted in increases that were threefold compared with baseline. In other published reports, concomitant use of clozapine and SSRIs (fluvoxamine, paroxetine, sertraline) resulted in modest increases (less than twofold) in clozapine and metabolite concentrations. The manufacturer of clozapine states that caution should be exercised and patients closely monitored if clozapine is used in patients receiving SSRIs, and a reduction in clozapine dosage should be considered. (See Antipsychotic Agents and Other Dopamine Antagonists under Drug Interactions: Serotonergic Drugs.)

■ **Lithium** In a placebo-controlled trial, the administration of 2 doses of sertraline did not substantially alter steady-state plasma lithium concentrations or the renal clearance of lithium. Pending further accumulation of data, however, the manufacturers recommend that plasma lithium concentrations be monitored following initiation of sertraline in patients receiving lithium and that lithium dosage be adjusted accordingly. In addition, because of the potential risk of serotonin syndrome or NMS-like reactions, caution is advised during concurrent sertraline and lithium use. (See Drug Interactions: Serotonergic Drugs.)

■ **Hypoglycemic Drugs** In a placebo-controlled study in healthy male volunteers, sertraline administration for 22 days (including 200 mg daily for the final 13 days) caused a small but statistically significant decrease (16%) in the clearance of a 1-g IV dose of tolbutamide compared with baseline values and an increase in the terminal elimination half-life (from 6.9 to 8.6 hours). The decrease in clearance was not accompanied by any substantial changes in the plasma protein binding or the apparent volume of distribution of tolbutamide, which suggests that the change in tolbutamide clearance may be caused by a slight inhibition of the cytochrome P-450 isoenzyme CYP2C9/10 when sertraline is given in the maximum recommended dosage. The clinical importance of these findings remains to be determined.

■ **Digoxin** In a placebo-controlled trial in healthy volunteers, sertraline administration for 17 days (including 200 mg daily for the final 10 days) did not alter serum digoxin concentrations or renal clearance of digoxin. The results of this study suggest that dosage adjustment of digoxin may not be necessary in patients receiving concomitant sertraline.

■ **Atenolol** In a double-blind, placebo-controlled, randomized, crossover study, a single, 100-mg dose of sertraline had no effect on the β-adrenergic blocking activity of atenolol when administered to a limited number of healthy males.

■ **Amiodarone** A decrease in the plasma concentrations of amiodarone and its active metabolite, desmethylamiodarone, to 82 and 85% of the baseline values, respectively, occurred in one patient following the discontinuance of sertraline and carbamazepine therapy, suggesting that sertraline may have been inhibiting the metabolism of amiodarone by CYP3A4.

■ **Phenytoin** In a randomized, double-blind, placebo-controlled trial, chronic administration of high dosages of sertraline (200 mg daily) did not substantially affect the pharmacokinetics or pharmacodynamics of phenytoin when the 2 drugs were given concurrently in healthy volunteers. However, substantial reductions in plasma sertraline concentrations have been observed in sertraline-treated patients concurrently receiving phenytoin; it was suggested that induction of the cytochrome P-450 isoenzymes may be responsible. In addition, concurrent administration of sertraline and phenytoin reportedly resulted in elevated phenytoin concentrations in 2 geriatric patients. Pending further accumulation of data, the manufacturers and some clinicians recommend that plasma phenytoin concentrations be monitored following initiation of sertraline therapy and that phenytoin dosage should be adjusted as necessary, particularly in patients with multiple underlying medical conditions and/or those receiving multiple concomitant drugs.

■ **Pimozide** Concomitant use of sertraline and pimozide has resulted in substantial increases in peak plasma concentrations and area under the plasma concentration-time curve (AUC) of pimozide. In one controlled study, administration of a single 2-mg dose of pimozide in individuals receiving sertraline 200 mg daily resulted in a mean increase in pimozide AUC and peak plasma concentrations of about 40%, but was not associated with changes in ECG parameters. The effects on QT interval and pharmacokinetic parameters of pimozide administered in higher doses (i.e., doses exceeding 2 mg) in combination with sertraline are as yet unknown. Concomitant use of sertraline and pimozide is contraindicated because of the low therapeutic index of pimozide and because the reported interaction between the 2 drugs occurred at a low dose of pimozide. The mechanism of this interaction is as yet unknown. (See Antipsychotic Agents and Other Dopamine Antagonists under Drug Interactions: Serotonergic Drugs.)

■ **Valproic Acid** The effect of sertraline on plasma valproic acid concentrations remains to be evaluated in clinical studies. In the absence of such data, the manufacturers recommend monitoring plasma valproic acid concentrations following initiation of sertraline therapy and adjusting the dosage of valproic acid as necessary.

Acute Toxicity

■ **Pathogenesis** The acute lethal dose of sertraline in humans is not known. One patient who ingested 13.5 g of sertraline alone subsequently recovered. However, death occurred in another patient who ingested 2.5 g of the drug alone.

In general, overdosage of sertraline may be expected to produce effects that are extensions of the drug's pharmacologic and adverse effects. The most common signs and symptoms associated with nonfatal sertraline overdosage include somnolence, nausea, vomiting, tachycardia, dizziness, agitation, and tremor. Other adverse events observed in patients who received overdosages of sertraline (alone or in combination with other drugs) include bradycardia, bundle branch block, coma, seizures, delirium, hallucinations, hypertension, hypotension, manic reaction, pancreatitis, QT-interval prolongation, serotonin syndrome, stupor, and syncope. Prolonged tachycardia, hypertension, hallucinations, hyperthermia, tremors of the extremities, and skin flushing have occurred in a child after accidental sertraline ingestion; the reaction resembled serotonin syndrome. Flushing, anger, emotional lability, and distractability developed 1 hour after an adult female ingested 2 g of sertraline; recovery was uneventful apart from watery bowel movements.

■ **Treatment** Because fatalities and severe toxicity have been reported when sertraline was ingested alone or in combination with other drugs and/or alcohol, the manufacturers and some clinicians recommend that any overdosage involving sertraline be managed aggressively. Clinicians also should consider the possibility of serotonin syndrome or NMS-like reactions in patients presenting with similar clinical features and a recent history of sertraline and/or ingestion of other serotonergic agents and/or antipsychotic agents or other dopamine antagonists. (See Cautions: Precautions and Contraindications and see also Drug Interactions: Serotonergic Drugs.)

Management of sertraline overdosage generally involves symptomatic and supportive care. A patent airway should be established and maintained, and adequate oxygenation and ventilation should be ensured. ECG and vital sign monitoring is recommended following acute overdosage with the drug, although the value of ECG monitoring in predicting the severity of sertraline-induced cardiotoxicity is not known. (See Acute Toxicity: Manifestations, in the Tricyclic Antidepressants General Statement 28:16.04.28.) There is no specific antidote for sertraline intoxication. Because suicidal ingestion often involves more than one drug, clinicians treating sertraline overdosage should be alert to possible manifestations caused by drugs other than sertraline.

If the patient is comatose, having seizures, or lacks the gag reflex, gastric lavage may be performed if an endotracheal tube with cuff inflated is in place to prevent aspiration of gastric contents. Since administration of activated charcoal (which may be used in conjunction with sorbitol) may be as effective as or more effective than induction of emesis or gastric lavage, its use has been recommended either in the initial management of sertraline overdosage or following induction of emesis or gastric lavage in patients who have ingested a potentially toxic quantity of the drug.

Limited data indicate that sertraline is not appreciably removed by hemodialysis. Because of the large volume of distribution of sertraline and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion also are likely to be ineffective in removing substantial amounts of sertraline and *N*-desmethylsertraline from the body.

Clinicians should consult a poison control center for additional information on the management of sertraline overdosage.

Chronic Toxicity

Sertraline has not been studied systematically in animals or humans to determine whether therapy with the drug is associated with abuse, tolerance, or physical dependence.

The premarketing clinical experience with sertraline did not reveal any tendency for a withdrawal syndrome or any drug-seeking behavior. However, fatigue, severe abdominal cramping, memory impairment, and influenza-like symptoms were reported 2 days following abrupt discontinuance of sertraline in one patient; when sertraline was restarted, the symptoms remitted. Electric shock-like sensations occurred in another patient 1 day after the last administered dose of sertraline; these sensations became less intense and eventually disappeared 13 weeks after sertraline therapy was discontinued. When evaluating these cases and those reported with other serotonin-reuptake inhibitors, it appears that a withdrawal syndrome may occur within several days following abrupt discontinuance of these drugs. The most commonly observed symptoms are those that resemble influenza, such as fatigue, stomach complaints (e.g., nausea), dizziness or lightheadedness, tremor, anxiety, chills, sweating, and incoordination. Other reported symptoms include memory impairment, insomnia, paresthesia, shock-like sensations, headache, palpitations, agitation, or aggression. Such reactions appear to be self-limiting and improve over 1 to several weeks. Pending further experience, sertraline therapy should be discontinued gradually to prevent the possible development of withdrawal reactions.

As with other CNS-active drugs, clinicians should carefully evaluate patients for a history of substance abuse prior to initiating sertraline therapy. If sertraline therapy is initiated in patients with a history of substance abuse, such patients should be monitored closely for signs of misuse or abuse of the drug (e.g., development of tolerance, use of increasing doses, drug-seeking behavior).

The potential for misuse of sertraline in patients with concurrent eating disorders and/or those who may seek the drug for its appetite-suppressant effects also may be considered.

Pharmacology

The pharmacology of sertraline is complex and in many ways resembles that of other antidepressant agents, particularly those agents (e.g., fluoxetine, fluvoxamine, paroxetine, clomipramine, trazodone) that predominantly potentiate the pharmacologic effects of serotonin (5-HT). Like other selective serotonin-reuptake inhibitors (SSRIs), sertraline is a potent and highly selective reuptake inhibitor of serotonin and has little or no effect on other neurotransmitters.

■ **Nervous System Effects** The precise mechanism of antidepressant action of sertraline is unclear, but the drug has been shown to selectively inhibit the reuptake of serotonin at the presynaptic neuronal membrane. Sertraline-induced inhibition of serotonin reuptake causes increased synaptic concentrations of serotonin in the CNS, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission. Like other SSRIs (e.g., fluoxetine, fluvoxamine, paroxetine), sertraline appears to have only very weak effects on the reuptake of norepinephrine or dopamine and does not exhibit clinically important anticholinergic, antihistaminic, or adrenergic (α_1, α_2, β) blocking activity at usual therapeutic dosages.

Although the mechanism of antidepressant action of antidepressant agents may involve inhibition of the reuptake of various neurotransmitters (i.e., serotonin, norepinephrine) at the presynaptic neuronal membrane, it has been suggested that postsynaptic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of antidepressant agents. During long-term therapy with most antidepressants (e.g., tricyclic antidepressants, monoamine oxidase [MAO] inhibitors), these adaptive changes mainly consist of subsensitivity of the noradrenergic adenylate cyclase system in association with a decrease in the number of β-adrenergic receptors; such effects on noradrenergic receptor function are commonly referred to as "down regulation." In animal studies, long-term administration of sertraline has been shown to downregulate noradrenergic receptors in the CNS as has been observed with many other clinically effective antidepressants. In addition, some antidepressants (e.g., amitriptyline) reportedly decrease the number of serotonergic (5-HT) binding sites following chronic administration. Although changes in the density of type 2 serotonergic (5-HT_2) binding sites were not observed during chronic administration of sertraline in animals in one study, the drug caused desensitization of the 5-HT_2 receptor transmembrane signaling system; the clinical importance of these findings requires further study.

The precise mechanism of action that is responsible for the efficacy of sertraline in the treatment of obsessive-compulsive disorder is unclear. However, because of the potency of clomipramine and other selective serotonin-reuptake inhibitors (e.g., fluoxetine, fluvoxamine, paroxetine) in inhibiting se-

rotonin reuptake and their efficacy in the treatment of obsessive-compulsive disorder, a serotonin hypothesis has been developed to explain the pathogenesis of the condition. The hypothesis postulates that a dysregulation of serotonin is responsible for obsessive-compulsive disorder and that sertraline and these other agents are effective because they correct this imbalance. Although the available evidence supports the serotonergic hypothesis of obsessive-compulsive disorder, additional studies are necessary to confirm this hypothesis.

Serotonergic mechanisms also appear to be involved at least in part in a number of other pharmacologic effects associated with selective serotonin-reuptake inhibitors, including sertraline, such as decreased food intake and altered food selection as well as decreased alcohol intake.

Serotonergic Effects Sertraline is a highly selective inhibitor of serotonin reuptake at the presynaptic neuronal membrane. Sertraline-induced inhibition of serotonin reuptake causes increased synaptic concentrations of the neurotransmitter, resulting in numerous functional changes associated with enhanced serotonergic neurotransmission.

Data from in vitro studies suggest that sertraline is more potent than fluvoxamine, fluoxetine, or clomipramine as a serotonin-reuptake inhibitor. Like some other serotonin-reuptake inhibitors, sertraline undergoes metabolism via *N*-demethylation to form *N*-desmethylsertraline, the principal metabolite. Data from in vivo and in vitro studies have shown that *N*-desmethylsertraline is approximately 5–10 times less potent as an inhibitor of serotonin reuptake than sertraline; however, the metabolite retains selectivity for serotonin reuptake compared with either norepinephrine or dopamine reuptake.

At therapeutic dosages (50–200 mg daily) in healthy individuals, sertraline has been shown to inhibit the reuptake of serotonin into platelets in a dose-dependent manner. Like other serotonin-reuptake inhibitors, sertraline inhibits the spontaneous firing of serotonergic neurons in the dorsal raphe nucleus. In vitro data have demonstrated that sertraline has substantial affinity for serotonergic (5-HT_{1A}, 5-HT_{1B}, 5-HT_2) receptors.

Effects on Other Neurotransmitters Like other serotonin-reuptake inhibitors, sertraline has been shown to have little or no activity in inhibiting the reuptake of norepinephrine. In addition, the drug has demonstrated a substantially higher selectivity ratio of serotonin-to-norepinephrine reuptake inhibiting activity than fluoxetine or tricyclic antidepressant agents, including clomipramine.

Although sertraline has only weak activity in inhibiting the reuptake of dopamine, the relative selectivity of sertraline for inhibiting serotonin reuptake relative to dopamine reuptake appears to be somewhat less than that of fluoxetine, fluvoxamine, zimelidine, or clomipramine. In addition, sertraline does not inhibit monoamine oxidase.

Unlike tricyclic and some other antidepressants, sertraline does not exhibit clinically important anticholinergic, α- or β-adrenergic blocking, or antihistaminic activity at usual therapeutic dosages. As a result, the incidence of adverse effects commonly associated with blockade of muscarinic cholinergic receptors (e.g., dry mouth, blurred vision, urinary retention, constipation, confusion), α-adrenergic receptors (e.g., orthostatic hypotension), and histamine H_1- and H_2-receptors (e.g., sedation) is lower in sertraline-treated patients. In vitro studies have demonstrated that sertraline does not possess clinically important affinity for α_1- or α_2-adrenergic, β-adrenergic, histaminergic, muscarinic, GABA, benzodiazepine, or dopamine receptors.

Effects on Sleep Like tricyclic and most other antidepressants, sertraline suppresses rapid eye movement (REM) sleep. Although not clearly established, there is some evidence that the REM-suppressing effects of antidepressant agents may contribute to the antidepressant activity of these drugs. In animal studies, sertraline suppressed REM sleep; the drug appears to reduce the amount of REM sleep by decreasing the number as well as the duration of REM episodes. Although the precise mechanism has not been fully elucidated, results of animal studies indicate that sertraline's effects on REM sleep are serotonergically mediated.

Effects on EEG Limited data currently are available regarding the effects of sertraline on the EEG. EEG changes in healthy individuals receiving single, 100-mg doses of sertraline resembled the EEG profiles of patients receiving desipramine-type antidepressants (increased alpha and decreased but accelerated delta activity) and suggest improved vigilance and psychometric performance. In individuals receiving higher single doses (200 and 400 mg) of the drug, sertraline produced EEG changes similar to imipramine-type antidepressants (reduced alpha and low beta activity and increased theta and fast beta activity), which reflect vigilance changes of the dissociative type and therefore possible sedative activity.

Effects on Psychomotor Function Sertraline does not appear to cause clinically important sedation and does not interfere with psychomotor performance. The drug did not appear to have any adverse effects on psychomotor performance when given to healthy women in single doses up to 100 mg. In healthy individuals over 50 years of age, single, 100-mg doses of sertraline increased the critical flicker fusion frequency slightly and the subjective perception of sedation; however, the drug had no depressant effect on objective tests of psychomotor performance. In addition, no adverse effects on psychomotor performance were observed in geriatric individuals who received the drug in a controlled study.

■ **Cardiovascular Effects** Sertraline appears to have little effect on the ECG. Data from controlled studies indicate sertraline does not produce clinically important changes in heart rate, cardiac conduction, or other ECG parameters in depressed patients.

■ **Effects on Appetite and Body Weight** Like some other serotonergic agents (e.g., fenfluramine [no longer commercially available in the US], fluoxetine, zimelidine), sertraline possesses anorexigenic activity. Limited data from animal studies suggest that fenfluramine has been the most effective inhibitor of food intake followed by fluoxetine and then sertraline. Although the precise mechanism has not been clearly established, results from animal studies indicate that sertraline's appetite-inhibiting action may result at least in part from serotonin-reuptake blockade and the resultant increase in serotonin availability at the neuronal synapse. Because sertraline's anorexigenic activity was not antagonized by prior administration of serotonergic antagonists, other mechanisms also may be involved but require further study. Following administration of single doses of sertraline in meal-fed animals, food intake was reduced in a dose-dependent manner. At a dose of 3 mg/kg, the reduction in food intake was substantially reduced and higher doses of 10 or 30 mg/kg reduced food intake by 45 or 74%, respectively.

Sertraline therapy has resulted in dose-dependent decreases in body weight in animals receiving the drug for 3 days; the weight loss was not accompanied by any overt signs of behavioral abnormality. Sertraline therapy also has resulted in decreases in body weight in individuals receiving the drug. However, weight loss is usually minimal and averaged about 0.45–0.9 kg in individuals treated with the drug in controlled clinical trials. (See Cautions: Metabolic Effects and see also Cautions: Pediatric Precautions.) Rarely, weight loss has required discontinuance of therapy.

■ **Effects on Alcohol Intake** Like some other serotonergic agents, sertraline produces a substantial decrease in voluntary alcohol intake in animals. Because serotonin appears to be involved in the regulation of alcohol intake, it has been suggested that selective serotonin-reuptake inhibitors may attenuate alcohol consumption via enhanced serotonergic neurotransmission. (See Cautions.)

■ **Neuroendocrine Effects** Limited data currently are available regarding the effects of sertraline on the endocrine system. In one animal study, sertraline did not demonstrate substantial neuroendocrine effects at a dose that substantially reduced gross activity.

Although a causal relationship has not been established, hypothyroidism, decreased serum thyroxine concentrations, and/or increased serum thyrotropin (thyroid-stimulating hormone, TSH) concentrations have been reported in a limited number of sertraline patients, some of whom were receiving thyroxine concurrently. (See Cautions: Other Adverse Effects and also see Precautions and Contraindications.)

■ **Other Effects** Sertraline appears to have a weak uricosuric effect; mean decreases in serum uric acid of approximately 7% have been reported in patients receiving the drug. The clinical importance of these findings is unknown, and there have been no reports of acute renal failure associated with the drug. (See Cautions: Precautions and Contraindications.)

Pharmacokinetics

In all human studies described in the Pharmacokinetics section, sertraline was administered as the hydrochloride salt; dosages and concentrations are expressed in terms of sertraline.

■ **Absorption** Sertraline appears to be slowly but well absorbed from the GI tract following oral administration. The oral bioavailability of sertraline in humans has not been fully elucidated to date because a preparation for IV administration is not available. However, the relative proportion of an oral dose that reaches systemic circulation unchanged appears to be relatively small because sertraline undergoes extensive first-pass metabolism. In animals, the oral bioavailability of sertraline ranges from 22–36%. The manufacturers state that the bioavailability of a single dose of sertraline hydrochloride tablets is approximately equal to that of an equivalent dose of sertraline hydrochloride oral solution. In a study in healthy adults who received a single 100-mg dose of sertraline as a tablet or oral solution, the solution to tablet ratios of the mean geometric AUC and peak plasma concentration were 114.8 and 120.6%, respectively.

The effect of food on the absorption of sertraline hydrochloride given as tablets or the oral solution has been studied in single-dose studies. Administration of a sertraline hydrochloride tablet with food slightly increased the area under the concentration-time curve (AUC) of sertraline, increased peak plasma concentrations by approximately 25%, and decreased the time to achieve peak plasma concentrations from about 8 to 5.5 hours. Administration of sertraline hydrochloride oral solution with food increased the time to achieve peak plasma concentrations from 5.9 to 7.0 hours.

Peak plasma sertraline concentrations usually occur within 4.5–8.4 hours following oral administration of 50–200 mg once daily for 14 days. Peak plasma sertraline concentrations following administration of single oral doses of 50–200 mg are proportional and linearly related to dose. Peak plasma concentrations and bioavailability are increased in geriatric individuals.

Following multiple dosing, steady-state plasma sertraline concentrations should be achieved after approximately 1 week of once-daily dosing. When compared with a single dose, there is an approximate twofold accumulation of sertraline after multiple daily dosing in dosages ranging from 50–200 mg daily.

N-Desmethylsertraline, sertraline's principal metabolite, exhibits time-related, dose-dependent increases in AUC (0–24 hour), peak plasma concentrations, and trough plasma concentrations with about a 5- to 9-fold increase in these parameters between day 1 and 14.

As with other serotonin-reuptake inhibitors, the relationship between plasma sertraline and *N*-desmethylsertraline concentrations and the therapeutic and/or toxic effects of the drug has not been clearly established.

■ **Distribution** Distribution of sertraline and its metabolites into human body tissues and fluids has not been fully characterized. However, limited pharmacokinetic data suggest that the drug and some of its metabolites are widely distributed in body tissues. Although the apparent volume of distribution of sertraline has not been determined in humans, values exceeding 20 L/kg have been reported in rats and dogs. The drug crosses the blood-brain barrier in humans and animals.

At in vitro plasma concentrations ranging from 20–500 ng/mL, sertraline is approximately 98% bound to plasma proteins, principally to albumin and α_1-acid glycoprotein. Protein binding is independent of plasma concentrations from 20–2000 mcg/mL. However, sertraline and *N*-desmethylsertraline did not alter the plasma protein binding of 2 other highly protein bound drugs, warfarin or propranolol, at concentrations of 300 and 200 ng/mL, respectively.

Sertraline and *N*-desmethylsertraline are distributed into milk. In a study involving 12 lactating women who received oral dosages of sertraline ranging from 25–200 mg daily, both sertraline and *N*-desmethylsertraline were present in all breast milk samples, with the highest concentrations observed in hind milk 7–10 hours after the maternal dose. Detectable concentrations of sertraline were found in 3 and *N*-desmethylsertraline in 6, respectively, out of 11 nursing infants.

■ **Elimination** The elimination half-life of sertraline averages approximately 25–26 hours and that of desmethylsertraline averages about 62–104 hours. In geriatric adults elimination half-life may be increased (e.g., to about 36 hours); however, such prolongation does not appear clinically important and does not warrant dosing alterations.

The exact metabolic fate of sertraline has not been fully elucidated. Sertraline appears to be extensively metabolized, probably in the liver, to *N*-desmethylsertraline and several other metabolites. Like some other serotonin-reuptake inhibitors, sertraline undergoes metabolism via *N*-demethylation to form *N*-desmethylsertraline, the principal metabolite. Unlike some other serotonin-reuptake inhibitors, the drug metabolizing isoenzyme CYP2D6 (a cytochrome P-450 isoenzyme implicated in the sparteine/debrisoquine polymorphism) does not appear to have a major role in the conversion of sertraline to *N*-desmethylsertraline. Nonetheless, sertraline has the potential for clinically important inhibition of this enzyme. (See Drug Interactions: Drugs Undergoing Hepatic Metabolism or Affecting Hepatic Microsomal Enzymes.) In vitro, the conversion of sertraline to *N*-desmethylsertraline correlates more with CYP3A3/4 activity than with CYP2D6 activity. Data from in vivo and in vitro studies have shown that *N*-desmethylsertraline is approximately 5–10 times less potent as an inhibitor of serotonin reuptake than sertraline; however, the metabolite retains selectivity for serotonin reuptake compared with either norepinephrine or dopamine reuptake. Both sertraline and desmethylsertraline undergo oxidative deamination and subsequent reduction, hydroxylation, and glucuronide conjugation. Desmethylsertraline has an elimination half-life approximately 2.5 times that of sertraline.

Following oral administration, sertraline and its metabolites are excreted in both urine and feces. Following oral administration of a single, radiolabeled dose in 2 healthy males, unchanged sertraline accounted for less than 5% of plasma radioactivity. Approximately 40–45% of the radiolabeled dose was excreted in urine within 9 days. Unchanged sertraline was not detectable in urine. During the same period, approximately 40–45% of the radiolabeled drug was eliminated in feces, including 12–14% of unchanged sertraline.

The effect of age on the elimination of sertraline has not been fully elucidated. Plasma clearance of sertraline was approximately 40% lower in a group of 16 geriatric patients (8 males and 8 females) who received 100 mg of the drug for 14 days than that reported in a similar study involving younger individuals (from 25–32 years of age). Based on these results, the manufacturers state that steady-state should be achieved in about 2–3 weeks in older individuals. In addition, decreased clearance of *N*-desmethylsertraline was noted in older males but not in older females. (See Dosage and Administration: Dosage in Geriatric Patients.)

Because sertraline is extensively metabolized by the liver, hepatic impairment can affect the elimination of the drug. In one study in patients with chronic mild hepatic impairment (Child-Pugh scores of 5–8) who received 50 mg of sertraline daily for 21 days, sertraline clearance was reduced resulting in a 2–3 times greater exposure to the drug and its metabolite (desmethylsertraline) than that reported for age-matched individuals without hepatic impairment. In a single-dose study in patients with mild, stable cirrhosis, the elimination half-life of sertraline was prolonged to a mean of 52 hours compared with 22 hours in individuals without hepatic disease. In addition, peak plasma concentrations and AUC values for sertraline were 1.7- and 4.4-fold higher, respectively, in patients with hepatic impairment when compared with healthy individuals without liver disease, reflecting decreased clearance of the drug. The pharmacokinetics of sertraline have not been studied to date in patients with moderate and severe hepatic impairment; therefore, the manufacturers recommend that sertraline be administered with caution and in reduced dosage or less frequently in patients with hepatic impairment. (See Cautions: Precautions and Contraindications and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Because sertraline is extensively metabolized in the liver and renal clearance of the drug is negligible, the manufacturers state that clinically important decreases in sertraline clearance are not anticipated if the drug is used in patients with renal impairment. Results of a multiple-dose study indicate that the pharmacokinetics of sertraline are not affected by renal impairment. In this study, individuals with mild to moderate renal impairment (creatinine clearance: 30–60 mL/minute), moderate to severe renal impairment (creatinine clearance: 10–29 mL/minute), or severe renal impairment (undergoing hemodialysis) received 200 mg of sertraline daily for 21 days; the pharmacokinetics and protein binding of the drug in these patients were similar to those reported for age-matched individuals without renal impairment. (See Cautions: Precautions and Contraindications and see Dosage and Administration: Dosage in Renal and Hepatic Impairment.)

Limited data indicate that sertraline is not appreciably removed by hemodialysis. Because of the large volume of distribution of sertraline and its principal metabolite, peritoneal dialysis, forced diuresis, hemoperfusion, and/or exchange transfusion also are likely to be ineffective in removing substantial amounts of sertraline and *N*-desmethylsertraline from the body.

Chemistry and Stability

■ **Chemistry** Sertraline, a selective serotonin-reuptake inhibitor antidepressant agent, is a naphthalenamine (naphthylamine)-derivative. Sertraline differs structurally from other selective serotonin-reuptake inhibitor antidepressants (e.g., citalopram, fluoxetine, paroxetine) and also differs structurally and pharmacologically from other currently available antidepressants (e.g., tricyclic antidepressants, monoamine oxidase inhibitors). Like most other serotonin-reuptake inhibitors, sertraline contains an asymmetric carbon; therefore, there are 2 existing optical isomers of the drug. However, only one of the optical isomers is present in the commercially available form of the drug.

Sertraline is commercially available as the hydrochloride salt, which occurs as a white, crystalline powder that is slightly soluble in water and isopropyl alcohol and sparingly soluble in ethanol. Commercially available sertraline hydrochloride oral solution is a clear, colorless solution with a menthol scent containing 20 mg of sertraline per mL and 12% alcohol.

■ **Stability** Commercially available sertraline hydrochloride tablets and oral solution should be stored at 25°C, but may be exposed to temperatures ranging from 15–30°C. Sertraline hydrochloride oral solution should be diluted only in the liquids specified by the manufacturer, and should be used immediately after dilution.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

Olanzapine

28:16.08.04 Atypical Antipsychotics (AHFS primary)

Special Alerts:

[Posted 01/29/2010] Lilly and FDA notified healthcare professionals of changes to the Prescribing Information for olanzapine (Zyprexa) related to its indication for use in adolescents (ages 13-17) for treatment of schizophrenia and bipolar I disorder [manic or mixed episodes]. The revised labeling states that:

- Section 1, Indications and Usage: When deciding among the alternative treatments available for adolescents, clinicians should consider the increased potential (in adolescents as compared with adults) for weight gain and hyperlipidemia. Clinicians should consider the potential long-term risks when prescribing to adolescents, and in many cases this may lead them to consider prescribing other drugs first in adolescents.
- Section 17.14, Need for comprehensive Treatment Program in Pediatric Patients: Olanzapine is indicated as an integral part of a total treatment program for pediatric patients with schizophrenia and bipolar disorder that may include other measures (psychological, educational, social) for patients with the disorder. Effectiveness and safety of olanzapine have not been established in pediatric patients less than 13 years of age.

For more information visit the FDA website at: http://www.fda.gov/Safety/MedWatch/SafetyInformation and http://www.fda.gov/Drugs/DrugSafety.

■ Olanzapine is considered an atypical or second-generation antipsychotic agent.

Uses

Pending revision, the material in this section should be considered in light of more recently available information in the MedWatch notification at the beginning of this monograph.

Olanzapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). In addition, olanzapine is used alone or in conjunction with lithium or divalproex sodium for the management of acute mixed or manic episodes associated with bipolar I disorder; the drug also is used for longer-term maintenance monotherapy in patients with this disorder. Olanzapine also is used for the management of acute agitation in patients with bipolar disorder or schizophrenia.

■ Psychotic Disorders

Olanzapine is used for the symptomatic management of psychotic disorders (e.g., schizophrenia). Drug therapy is integral to the management of acute psychotic episodes and accompanying violent behavior in patients with schizophrenia and generally is required for long-term stabilization to sustain symptom remission or control and to minimize the risk of relapse. Antipsychotic agents are the principal class of drugs used for the management of all phases of schizophrenia. Patient response and tolerance to antipsychotic agents are variable, and patients who do not respond to or tolerate one drug may be successfully treated with an agent from a different class or with a different adverse effect profile.

Schizophrenia

Olanzapine is used orally for the management of schizophrenia. Schizophrenia is a major psychotic disorder that frequently has devastating effects on various aspects of the patient's life and carries a high risk of suicide and other life-threatening behaviors. Manifestations of schizophrenia involve multiple psychologic processes, including perception (e.g., hallucinations), ideation, reality testing (e.g., delusions), emotion (e.g., flatness, inappropriate affect), thought processes (e.g., loose associations), behavior (e.g., catatonia, disorganization), attention, concentration, motivation (e.g., avolition, impaired intention and planning), and judgment. The principal manifestations of this disorder usually are described in terms of positive and negative (deficit) symptoms, and more recently, disorganized symptoms. Positive symptoms include hallucinations, delusions, bizarre behavior, hostility, uncooperativeness, and paranoid ideation, while negative symptoms include restricted range and intensity of emotional expression (affective flattening), reduced thought and speech productivity (alogia), anhedonia, apathy, and decreased initiation of goal-directed behavior (avolition). Disorganized symptoms include disorganized speech (thought disorder) and behavior and poor attention.

The American Psychiatric Association (APA) considers certain atypical antipsychotic agents (i.e., olanzapine, aripiprazole, quetiapine, risperidone, ziprasidone) first-line drugs for the management of the acute phase of schizophrenia (including first psychotic episodes), principally because of the decreased risk of adverse extrapyramidal effects and tardive dyskinesia, with the understanding that the relative advantages, disadvantages, and cost-effectiveness of conventional (first-generation) and atypical antipsychotic agents remain controversial. The APA states that, with the possible exception of clozapine for the management of treatment-resistant symptoms, there currently is no definitive evidence that one atypical antipsychotic agent will have superior efficacy compared with another agent in the class, although meaningful differences in response may be observed in individual patients. Conventional antipsychotic agents may be considered first-line in patients who have been treated successfully in the past with or who prefer conventional agents. The choice of an antipsychotic agent should be individualized, considering past response to therapy, adverse effect profile (including the patient's experience of subjective effects such as dysphoria), and the patient's preference for a specific drug, including route of administration.

To compare the long-term effectiveness and tolerability of older, first-generation antipsychotic agents (i.e., perphenazine) with those of newer, atypical antipsychotic agents (i.e., olanzapine, quetiapine, risperidone, ziprasidone), a double-blind, multicenter study (the first phase of Clinical Antipsychotic Trials of Intervention Effectiveness [CATIE]) was sponsored by the National Institute of Mental Health. More than 1400 patients with schizophrenia received one of the drugs for up to 18 months or until therapy was discontinued for any reason. Patients with tardive dyskinesia could enroll in this trial; however, the randomization scheme prevented their assignment to the perphenazine group. The primary outcome measure in this study was the discontinuance of treatment for any cause; this measure was selected because discontinuing or switching an antipsychotic agent occurs frequently and is an important problem in the management of schizophrenia. In addition, this measure integrates the patient's and clinician's judgments concerning efficacy, safety, and tolerability into a more comprehensive measure of effectiveness reflecting therapeutic benefits in relation to adverse effects. Overall, 74% of patients in this study discontinued their medication before receiving the full 18 months of therapy because of inadequate efficacy, intolerable adverse effects, or for other reasons, suggesting substantial limitations in the long-term clinical effectiveness of currently available antipsychotic agents. Olanzapine appeared to be more effective than the other drugs evaluated in this study with a lower (64%) discontinuance rate and a lower rate of hospitalization for exacerbation of schizophrenia, while no significant differences between the effectiveness of the conventional agent, perphenazine, and the other second-generation agents studied were observed (discontinuance rates were 75, 82, 74, and 79% for perphenazine, quetiapine, risperidone, and ziprasidone, respectively). The time to discontinuance of therapy for any cause was found to be longer in the olanzapine group than in the quetiapine, risperidone, perphenazine, and ziprasidone groups in this study; however, the differences between the olanzapine and perphenazine groups and between the olanzapine and ziprasidone groups did not achieve statistical significance. Although there were no significant differences in the time until discontinuance of therapy because of drug intolerance among the drugs studied, the incidences of discontinuance for certain adverse effects differed among the drugs with olanzapine discontinued more frequently because of weight gain or metabolic effects (e.g., increases in glycosylated hemoglobin [hemoglobin A_{1c}; HbA_{1c}], cholesterol, and triglycerides) and perphenazine discontinued more frequently because of adverse extrapyramidal effects.

An open, multicenter, randomized, controlled trial comparing the relative long-term effectiveness (over a 1-year period) of a group of first-generation antipsychotic agents (e.g., chlorpromazine, flupentixol [not commercially available in the US], flupentixol decanoate [not commercially available in the US], fluphenazine decanoate, haloperidol, haloperidol decanoate, loxapine, methotrimeprazine (no longer commercially available in the US), pipothiazine palmitate [not commercially available in the US], sulpiride [not commercially available in the US], trifluoperazine, zuclopenthixol [not commercially available in the US], zuclopenthixol decanoate [not commercially available in the US]) with a group of second-generation antipsychotic agents other than clozapine (e.g., olanzapine, amisulpride [not commercially available in the US], quetiapine, risperidone, zotepine [not commercially available in the US]) in patients with schizophrenia was conducted throughout the United Kingdom by the National Health Service. In the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS 1), the primary outcome measure was the Quality of Life Scale score, and secondary outcome measures included symptom improvement, adverse effects, patient satisfaction, and costs of health care. Patients in the first-generation antipsychotic group demonstrated a trend toward greater improvements in the Quality of Life Scale and symptom improvements scores in this study. In addition, the patients studied did not report a clear preference for either group of drugs and costs of health care in the 2 groups were found to be similar.

Emerging data from the first phase of the pivotal CATIE trial and the CUtLASS 1 trial suggest that newer, atypical antipsychotics may not provide clinically important advantages over older, first-generation antipsychotics in patients with chronic schizophrenia and that several factors, including adequacy of symptom relief, tolerability of adverse effects, and cost of therapy, may influence a patient's ability and willingness to remain on long-term antipsychotic medication. In addition, these results suggest that it may often be necessary to try 2 or more different antipsychotic agents in an individual patient in order to provide optimal therapeutic benefit with an acceptable adverse effect profile.

In a randomized, double-blind, second phase trial, patients with schizophrenia who had discontinued an atypical antipsychotic agent during the first phase of the CATIE trial were reassigned to treatment with a different atypical antipsychotic agent (olanzapine, quetiapine, risperidone, or ziprasidone). Similarly to the first phase of the CATIE trial, efficacy and tolerability in this second phase study were principally measured by time until drug discontinuance for any reason. The time until antipsychotic treatment was discontinued was longer for patients receiving risperidone and olanzapine than for those receiving quetiapine and ziprasidone (median: 7, 6.3, 4, and 2.8 months, respectively). Among patients who discontinued their prior antipsychotic agent because of lack of efficacy, olanzapine was found to be more effective than quetiapine and ziprasidone, while risperidone was more effective than quetiapine.

In another study that was part of the second phase of the CATIE investigation, schizophrenic patients who had discontinued treatment with olanzapine, quetiapine,

risperidone, or ziprasidone during the first phase of the CATIE investigation, principally because of inadequate efficacy, were randomized to receive open-label clozapine therapy or blinded treatment with another atypical antipsychotic agent not previously received in the trial. Clozapine was found to be more effective in this study than switching to another atypical antipsychotic agent. Patients receiving clozapine also were found to be less likely to discontinue treatment for any reason than patients receiving quetiapine or risperidone. In addition, the clozapine-treated patients were less likely to discontinue therapy because of an inadequate clinical response than were patients receiving the other atypical antipsychotic agents.

Pending further data clarifying the relative effectiveness and tolerability of first- and second-generation antipsychotics in the treatment of schizophrenia, many clinicians recommend that the choice of an antipsychotic agent be carefully individualized taking into consideration the clinical efficacy and adverse effect profile (including the risk for extrapyramidal effects, weight gain, and adverse metabolic effects) of the antipsychotic agent as well as the individual patient's risk factors; the patient's previous experience of subjective effects such as dysphoria; the patient's preference for and willingness to take (i.e., compliance) a specific drug, including route of administration; and the relative cost of therapy. Olanzapine and clozapine may be reasonable alternatives in any patient with schizophrenia who has not achieved a full clinical remission with other antipsychotic agents; however, the risk of adverse metabolic effects with both drugs necessitates dietary and exercise counseling before therapy is initiated, monitoring during drug therapy, and possible discontinuance of therapy if these effects become troublesome during therapy. Additional analyses from data generated by the CATIE trial addressing other schizophrenia treatment-related issues such as quality of life and predictors of response are ongoing.

For additional information on the symptomatic management of schizophrenia, see Schizophrenia and Other Psychotic Disorders under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

Atypical antipsychotic agents, including olanzapine, generally appear less likely to induce adverse extrapyramidal effects and tardive dyskinesia than conventional, first-generation antipsychotic agents. In addition, stabilization of or improvement in tardive dyskinesia associated with conventional antipsychotic agents has been reported in some patients when they have been switched to second-generation antipsychotic therapy, including olanzapine. Therefore, the APA and some clinicians recommend that atypical antipsychotic agents be considered in patients with schizophrenia who have experienced tardive dyskinesia associated with conventional antipsychotic agents.

The efficacy of oral olanzapine for the management of psychotic disorders has been established in hospital settings by 2 placebo-controlled studies of 6 weeks' duration in patients who met the DSM-III-R criteria for schizophrenia. In these and several other studies, improvement in manifestations of schizophrenia was based principally on the results of various psychiatric rating scales, including the Brief Psychiatric Rating Scale (BPRS) that assesses factors such as anergy, thought disturbances, activation, hostility/suspiciousness, and anxiety/depression; the Scale for the Assessment of Negative Symptoms (SANS); the Positive and Negative Symptoms Scale (PANSS); and the Clinical Global Impression (CGI).

In the first 6-week, placebo-controlled study, olanzapine was given in a fixed dosage of 1 or 10 mg once daily. Results indicated that the 10-mg, but not the 1-mg, once-daily dosage was more effective than placebo in improving the scores on the PANSS total (also on the extracted BPRS total), the BPRS psychosis cluster, the PANSS Negative subscale, and the CGI Severity assessments. Results of the second 6-week, placebo-controlled study, which evaluated 3 fixed dosage ranges (5 ± 2.5 mg once daily, 10 ± 2.5 mg once daily, and 15 ± 2.5 mg once daily), found that the 2 highest dosages (actual mean dosages were 12 and 16 mg once daily, respectively) were more effective than placebo in reducing the BPRS total score, BPRS psychosis cluster, and CGI severity score; the highest dosage also was superior to placebo on the SANS. There appeared to be no therapeutic advantage for the higher dosage of olanzapine compared with the medium dosage in this study. No race- or gender-related differences in outcome were noted in either of these studies.

The efficacy of oral olanzapine for long-term use (i.e., longer than 6 weeks) in schizophrenia has been established in one controlled study, and the drug has been used in some other patients for prolonged periods (e.g., reportedly up to 1 year) without apparent loss of clinical effect. In the long-term clinical trial, adult outpatients who predominantly met DSM-IV criteria for schizophrenia and who remained stable on olanzapine therapy during an open-label treatment phase lasting at least 8 weeks were randomized to continue receiving their current olanzapine dosage (ranging from 10–20 mg daily) or to receive placebo. Although the follow-up period to observe patients for relapse, which was defined in terms of increases in BPRS positive symptoms or hospitalization, initially was planned for 12 months, criteria were met for stopping the trial early because of an excess of placebo relapses compared with olanzapine relapses. In addition, olanzapine was found to be superior to placebo on prolonging time to relapse, which was the primary outcome measure in this study. Therefore, olanzapine was more effective than placebo at maintaining efficacy in schizophrenic patients stabilized for approximately 8 weeks and followed for an observation period of up to 8 months. If olanzapine is used for extended periods, the need for continued therapy should be reassessed periodically.

Olanzapine has been shown to be an effective, relatively rapid-acting, broad-spectrum antipsychotic agent in both controlled and uncontrolled studies of patients with schizophrenia. Like other second-generation antipsychotic agents, olanzapine appears to improve both positive (florid symptomatology such as hallucinations, conceptual disorganization, and suspiciousness) and negative ("deficit" symptomatology such as emotional withdrawal, motor retardation, blunted affect, and disorientation) manifestations of schizophrenia; conventional antipsychotic agents may have lesser effects on negative manifestations of the disorder. Some evidence also suggests that atypical antipsychotic agents may be more effective in treating cognitive and mood symptoms as well as global psychopathology than conventional antipsychotic agents, but this is controversial and remains to be fully established. In addition, some patients with schizophrenia who have been stabilized on long-term conventional antipsychotic therapy have demonstrated further improvement following a switch to an atypical antipsychotic agent.

Results from one comparative study suggest that oral olanzapine dosages of 7.5–17.5 mg daily may be as effective as oral haloperidol dosages of 10–20 mg daily in reducing positive symptoms of schizophrenia, while oral olanzapine dosages of 12.5–17.5 mg daily may be more effective than oral haloperidol dosages of 10–20 mg daily in reducing negative symptoms of schizophrenia. However, a randomized, controlled trial comparing the long-term (i.e., 1 year) effectiveness and cost of olanzapine and haloperidol therapy in patients with schizophrenia or schizoaffective disorder did not reveal any important advantage of olanzapine compared with haloperidol on measures of compliance, symptom improvement, adverse extrapyramidal effects, overall quality of life, and cost; olanzapine also was more frequently associated with weight gain. However, olanzapine therapy was associated with reduced akathisia, less tardive dyskinesia in a secondary analysis, and small but significant improvements in measures of memory and motor function compared with haloperidol. In other comparative studies, olanzapine usually was found to be at least as effective as or more effective than haloperidol and several other atypical antipsychotic agents, including quetiapine, risperidone, and ziprasidone. In a comparative, double-blind trial conducted in patients with schizophrenia or schizoaffective disorder, both olanzapine and risperidone were found to be effective and well tolerated, although greater reductions in the severity of positive and affective symptoms were noted in the risperidone-treated patients compared with those receiving olanzapine.

Olanzapine also has been studied in patients with treatment-refractory schizophrenia (i.e., patients who have demonstrated an inadequate response to prior antipsychotic therapy) in both open and comparative clinical trials. In an open trial of 6 weeks' duration, olanzapine (15–25 mg daily) was found to be effective and well tolerated in patients with treatment-refractory schizophrenia with 36% responding to the drug. In a double-blind trial of 8 weeks' duration, although olanzapine (25 mg daily) was found to be as effective as chlorpromazine (1.2 g daily with benztropine), the total amount of improvement with either drug was modest; olanzapine was better tolerated than chlorpromazine. In a double-blind trial of 14 weeks' duration comparing efficacy and safety of several atypical antipsychotics (olanzapine, clozapine, and risperidone) with each other and with haloperidol, olanzapine (mean dosage of approximately 30 mg daily) and clozapine produced greater clinical improvement in global psychopathology and negative symptoms than haloperidol (mean dosage of approximately 26 mg daily) in patients with chronic schizophrenia or schizoaffective disorder, but the effects of atypical antipsychotic agents were considered small and of limited clinical importance. In another study using the manufacturer's clinical trial database to retrospectively identify treatment-resistant schizophrenic patients, olanzapine (mean dosage of approximately 11 mg daily) was found to be more effective than haloperidol therapy (mean dosage of approximately 10 mg daily) in improving positive, negative, and mood symptoms and produced fewer extrapyramidal effects. The results of clinical trials to date suggest that olanzapine may be somewhat less effective than or similarly effective to clozapine in the management of resistant schizophrenia patients. Clozapine generally appears to be more effective in the management of treatment-refractory schizophrenia than most first-generation and other second-generation antipsychotic agents and may produce greater improvement in negative symptoms of schizophrenia than other antipsychotic agents; however, tolerability concerns (e.g., hematologic toxicity, hypotension, dizziness, sedation) limit its use in many patients. Although higher olanzapine dosages (i.e., up to 60 mg daily) have been used in some patients with treatment-resistant schizophrenia, it remains to be established whether higher dosages of the drug result in improved efficacy in such patients, and higher dosages may increase the risk of extrapyramidal and other adverse effects.

Like some other atypical antipsychotic agents (e.g., clozapine, risperidone), olanzapine therapy appears to reduce the risk of violent behavior in patients with schizophrenia. Although the precise mechanism(s) for the antiaggressive effects are not known, improved compliance with atypical antipsychotic agents may play a role.

Olanzapine also has been used with a variety of adjunctive agents, including other antipsychotic agents, antidepressants (including selective serotonin-reuptake inhibitors such as fluoxetine and fluvoxamine), valproate (e.g., divalproex sodium, valproic acid, valproate sodium), and topiramate, in some patients with treatment-refractory schizophrenia, inadequate response to antipsychotic therapy, or acute exacerbations of schizophrenia in both controlled and uncontrolled trials. Further controlled trials of olanzapine combined with these agents are necessary to more clearly determine the potential risks and benefits of such combined therapy.

Pediatric Considerations.

Pending revision, the material in this section should be considered in light of more recently available information in the MedWatch notification at the beginning of this monograph.

Although the manufacturer states that the safety and efficacy of olanzapine in children and adolescents with schizophrenia have not been established, the drug has

been successfully used for the management of childhood-onset schizophrenia in a limited number of children and adolescents†. In addition, a double-blind, placebo-controlled trial of 6 weeks' duration conducted in adolescents 13–17 years of age with schizophrenia has demonstrated that olanzapine is effective in the management of schizophrenia, but that the drug's adverse effects on weight and prolactin concentrations may be greater in adolescents.

Based on the observed efficacy and tolerability of atypical antipsychotics in adults and the available clinical experience in pediatric patients, the American Academy of Child and Adolescent Psychiatry (AACAP) currently states that the use of atypical antipsychotic agents in children and adolescents with schizophrenia is justified, and many clinicians consider atypical antipsychotic agents, with the exception of clozapine, the drugs of first choice in the management of childhood-onset schizophrenia . However, well-controlled studies are necessary to more clearly establish the efficacy and safety of atypical antipsychotics in pediatric patients, particularly during long-term therapy. For additional information on the symptomatic management of childhood-onset schizophrenia, see Pediatric Considerations under Psychotic Disorders: Schizophrenia, in Uses in the Phenothiazines General Statement 28:16.08.24.

Acute Agitation.

Olanzapine is used IM for the management of acute agitation in patients with schizophrenia for whom treatment with olanzapine is appropriate and who require an IM antipsychotic agent for rapid control of behaviors that interfere with diagnosis and care (e.g., threatening behaviors, escalating or urgently distressing behavior, self-exhausting behavior). According to DSM-IV, psychomotor agitation is excessive motor activity associated with a feeling of inner tension. The efficacy of IM olanzapine for the management of acute agitation in patients with schizophrenia was established in 2 short-term (single-day), placebo-controlled trials in hospital settings; an active comparator treatment arm using haloperidol injection was included in both studies. The patients in this study exhibited a level of agitation that met or exceeded a threshold score of 14 on the 5 items comprising the Positive and Negative Syndrome Scale (PANSS) Excited Component (i.e., poor impulse control, tension, hostility, uncooperativeness, and excitement items) with at least one individual item score of 4 ("moderate") or greater using a 1–7 scoring system, where scores of 1 or 7 indicate absent or extreme agitation, respectively. The primary measure used for assessing efficacy in managing agitation in these trials was the change from baseline in the PANSS Excited Component at 2 hours post-injection. Patients could receive up to 3 injections of IM olanzapine; however, patients could not receive the second injection until after the initial 2-hour period when the primary efficacy measure was assessed.

In the first placebo-controlled trial, IM olanzapine was given in fixed single doses of 2.5, 5, 7.5, or 10 mg in agitated hospitalized patients with schizophrenia. All 4 IM olanzapine doses were found to be statistically superior to placebo in reducing the PANSS Excited Component score at 2 hours following injection; however, the effect was larger and more consistent for the 3 highest doses studied. There were no significant differences in efficacy noted for the 7.5- and 10-mg doses compared with the 5-mg dose in this study. In the second placebo-controlled trial in agitated patients with schizophrenia, a fixed, 10-mg dose of IM olanzapine was evaluated and found to be superior to placebo on the PANSS Excited Component at 2 hours following injection. An analysis of these 2 controlled studies as well as an additional controlled study conducted in agitated patients with bipolar mania for possible age-, race-, or gender-related effects on treatment outcome did not suggest any difference in efficacy based on these patient characteristics.

■ Bipolar Disorder

Oral olanzapine is used alone or in conjunction with lithium or divalproex sodium for the management of acute mixed or manic episodes associated with bipolar I disorder; the drug also is used orally for longer-term maintenance monotherapy in patients with this disorder. According to DSM-IV criteria, manic episodes are distinct periods lasting 1 week or longer (or less than 1 week if hospitalization is required) of abnormally and persistently elevated, expansive, or irritable mood accompanied by at least 3 (or 4 if the mood is only irritability) of the following 7 symptoms: grandiosity, reduced need for sleep, pressure of speech, flight of ideas, distractibility, increased goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation, and engaging in high-risk behavior (e.g., unrestrained buying sprees, sexual indiscretions, foolish business investments).

For the initial management of less severe manic or mixed episodes in patients with bipolar disorder, current APA recommendations state that monotherapy with lithium, valproate (e.g., valproate sodium, valproic acid, divalproex), or an antipsychotic such as olanzapine may be adequate. For more severe manic or mixed episodes, combination therapy with an antipsychotic and lithium or valproate is recommended as first-line therapy. For further information on the management of bipolar disorder, see Uses: Bipolar Disorder, in Lithium Salts 28:28.

Acute Manic Episodes

Efficacy of oral olanzapine monotherapy in the treatment of acute manic episodes has been demonstrated in 2 short-term (i.e., 3 or 4 weeks' duration), randomized, double-blind, placebo-controlled, parallel-group trials in patients who met the DSM-IV criteria for bipolar I disorder (with or without a rapid-cycling course) and who met diagnostic criteria for an acute manic or mixed episode (with or without psychotic features). Olanzapine was given in an initial dosage of 10 mg once daily in the 3-week trial and 15 mg once daily in the 4-week trial; the dosage was subsequently adjusted within the range of 5–20 mg once daily in both of these trials. The principal rating instrument used for assessing manic symptoms in these trials was the Y-MRS score, an 11-item clinician-rated scale traditionally used to assess the degree of manic symptomatology (e.g., irritability, disruptive/aggressive behavior, sleep, elevated mood, speech, increased activity, sexual interest, language/thought disorder, thought content, appearance, insight) in a range from 0 (no manic features) to 60 (maximum score). All patients were hospitalized at the onset of these trials, but some patients were allowed to continue the studies on an outpatient basis after 1 week of hospitalization if their Clinical Global Impressions-Bipolar Version of severity of illness (CGI-BP) mania score was no greater than 3 (mild) and they had at least a 50% reduction in their Young Mania Rating Scale (Y-MRS) scores. In the 3- and 4-week placebo-controlled trials, approximately 49–65% of patients receiving 5–20 mg of olanzapine once daily achieved a 50% or greater improvement in Y-MRS total score from baseline compared with approximately 24–43% of those who received placebo. In addition, unlike therapy with typical antipsychotic agents, patients receiving olanzapine in these clinical studies did not experience a worsening in depressive symptoms (defined as an increase in the Hamilton Psychiatric Rating Scale for Depression-21 item [HAMD-21] score of at least 3 points) compared with those receiving placebo. In another 3-week, placebo-controlled trial that was designed identically to the first 3-week trial and was conducted simultaneously, olanzapine demonstrated a similar treatment difference in reduction of the Y-MRS total score but was not found to be superior to placebo on this outcome measure, possibly due to sample size and site variability.

Data from one limited comparative study suggest that oral olanzapine dosages of 10 mg daily may be as effective as lithium carbonate dosages of 400 mg twice daily in the treatment of manic episodes in patients with bipolar disorder. In a randomized, double-blind trial of 3 weeks' duration comparing olanzapine (5–20 mg daily) and divalproex sodium therapy in hospitalized patients with bipolar disorder experiencing acute manic or mixed episodes, olanzapine therapy was found to produce greater improvement in Y-MRS total scores, which was the primary efficacy measure in this trial. In addition, a significantly greater proportion of patients in the olanzapine group achieved remission compared with the divalproex group. In a randomized, double-blind study of 12 weeks' duration comparing olanzapine and divalproex sodium in patients with bipolar I disorder hospitalized for acute mania, the drugs were found to be equally effective although divalproex sodium was somewhat better tolerated than olanzapine.

Combined Therapy

Efficacy of oral olanzapine when used in combination with lithium or divalproex sodium in the short-term treatment of acute manic episodes has been demonstrated in 2 randomized, double-blind, placebo-controlled studies of 6 weeks' duration in patients who met the DSM-IV criteria for bipolar I disorder (with or without a rapid-cycling course) and who met diagnostic criteria for an acute manic or mixed episode (with or without psychotic features). In these studies, patients with bipolar disorder experiencing manic or mixed episodes (Y-MRS scores of 16 or greater) who had not responded to at least 2 weeks of lithium or divalproex sodium monotherapy despite adequate plasma drug concentrations (in a therapeutic range of 0.6–1.2 mEq/L for lithium or 50–125 mcg/mL of valproate for divalproex sodium) were randomized to receive either olanzapine (initial dosage of 10 mg once daily; range: 5–20 mg once daily) or placebo, in combination with their original therapy. Addition of olanzapine to lithium or divalproex sodium was shown to be superior to continued monotherapy with lithium or divalproex sodium in the reduction of Y-MRS total score in both of these studies.

Maintenance Monotherapy of Bipolar Disorder

Oral olanzapine also is used for maintenance monotherapy in patients with bipolar disorder. The long-term efficacy of oral olanzapine as maintenance monotherapy in bipolar disorder has been demonstrated in a double-blind, placebo-controlled trial and in double-blind comparative trials. In the placebo-controlled study, patients who met DSM-IV criteria for bipolar I disorder and experienced manic or mixed episodes and who had responded during an initial open-label treatment phase to oral olanzapine therapy (5–20 mg daily) for an average of about 2 weeks were randomized either to continue olanzapine at the same dosage or to receive placebo for up to 48 weeks and were observed for relapse. Response during the open-label phase was defined as a reduction in the Y-MRS total score of 12 or more and in the 21-item Hamilton Depression Rating Scale (HAM-D 21) of 8 or more; relapse during the double-blind phase of the study was defined as an increase in the Y-MRS or HAM-D 21 total score to 15 or more or being hospitalized for either mania or depression. Approximately 50% of the patients in the olanzapine group had discontinued therapy by day 59, and approximately 50% of the patients in the placebo group had discontinued placebo by day 23 of the double-blind phase. A longer time until relapse was observed in the patients receiving olanzapine compared with those receiving placebo (median of 174 and 22 days, respectively, for relapse into any mood episode) during the randomized phase of this study. The relapse rate also was significantly lower in the olanzapine group (approximately 47%) than in the placebo group (approximately 80%). If olanzapine is used for extended periods, the need for continued therapy should be reassessed periodically.

In a double-blind, 52-week trial comparing olanzapine and lithium maintenance therapy in patients with bipolar disorder, olanzapine was found to be significantly more effective than lithium in preventing relapses and recurrences of manic and mixed episodes following initial stabilization with combined olanzapine and lithium therapy. Olanzapine and lithium demonstrated comparable efficacy in preventing relapses and recurrences of depression in this study. In a retrospective analysis from this trial, patients were subcategorized into illness stage (early, intermediate, or later) based on the number of prior manic or mixed episodes they had experienced. The rates of relapse or recurrence of manic or mixed episodes were approximately 2 and 26%, 13 and 24%,

and 24 and 33% for olanzapine and lithium in the early, intermediate, and later stage groups of bipolar patients, respectively; no substantial treatment effect for treatment or illness stage for depressive relapse or recurrence was observed. Because olanzapine was associated with a lower rate of relapse or recurrence of manic and mixed episodes in early-stage patients, it was suggested that the drug may be particularly effective early in the course of bipolar disorder.

In a double-blind, 47-week trial comparing monotherapy with olanzapine or divalproex sodium in patients with bipolar disorder experiencing manic or mixed episodes, mean improvement in Y-MRS scores was greater for olanzapine-treated patients. In addition, the median time to symptomatic mania remission was shorter for patients receiving olanzapine compared with those receiving divalproex sodium (14 days vs. 62 days, respectively). However, no significant differences in the rates of symptomatic mania remission and symptomatic relapse into mania or depression between the olanzapine- and divalproex-treated patients were observed in this study. In a double-blind, 18-month, relapse prevention trial comparing the efficacy of combined olanzapine plus lithium or valproate therapy with lithium or valproate therapy alone in patients with bipolar disorder, more sustained symptomatic remission (163 days vs 42 days, respectively) occurred in the group receiving combined olanzapine plus lithium or valproate therapy than in the group receiving lithium or valproate therapy alone.

Rapid-Cycling Bipolar Disorder

In an analysis of pooled data from several trials comparing the clinical response to olanzapine therapy in rapid-cycling and non-rapid-cycling patients with bipolar disorder, relative clinical response to olanzapine was found to be similar in the 2 groups, although earlier responses were observed in the rapid-cycling group of patients, and long-term outcomes were more favorable in the non-rapid-cycling group. Rapid-cycling patients were found to be less likely to achieve an initial symptomatic remission, more likely to experience recurrences, especially of depression, and had more hospitalizations and suicide attempts than non-rapid-cycling patients in this study.

Acute Depressive Episodes in Bipolar Disorder

In a secondary analysis of data from dysphoric manic patients participating in a placebo-controlled trial evaluating olanzapine combined with lithium or valproate therapy in patients with bipolar I disorder, the addition of olanzapine was found to improve symptoms of depression, mania, and suicidality compared with lithium or valproate therapy alone.

Olanzapine also is used in combination with fluoxetine for the treatment of acute depressive episodes in patients with bipolar disorder. In 2 randomized, double-blind studies of 8 weeks' duration comparing a fixed combination of olanzapine and fluoxetine hydrochloride (Symbyax®) with olanzapine monotherapy and placebo, the fixed combination (flexible daily dosages of 6 mg olanzapine with 25 or 50 mg of fluoxetine or 12 mg of olanzapine with 50 mg of fluoxetine) was more effective than olanzapine monotherapy (5–20 mg daily) or placebo in improvement in depressive symptoms as assessed by the Montgomery-Asberg Depression Rating Scale (MADRS). Although the manufacturer states that efficacy beyond 8 weeks' duration remains to be established, patients have received the fixed combination for up to 24 weeks in clinical trials. Clinicians who elect to extend therapy beyond 8 weeks should reevaluate the risks and benefits of continued therapy periodically.

Pediatric Considerations

Although the manufacturer states that the safety and efficacy of olanzapine in children and adolescents with bipolar disorder have not been established, the drug has been successfully used for the management of bipolar disorder in a limited number of children and adolescents†. In a double-blind, placebo-controlled, 3-week study in adolescents 13–17 years of age with bipolar disorder, olanzapine was found to be effective in the treatment of acute manic or mixed episodes; however, weight gain and hyperprolactinemia occurred more often in patients receiving olanzapine compared with those receiving placebo.

Based on the observed efficacy and tolerability of mood stabilizers and atypical antipsychotic agents in clinical trials in adults and the available clinical experience in pediatric patients, the American Academy of Child and Adolescent Psychiatry (AACAP) currently states that the mood stabilizers lithium, divalproex sodium, and carbamazepine and the atypical antipsychotics olanzapine, quetiapine, and risperidone are drugs of first choice in the acute management of pediatric patients with bipolar I disorder experiencing manic or mixed episodes without psychosis. The AACAP also currently recommends that a mood stabilizer such as lithium, divalproex sodium, or carbamazepine combined with an atypical antipsychotic be used as first line therapy in pediatric patients with bipolar I disorder experiencing manic or mixed episodes accompanied by psychosis. Additional controlled studies are necessary to more clearly establish the efficacy and safety of atypical antipsychotics in pediatric patients with bipolar disorder, particularly during long-term therapy.

Acute Agitation

Olanzapine is used IM for the management of acute agitation in patients with bipolar I disorder for whom treatment with olanzapine is appropriate and who require an IM antipsychotic agent for rapid control of behaviors that interfere with their diagnosis and care (e.g., threatening behaviors, escalating or urgently distressing behavior, self-exhausting behavior). According to DSM-IV, psychomotor agitation is excessive motor activity associated with a feeling of inner tension.

The efficacy of IM olanzapine for the management of acute agitation in patients with bipolar mania was established in a short-term (single-day), double-blind, placebo-controlled trial in agitated, hospitalized patients who met the DSM-IV criteria for bipolar I disorder and who displayed an acute manic or mixed episode with or without psychotic features. The patients in this study exhibited a level of agitation that met or exceeded a threshold score of 14 on the 5 items comprising the Positive and Negative Syndrome Scale (PANSS) Excited Component (i.e., poor impulse control, tension, hostility, uncooperativeness, and excitement items) with at least one individual item score of 4 ("moderate") or greater using a 1–7 scoring system where scores of 1 or 7 indicate absent or extreme agitation, respectively. An active comparator treatment arm using IM lorazepam was included in this study. The primary measure used for assessing efficacy in managing agitation in this trial was the change from baseline in the PANSS Excited Component at 2 hours post-injection of a fixed, 10-mg IM dose of olanzapine. Patients in this study could receive up to 3 injections of IM olanzapine; however, patients could not receive the second injection until after the initial 2-hour period when the efficacy was assessed. IM olanzapine was found to be statistically superior to placebo in reducing the PANSS Excited Component score at 2 hours and at 24 hours following the initial injection. An analysis of this study as well as 2 additional controlled studies conducted in agitated patients with schizophrenia for possible age-, race-, or gender-related effects on treatment outcome did not suggest any difference in efficacy based on these patient characteristics.

Dosage and Administration

■ Reconstitution and Administration

Olanzapine is administered orally or by IM injection.

Oral Administration

Olanzapine conventional tablets and orally disintegrating tablets are administered orally. Since food does not appear to affect GI absorption of olanzapine, the drug generally can be administered as conventional tablets or orally disintegrating tablets without regard to meals. In patients who experience persistent or troublesome daytime sedation during oral olanzapine therapy, administration of the daily dosage in the evening at bedtime may be helpful.

Patients receiving olanzapine orally disintegrating tablets should be instructed not to remove a tablet from the blister until just prior to dosing. The tablet should not be pushed through the foil. With dry hands, the blister backing should be peeled completely off the blister. The tablet should then be gently removed and immediately placed on the tongue, where it rapidly disintegrates in saliva, and then subsequently swallowed with or without liquid.

The fixed combination capsules of olanzapine with fluoxetine hydrochloride are administered orally once daily in the evening. Although the manufacturer states that food has no appreciable effect on absorption of either drug when administered alone, absorption of the drugs when administered as the fixed combination has not been studied.

Dispensing and Administration Precautions

Because of similarities in spelling, dosage intervals (once daily), and tablet strengths (5 and 10 mg) of Zyprexa® (olanzapine) and Zyrtec® (cetirizine hydrochloride, an antihistamine), extra care should be exercised in ensuring the accuracy of prescriptions for these drugs. (See Cautions: Precautions and Contraindications.)

IM Administration

Commercially available olanzapine for injection must be reconstituted prior to administration by adding 2.1 mL of sterile water for injection to single-dose vials labeled as containing 10 mg of olanzapine to provide a solution containing approximately 5 mg/mL. Other solutions should not be used to reconstitute olanzapine for injection.

Following reconstitution, olanzapine for injection should be used immediately (within 1 hour). If necessary, the reconstituted solution may be stored for up to 1 hour at 20–25°C; after 1 hour, any unused portion should be discarded. Olanzapine for injection should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Olanzapine for injection is administered only by IM injection and should *not* be administered IV or subcutaneously. The drug should be injected slowly, deep into the muscle mass.

■ Dosage

Pending revision, the material in this section should be considered in light of more recently available information in the MedWatch notification at the beginning of this monograph.

Conventional olanzapine tablets and orally disintegrating tablets of the drug are bioequivalent. However, IM administration of a 5-mg dose of the commercially available injection results in a maximum plasma olanzapine concentration that is about fivefold higher than that resulting from a 5-mg oral dose. Dosage of olanzapine must be adjusted carefully according to individual requirements and response, using the lowest possible effective dosage.

Oral Dosage

Schizophrenia.

For the management of schizophrenia, the recommended initial oral dosage of olanzapine is 5–10 mg daily, usually given as a single daily dose. Dosage may be increased by 5 mg daily within several days, to a target dosage of 10 mg daily. Because steady-state plasma concentrations of olanzapine may not be attained for 7 days at a given dosage, subsequent dosage adjustments generally should be made at intervals of not less than 7 days, usually in increments or decrements of 5 mg once daily. An initial

dosage of 5 mg daily is recommended in debilitated patients, in those predisposed to hypotension, in those who may be particularly sensitive to the effects of olanzapine, or in those who might metabolize olanzapine slowly (e.g., nonsmoking female patients who are 65 years of age or older).

While a relationship between dosage and antipsychotic effect has not been established, the effective oral dosage of olanzapine in clinical studies generally ranged from 10–15 mg daily. The manufacturer states that increasing olanzapine dosages beyond 10 mg daily usually does not result in additional therapeutic effect and recommends that such increases generally should occur only after the patient's clinical status has been assessed. In addition, the manufacturer states that safety of dosages exceeding 20 mg daily has not been established in clinical trials. However, olanzapine occasionally has been used in controlled and uncontrolled trials and in individual patients in dosages of up to 40 mg daily; dosages of up to 60 mg daily have been used in some patients with treatment-resistant schizophrenia. It remains to be established whether higher dosages of the drug are safe and result in improved efficacy in such patients. Some clinicians state that olanzapine dosages of up to 30 mg daily may produce further clinical improvement in schizophrenia patients who did not respond adequately to dosages of up to 20 mg daily; however, they recommend that caution be exercised when dosage of the drug exceeds 40 mg daily because of the potential for serious adverse effects (e.g., extrapyramidal reactions, excitement, metabolic changes, weight gain, cardiovascular complications).

Although clinical experience generally has not revealed age-related differences in tolerance of olanzapine in adults, dosage generally should be titrated carefully in geriatric patients 65 years of age or older, usually initiating therapy at the low end of the dosage range.

The optimum duration of olanzapine therapy currently is not known, but maintenance therapy with antipsychotic agents is well established. Patients responding to olanzapine therapy should continue to receive the drug as long as clinically necessary and tolerated, but at the lowest possible effective dosage, and the need for continued therapy with the drug should be reassessed periodically.

Bipolar Disorder.

As monotherapy for the management of acute mania associated with bipolar I disorder, the recommended initial oral dosage of olanzapine is 10 or 15 mg daily, usually given as a single dose. Dosage may be increased by 5 mg daily at intervals of not less than 24 hours, reflecting the procedures in the placebo-controlled trials. The effective dosage of olanzapine in clinical studies generally has ranged from 5–20 mg daily. Safety of dosages exceeding 20 mg daily has not been established.

When administered in conjunction with lithium or divalproex sodium for the management of acute manic episodes associated with bipolar I disorder, the recommended initial oral dosage of olanzapine is 10 mg once daily. The effective dosage of olanzapine as adjunctive therapy for up to 6 weeks in clinical studies generally ranged from 5–20 mg daily. Safety of dosages exceeding 20 mg daily has not been established.

When used in fixed combination with fluoxetine hydrochloride for acute depressive episodes in patients with bipolar disorder, olanzapine is administered once daily in the evening, usually initiating therapy with a dosage of 6 mg of olanzapine and 25 mg of fluoxetine (Symbyax® 6/25). This dosage generally should be used as initial and maintenance therapy in patients with a predisposition to hypotensive reactions, patients with hepatic impairment, or those with factors that may slow metabolism of the drugs(s) (e.g., female gender, geriatric age, nonsmoking status); when indicated, dosage should be escalated with caution. In other patients, dosage can be increased according to patient response and tolerance as indicated. In clinical trials, antidepressive efficacy was demonstrated at olanzapine dosages ranging from 6–12 mg daily and fluoxetine dosages ranging from 25–50 mg daily. Dosages exceeding 18 mg of olanzapine and 75 mg of fluoxetine have not been evaluated in clinical studies.

The long-term efficacy of oral olanzapine (dosage range: 5–20 mg daily) for maintenance monotherapy in patients with bipolar disorder has been demonstrated in a double-blind, placebo-controlled trial of 52 weeks' duration and in comparative studies of 47–52 weeks' duration. The mean modal dosage of olanzapine in the placebo-controlled study was 12.5 mg daily. The manufacturer states that patients receiving oral olanzapine for extended periods should be reassessed periodically to determine the need for continued therapy.

Although the manufacturer states that efficacy of the fixed-combination of olanzapine and fluoxetine beyond 8 weeks' duration remains to be established, patients have received the fixed combination for up to 24 weeks in clinical trials. Clinicians who elect to use the fixed combination for extended periods should periodically reevaluate the long-term risks and benefits of the drug for the individual patient.

IM Dosage for Acute Agitation in Schizophrenia or Bipolar Mania

For the prompt control of acute agitation in patients with schizophrenia or bipolar mania, the recommended initial adult IM dose is 10 mg given as a single dose. A lower initial IM dose (2.5, 5, or 7.5 mg) may be considered when clinically warranted. In clinical trials, the efficacy of IM olanzapine for controlling agitation in patients with schizophrenia or bipolar mania has been demonstrated in a dosage range of 2.5–10 mg.

If agitation necessitating additional IM doses of olanzapine persists following the initial dose, subsequent single doses of up to 10 mg may be given. However, the manufacturer states that the efficacy of repeated doses of IM olanzapine in agitated patients has not been systematically evaluated in controlled clinical trials. In addition, the safety of IM dosages exceeding 30 mg daily or of 10-mg IM doses given more frequently than 2 hours after the initial dose and 4 hours after the second dose has not been evaluated in clinical trials.

Maximal dosing of IM olanzapine (e.g., 3 doses of 10 mg administered 2–4 hours apart) may be associated with a substantial risk of clinically important orthostatic hypotension. Patients who experience drowsiness or dizziness after the IM injection should remain recumbent until an examination indicates that they are not experiencing orthostatic hypotension, bradycardia, and/or hypoventilation. (See Cardiovascular Effects under Precautions and Contraindications in Cautions.)

The manufacturer states that oral therapy should replace IM therapy as soon as possible. In one controlled study evaluating IM olanzapine in acutely agitated patients, patients initially received 1–3 IM injections of olanzapine 10 mg and were then switched to oral olanzapine therapy in dosages ranging from 5–20 mg daily for a period of 4 days.

A lower initial IM olanzapine dose of 5 mg may be considered for geriatric patients or when other clinical factors warrant. In addition, a lower IM dose of 2.5 mg per injection should be considered for patients who are debilitated, who may be predisposed to hypotensive reactions, or who may be more sensitive to the pharmacodynamic effects of olanzapine.

■ Dosage in Renal and Hepatic Impairment

The manufacturer states that because only minimal amounts of olanzapine (about 7%) are excreted in urine and because the pharmacokinetics of olanzapine appear not to be altered in patients with renal or hepatic impairment, dosage adjustment is not necessary in such patients.

Cautions

The adverse effect profile of olanzapine generally is similar to that of other atypical (second-generation) antipsychotic agents (e.g., aripiprazole, clozapine, quetiapine, risperidone, ziprasidone). Although olanzapine differs chemically from the phenothiazines, the drug also may be capable of producing many of the toxic manifestations of phenothiazine derivatives. (See Cautions in the Phenothiazines General Statement 28:16.08.24.) Not all adverse effects of the phenothiazines have been reported with olanzapine, but the possibility that they may occur should be considered. Adverse effects of olanzapine, other atypical antipsychotics, and the phenothiazines are numerous and may involve nearly all body organ systems.

In controlled studies, the most common adverse effects occurring more frequently in patients receiving oral olanzapine for schizophrenia or bipolar mania than in those receiving placebo included central and autonomic nervous system effects such as somnolence, asthenia, dry mouth, dizziness, tremor, personality disorder, and akathisia; cardiovascular system effects such as postural hypotension; GI effects such as constipation, dyspepsia, and increased appetite; and weight gain. There was no clear relationship between the incidence of adverse events and dosage in patients receiving oral olanzapine for schizophrenia in placebo-controlled trials except for certain extrapyramidal symptoms, asthenia, dry mouth, nausea, somnolence, and tremor. Discontinuance of olanzapine therapy was required in 5% of patients with schizophrenia compared with 6% for placebo in controlled trials; however, discontinuance because of increased serum ALT (SGPT) concentrations was required in 2% of the olanzapine-treated patients compared with none of those receiving placebo, and this adverse effect was considered to be drug related. Similar between olanzapine and placebo discontinuance rates were observed in the controlled trials for oral olanzapine for bipolar mania (2% for olanzapine and 2% for placebo) and IM olanzapine for acute agitation (0.4% for IM olanzapine and 0% for placebo).

Adverse effects occurring in 5% or more of patients with schizophrenia receiving oral olanzapine in short-term clinical studies and with an incidence of at least twice that of placebo included dizziness (11%), constipation (9%), personality disorder (i.e., nonaggressive objectionable behavior; 8%), weight gain (6%), postural hypotension (5%), and akathisia (5%).

Adverse effects occurring in 6% or more of patients with acute mania associated with bipolar disorder receiving oral olanzapine in clinical studies and with an incidence of at least twice that of placebo included somnolence (35%), dry mouth (22%), dizziness (18%), asthenia (15%), constipation (11%), dyspepsia (11%), increased appetite (6%), and tremor (6%).

When oral olanzapine was used in conjunction with lithium or divalproex sodium for treatment of acute mania associated with bipolar disorder, adverse effects occurring in 5% or more of patients in clinical studies and with an incidence of at least twice that of placebo included dry mouth (32%), weight gain (26%), increased appetite (24%), dizziness (14%), back pain (8%) constipation (8%), speech disorder (7%), increased salivation (6%), amnesia (5%), and paresthesia (5%).

When IM olanzapine was used for the management of acute agitation in short-term clinical studies, somnolence was the only adverse effect that occurred in 5% or more of patients with schizophrenia or bipolar mania and with an incidence at least twice that of placebo (6% and 3%, respectively).

Nervous System Effects Seizures

Seizures occurred in about 0.9% of patients receiving oral olanzapine in controlled clinical trials during premarketing testing. Confounding factors that may have contributed to the occurrence of seizures were present in many of these cases. Myoclonic status reportedly occurred shortly after initiation of olanzapine in one patient with probable dementia of the Alzheimer's type (Alzheimer's disease) who was concurrently receiving citalopram and donepezil; the myoclonic jerks in this patient

coincided with EEG changes indicative of seizure activity (spikes and polyspike/wave complexes), and the seizures subsided following discontinuance of olanzapine. A new-onset seizure also reportedly occurred in an adult female patient upon the addition of quetiapine to maintenance therapy with olanzapine and following discontinuance of clonazepam therapy. In addition, an apparent lowering of seizure threshold occurred in at least 2 epileptic patients who experienced increased seizure activity following initiation of olanzapine therapy that resolved upon discontinuance of the drug. Fatal status epilepticus also has been reported in a patient who had been receiving olanzapine therapy for 5 months.

Olanzapine should be administered with caution to patients with a history of seizures, with conditions known to lower the seizure threshold (e.g., Alzheimer's disease, geriatric patients), and during concurrent therapy with drugs that may lower seizure threshold.

Extrapyramidal Reactions

Like other atypical antipsychotic agents, olanzapine has a low potential for causing certain adverse extrapyramidal effects (e.g., dystonias). Results from controlled clinical trials suggest that extrapyramidal reactions associated with olanzapine therapy are dose related.

Tremor was reported in about 4% of patients receiving oral olanzapine and in about 1% of patients receiving IM olanzapine in controlled clinical trials; the incidence of tremor appears to be dose related. In addition, akathisia occurred in about 3% of patients receiving oral olanzapine and in less than 1% of patients receiving IM olanzapine; hypertonia occurred in about 3% of patients receiving oral olanzapine in short-term controlled clinical trials. Akinesia and cogwheel rigidity have been reported in less than 1% of patients; these adverse effects have not been definitely attributed to the drug. Oculogyric crisis also has been reported in a patient receiving olanzapine, lithium, and paroxetine concurrently. (See Drug Interactions: Other CNS-Active Agents and Alcohol.)

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), a potentially fatal symptom complex, has been reported in patients receiving antipsychotic agents, including olanzapine. Clinical manifestations of NMS generally include hyperpyrexia, muscle rigidity, altered mental status, and evidence of autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac arrhythmias). Additional signs of NMS may include increased serum creatine kinase (CK, creatine phosphokinase, CPK), myoglobinuria (rhabdomyolysis), and acute renal failure. NMS attributable to olanzapine therapy alone has been reported in some patients, and there also have been reports of NMS in olanzapine-treated patients concomitantly receiving other drugs, including antipsychotic agents, antidepressants, lithium, or valproate. Extrapyramidal reactions were present in approximately two-thirds of the olanzapine-treated patients diagnosed with NMS. Atypical presentations of NMS (e.g., absence of or lessened rigidity, presenting as fever of unknown origin) and less severe presentations of NMS also have been reported in some patients receiving olanzapine or other atypical antipsychotic agents.

The diagnostic evaluation of patients with NMS is complicated. In arriving at a diagnosis, serious medical illnesses (e.g., pneumonia, systemic infection) and untreated or inadequately treated extrapyramidal signs and symptoms must be excluded. In addition, clinical features of NMS and serotonin syndrome sometimes overlap, and it has been suggested that these 2 syndromes may share certain underlying pathophysiologic mechanisms. Other important considerations in the differential diagnosis include central anticholinergic toxicity, heat stroke, drug fever, and primary CNS pathology.

The management of NMS should include immediate discontinuance of antipsychotic agents and other drugs not considered essential to concurrent therapy, intensive symptomatic treatment and medical monitoring, and treatment of any concomitant serious medical problems for which specific treatments are available. There currently is no specific drug therapy for NMS, although dantrolene, bromocriptine, amantadine, and benzodiazepines have been used in a limited number of patients. If a patient requires antipsychotic therapy following recovery from NMS, the potential reintroduction of drug therapy after several weeks should be carefully considered. If antipsychotic therapy is reintroduced, the dosage generally should be increased gradually and an antipsychotic agent other than the agent believed to have precipitated NMS generally is chosen. In addition, such patients should be carefully monitored since recurrences of NMS have been reported in some patients. For additional information on NMS, see Neuroleptic Malignant Syndrome under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Tardive Dyskinesia

Use of antipsychotic agents may be associated with tardive dyskinesia, a syndrome of potentially irreversible, involuntary, dyskinetic movements. Although the incidence of tardive dyskinesia appears to be highest among geriatric individuals, particularly geriatric females, it is not possible to reliably predict at the beginning of antipsychotic therapy which patients are likely to develop this syndrome. Tardive dyskinesia has been reported in less than 1% of patients receiving olanzapine therapy. Although the manufacturer states that it is not yet known whether antipsychotic agents differ in their potential to cause tardive dyskinesia, available evidence suggests that the risk appears to be substantially less with second-generation antipsychotic agents, including olanzapine, than with conventional, first-generation antipsychotic agents. Analyses from controlled, long-term trials have found an approximately 12-fold lower risk of tardive dyskinesia with olanzapine therapy compared with haloperidol therapy. In addition, stabilization of or improvement in tardive dyskinesia associated with conventional antipsychotic agents has been reported in some patients when they have been switched to second-generation antipsychotic therapy, including olanzapine. However, a transient increase in dyskinetic movements (sometimes referred to as withdrawal-emergent dyskinesia) occasionally may occur when a patient is switched from a first-generation to a second-generation antipsychotic agent or upon dosage reduction of an antipsychotic agent.

The risk of developing tardive dyskinesia and the likelihood that it will become irreversible are believed to increase as the duration of treatment and the total cumulative dose of antipsychotic drugs administered to the patient increase. However, the syndrome can develop, although much less commonly, following relatively brief treatment periods at low dosages. There is no known treatment for established cases of tardive dyskinesia, although the syndrome may remit, partially or completely, if antipsychotic therapy is discontinued. However, antipsychotic therapy itself may suppress or partially suppress the signs and symptoms of the syndrome and thereby may possibly mask the underlying process. The effect that such symptomatic suppression has upon the long-term course of tardive dyskinesia is unknown. There also is some evidence that vitamin E administration may reduce the risk of development of tardive dyskinesia; therefore, the American Psychiatric Association (APA) currently states that patients receiving antipsychotic agents may be advised to take 400-800 units of vitamin E daily for prophylaxis. (See Cautions in Vitamin E 88:20.)

Olanzapine should be prescribed in a manner that is most likely to minimize the occurrence of tardive dyskinesia. Chronic antipsychotic treatment generally should be reserved for patients who suffer from a chronic illness that is known to respond to antipsychotic agents, and for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought, and the need for continued treatment should be reassessed periodically. The APA currently recommends that all patients receiving second-generation antipsychotic agents be assessed clinically for abnormal involuntary movements every 12 months and that patients considered to be at increased risk for tardive dyskinesia be assessed every 6 months. If signs and symptoms of tardive dyskinesia appear in a patient receiving olanzapine, drug discontinuance or a reduction in dosage should be considered. However, some patients may require treatment with olanzapine or another antipsychotic agent despite the presence of the syndrome. For additional information on tardive dyskinesia, see Tardive Dyskinesia under Cautions: Nervous System Effects, in the Phenothiazines General Statement 28:16.08.24.

Other Nervous System Effects

Somnolence or sedation, which usually appears to be moderate in severity compared with other antipsychotic agents and dose related, is among the most common adverse effects of olanzapine, occurring in approximately 29% of patients receiving oral olanzapine in controlled clinical trials. Somnolence associated with olanzapine and other antipsychotic agents generally is most pronounced during early therapy, since most patients develop some tolerance to the sedating effects with continued administration. Although sedation can have therapeutic benefits in some cases, persistent daytime drowsiness and increased sleep time can become troublesome in some patients and necessitate a lower dosage or evening administration of the drug. (See Administration under Dosage and Administration and see also Effects on Sleep under Pharmacology: Nervous System Effects.)

Insomnia occurred in about 12%, dizziness in about 11%, asthenia in about 10%, and abnormal gait in about 6% of patients receiving oral olanzapine in short-term controlled clinical trials. The incidence of asthenia appears to be dose related. In addition, articulation impairment was reported in about 2% of patients receiving oral olanzapine in short-term, controlled clinical trials.

Abnormal dreams, amnesia, delusions, emotional lability, euphoria, manic reaction, paresthesia, and schizophrenic reaction each has been reported in at least 1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been established. Alcohol misuse, antisocial reaction, ataxia, CNS stimulation, delirium, dementia, and depersonalization have been reported in less than 1% of patients; these adverse effects have not been definitely attributed to the drug.

Dysarthria, facial paralysis, hypesthesia, hypokinesia, hypotonia, incoordination, increased or decreased libido, migraine, obsessive-compulsive symptoms, phobias, somatization, and stimulant misuse have been reported in less than 1% of patients receiving oral olanzapine; these adverse effects have not been definitely attributed to the drug. Although a causal relationship has not been established, stupor, stuttering, vertigo, and withdrawal syndrome also have been reported in up to 1% of patients receiving oral olanzapine. Circumoral paresthesia, coma, encephalopathy, neuralgia, neuropathy, nystagmus, paralysis, suicide attempt, subarachnoid hemorrhage, and tobacco misuse have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established.

In short-term (i.e., 24-hour), controlled clinical trials of IM olanzapine for acute agitation, somnolence occurred in approximately 6%, dizziness in approximately 4%, and asthenia in about 2% of the patients. Abnormal gait, articulation impairment, confusion, and emotional lability have been reported in less than 1% of patients; these adverse effects have not been definitely attributed to the drug.

Cardiovascular Effects Hemodynamic Effects

Oral olanzapine may produce orthostatic hypotension that may be associated with dizziness, tachycardia, and, in some patients, syncope, particularly during the initial

period of dosage titration. In short-term, controlled clinical trials for oral olanzapine, postural hypotension and tachycardia occurred in approximately 3% and hypertension occurred in approximately 2% of patients. In addition, hypotension has been reported in at least 1% of patients receiving oral olanzapine in the short-term controlled clinical trials. Bradycardia, congestive heart failure, and vasodilatation have been reported in less than 1% of patients; these adverse effects have not been definitely attributed to the drug. These effects probably are due to the drug's α_1-adrenergic blocking activity.

Hypotension, bradycardia with or without hypotension, tachycardia, and syncope also were reported during the clinical trials with IM olanzapine. In an open trial in nonagitated patients with schizophrenia designed to evaluate the safety and tolerability of a dosage regimen of three 10-mg IM doses of olanzapine administered 4 hours apart, approximately one-third of the patients experienced a substantial orthostatic decrease in systolic blood pressure (i.e., decrease of 30 mm Hg or more).

Syncope was reported in 0.6% of olanzapine-treated patients in phase 2 and 3 clinical trials of oral olanzapine and in 0.3% of patients receiving IM olanzapine in the acute agitation clinical trials. In phase 1 trials of olanzapine, 3 healthy volunteers experienced hypotension, bradycardia, and sinus pauses of up to 6 seconds that spontaneously resolved; 2 of these cases occurred in association with IM olanzapine and one case involved oral olanzapine. In short-term, controlled clinical trials for IM olanzapine for acute agitation, hypotension occurred in approximately 2% and postural hypotension occurred in approximately 1% of the patients. Syncope has been reported in less than 1% of the patients receiving IM olanzapine in clinical trials. The manufacturer states that the risk for this sequence of hypotension, bradycardia, and sinus pause may be greater in nonpsychiatric patients compared with psychiatric patients, who may be more adapted to certain pharmacologic effects of psychotropic agents. (See Dosage and Administration and see also Cardiovascular Effects, under Cautions: Precautions and Contraindications.)

ECG Effects

Pooled analyses from controlled clinical trials did not reveal statistically significant differences in the proportions of olanzapine-treated patients experiencing potentially important ECG changes, including QT, QT_c, and PR intervals. Olanzapine was associated with a mean increase in heart rate of 2.4 beats per minute compared with no change among placebo patients in controlled trials. The manufacturer states that the slight tendency to cause tachycardia may be related to olanzapine's potential for inducing orthostatic changes in blood pressure. Like some other antipsychotic agents, olanzapine has been associated with prolongation of the QT_c interval in some patients and there is some evidence that higher dosages of the drug may increase the risk of QT_c interval prolongation; however, the clinical relevance of these findings remains to be established.

Other Cardiovascular Effects

In short-term, controlled clinical trials for oral olanzapine, chest pain occurred in approximately 3% of patients. Atrial fibrillation, cerebrovascular accident, cardiac arrest, hemorrhage, pallor, palpitation, and ventricular extrasystoles have been reported in less than 1% of patients; these adverse effects have not been definitely attributed to the drug.

Although a causal relationship has not been established, arteritis and heart failure have been reported in less than 0.1% of patients receiving oral olanzapine. In addition, venous thromboembolic effects, including pulmonary embolism and deep venous thrombosis, have been reported in patients receiving olanzapine during postmarketing surveillance.

In controlled clinical trials for IM olanzapine for acute agitation, AV block and heart block have been reported in less than 1% of the patients receiving IM olanzapine.

Hepatic Effects

During premarketing clinical trials, olanzapine therapy was associated with asymptomatic elevations in serum aminotransferase (transaminase) concentrations, including elevations in serum concentrations of ALT (SGPT), AST (SGOT), and γ-glutamyltransferase (GGT). Clinically important ALT elevations (3 or more times the upper limit of the normal range) were observed in 2% (6 of 243) of patients exposed to olanzapine in placebo-controlled clinical studies; none of these patients experienced jaundice. In 2 of these patients, the transaminases decreased toward normal values despite continued therapy, and in 2 other patients, the transaminases decreased upon discontinuance of olanzapine therapy. In the 2 remaining patients, one patient, who was seropositive for hepatitis C, had persistent transaminase elevations for 4 months after discontinuance of therapy, and the other patient had insufficient follow-up to determine whether the transaminase elevation normalized. Within the larger premarketing database of about 2400 patients with baseline ALT values of 90 IU/L or less, the incidence of SGPT elevation exceeding 200 IU/L was 2% (50 of 2381 patients). None of these patients experienced jaundice or other symptoms attributable to hepatic impairment, and most had transient changes that tended to normalize while olanzapine therapy was continued. Among 2500 patients receiving oral olanzapine in clinical trials, about 9% of the patients experienced transient elevations in serum transaminase levels, usually within 1–2 weeks following initiation of therapy, and the median time to maximal levels in these patients was about 4 weeks; olanzapine therapy was discontinued in about 1% (23 of 2500) of the patients because of transaminase elevations. (See Cautions: Precautions and Contraindications.)

Hepatitis has rarely been reported in postmarketing experience, as well as very rare cases of cholestatic or mixed hepatic injury. In addition, fatty deposit in the liver has been reported in less than 0.1% of patients receiving oral olanzapine in short-term clinical trials, although a causal relationship to the drug remains to be established.

Endocrine and Metabolic Effects Weight Gain

Like some conventional (first-generation) and atypical (second-generation) antipsychotic agents, olanzapine therapy may result in weight gain. In placebo-controlled studies of 6 weeks' duration, weight gain occurred in approximately 6% of patients receiving oral olanzapine, and increased appetite occurred in 3% of patients receiving oral olanzapine in short-term controlled trials. Patients receiving olanzapine in the 6-week, placebo-controlled studies gained an average of 2.8 kg compared with an average loss of 0.4 kg in those receiving placebo; 29% of the olanzapine-treated patients gained greater than 7% of their baseline weight compared with 3% of placebo recipients. Patients with a low body mass index (BMI) in these studies appeared to be more susceptible to olanzapine-induced weight gain than normal or overweight patients, although weight gain was substantially greater in all 3 groups compared with placebo. During long-term continuation therapy with olanzapine, 56% of olanzapine-treated patients gained greater than 7% of their baseline weight; the average weight gain observed during long-term therapy was 5.4 kg.

Although the precise mechanism(s) remains to be clearly established, weight gain may result at least in part from the drug's serotonergic-, histaminergic-, and adrenergic-blocking properties. Weight gain has been reported to be troublesome for some patients during long-term therapy with atypical antipsychotics, particularly olanzapine and clozapine, and may be an important cause of outpatient noncompliance. Some clinicians suggest regular physical exercise and nutritional counseling in the prevention and treatment of weight gain associated with these drugs. There currently are no well established pharmacologic treatments for antipsychotic agent-induced weight gain; however, a number of drugs, including amantadine, bupropion, histamine H_2-receptor antagonists (e.g., nizatidine) orlistat, metformin, sibutramine, and topiramate, have been used with limited success to date. Because the potential risk of adverse effects in patients receiving these drugs may outweigh their possible weight-reducing effects in some cases, routine use of pharmacologic therapy currently is not recommended by most clinicians, although individual patients may benefit. Additional controlled studies are needed to more clearly determine the optimum management of antipsychotic-associated weight gain during long-term therapy with these drugs.

Hyperglycemia and Diabetes Mellitus

Severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents, including olanzapine. While confounding factors such as an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes mellitus in the general population make it difficult to establish with certainty the relationship between use of agents in this drug class and glucose abnormalities, epidemiologic studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotic agents included in the studies (e.g., olanzapine, clozapine, quetiapine, risperidone). (See Cautions: Precautions and Contraindications.)

Precise risk estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics currently are not available. While some evidence suggests that the risk for diabetes may be greater with some atypical antipsychotics (e.g., olanzapine, clozapine) than with others (e.g., quetiapine, risperidone) in the class, available data are conflicting and insufficient to provide reliable estimates of relative risk associated with use of the various atypical antipsychotics.

Diabetes mellitus has been reported in less than 1% of patients and diabetic acidosis has been reported in less than 0.1% of patients receiving oral olanzapine in short-term, controlled clinical trials.

Hyperlipidemia

Like some other antipsychotic agents, particularly clozapine, olanzapine therapy has been associated with hyperlipidemia, including elevations in serum triglyceride and cholesterol concentrations.

In clinical trials in olanzapine-treated patients with random triglyceride concentrations of less than 150 mg/dL at baseline, 0.5% of patients experi-enced elevated triglyceride concentrations of 500 mg/dL or higher at any time, and severely elevated triglyceride concentrations of 1000 mg/dL or more have been reported rarely during postmarketing surveillance. During the same trials, olanzapine-treated patients experienced a mean increase of 20 mg/dL in triglyceride concentrations from a mean baseline value of 175 mg/dL.

In placebo-controlled trials, olanzapine-treated patients who had random cholesterol concentrations of less than 200 mg/dL at baseline experienced elevated cholesterol concentrations of 240 mg/dL or higher at any time during the trials more frequently than those receiving placebo (approximately 4% and 2% of patients, respectively). In these trials, olanzapine-treated patients had a mean increase of 0.4 mg/dL in serum cholesterol concentrations while those receiving placebo had a mean decrease of 4.6 mg/dL, both from a mean baseline value of 203 mg/dL.

Hypercholesterolemia and hyperlipidemia have been reported in less than 1% of patients receiving oral olanzapine in short-term trials. In addition, cholesterol concentration of 240 mg/dL or higher have been reported rarely during postmarketing surveillance.

Although the manufacturer currently does not recommend routine monitoring of lipid parameters in patients receiving olanzapine, the APA recommends a baseline

lipid panel in all patients with schizophrenia and recommends that this be repeated at least every 5 years. In addition, some clinicians recommend that lipid profiles be monitored at baseline and periodically (e.g., every 3–6 months) in all patients receiving long-term therapy with atypical antipsychotic agents. There is some evidence from a study in individuals with developmental disabilities that the risk of hyperlipidemia in patients receiving atypical antipsychotic agents may be minimized or avoided by careful monitoring, dietary management, and suitable physical activity. In patients who develop persistent and clinically important hyperlipidemia during olanzapine therapy, nondrug therapies and measures (e.g., dietary management, weight control, an appropriate program of physical activity) and drug therapy (e.g., antilipemic agents) may be helpful. Consideration also may be given to switching to an alternative antipsychotic agent that is less frequently associated with hyperlipidemia (such as aripiprazole, risperidone, or ziprasidone).

Hyperprolactinemia

As with other drugs that antagonize dopamine D_2 receptors, olanzapine can elevate serum prolactin concentrations, and a modest elevation may persist during chronic administration of the drug. However, in contrast to conventional (first-generation) antipsychotic agents and similar to many other atypical antipsychotic agents, olanzapine therapy in usual dosages generally produces relatively modest and transient elevations in serum prolactin concentrations in humans. It has been suggested that the more transient effect of atypical antipsychotic agents on prolactin may be because these drugs appear to dissociate from dopamine receptors more rapidly than conventional antipsychotic agents.

Olanzapine is considered by many experts to be low in its potential for inducing hyperprolactinemia, and it has been recommended along with other prolactin-sparing atypical antipsychotics (e.g., aripiprazole, clozapine, quetiapine, ziprasidone) in patients with schizophrenia who are at risk of hyperprolactinemia. Although clinical disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been associated with prolactin-elevating drugs, the clinical importance of elevated prolactin concentrations is unknown for most patients.

Like other drugs that increase prolactin, an increase in mammary gland neoplasia was observed in olanzapine carcinogenicity studies conducted in mice and rats. However, neither clinical studies nor epidemiologic studies have demonstrated an association between chronic administration of dopamine antagonists and tumorigenesis in humans; the available evidence is considered too limited to be conclusive. (See Cautions: Precautions and Contraindications and see also Cautions: Mutagenicity and Carcinogenicity.) In patients who develop elevated prolactin concentrations during antipsychotic therapy, some clinicians recommend reducing the dosage of the current antipsychotic agent or switching to a prolactin-sparing antipsychotic agent. Dopamine receptor agonists (e.g., bromocriptine) also may be helpful, and estrogen replacement therapy may be considered in hypoestrogenic female patients.

Other Endocrine and Metabolic Effects

Peripheral edema has been reported in approximately 3% of patients receiving oral olanzapine in short-term clinical trials. Acidosis, increased serum alkaline phosphatase concentrations, bilirubinemia, dehydration, hypoglycemia, hypokalemia, hyponatremia, lower extremity edema, and upper extremity edema have been reported in less than 1% of patients receiving oral olanzapine in short-term trials; however, a causal relationship remains to be established. Goiter, gout, hyperkalemia, hypernatremia, hypoproteinemia, ketosis, and water intoxication have been reported in less than 0.1% of patients receiving oral olanzapine; these adverse effects have not been definitely attributed to the drug.

Adverse metabolic effects that have been reported in less than 1% of patients receiving IM olanzapine in short-term clinical trials include increased serum creatine phosphokinase concentrations, dehydration, and hyperkalemia; however, a causal relationship remains to be established.

GI Effects

Dryness of the mouth and constipation both occurred in about 9%, dyspepsia in about 7%, vomiting in about 4%, and increased appetite in about 3% of patients receiving oral olanzapine in short-term controlled clinical trials.

Flatulence, increased salivation, and thirst have been reported in at least 1% of patients receiving oral olanzapine in short-term clinical trials. Dysphagia, esophagitis, fecal impaction, fecal incontinence, gastritis, gastroenteritis, gingivitis, melena, mouth ulceration, nausea and vomiting, oral moniliasis, periodontal abscess, rectal hemorrhage, stomatitis, tongue edema, and tooth caries have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug.

Abdominal pain, diarrhea, and nausea have been reported in less than 1% of patients receiving IM olanzapine in clinical trials; these adverse effects have not been definitely attributed to the drug.

Aphthous stomatitis, enteritis, eructation, esophageal ulcer, glossitis, ileus, intestinal obstruction, and tongue discoloration have been reported in less than 0.1% of patients receiving oral olanzapine in short-term clinical trials, although a causal relationship to the drug remains to be established.

Respiratory Effects

Rhinitis occurred in about 7%, increased cough in about 6%, and pharyngitis in about 4% of patients receiving oral olanzapine in short-term controlled clinical trials. Dyspnea has been reported in at least 1% of patients receiving oral olanzapine in short-term clinical trials. Apnea, asthma, epistaxis, hemoptysis, hyperventilation, hypoxia, laryngitis, and voice alteration have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug. In addition, dyspnea and hyperventilation, which appeared to be dose related, have been reported together in a patient treated with oral olanzapine.

Atelectasis, hiccup, hypoventilation, lung edema, and stridor have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established. Respiratory failure developed in a geriatric individual with chronic lung disease who was receiving olanzapine therapy; although not clearly established, it was suggested that the respiratory failure was due at least in part to the sedative effect of the drug.

Dermatologic and Sensitivity Reactions

Sweating has been reported in at least 1% of patients receiving oral olanzapine and in less than 1% of patients receiving IM olanzapine in short-term clinical trials. Alopecia, contact dermatitis, dry skin, eczema, maculopapular rash, photosensitivity reaction, pruritus, seborrhea, skin discoloration (e.g., hyperpigmentation), skin ulcer, urticaria, and vesiculobullous rash have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug. Hirsutism and pustular rash have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established.

Allergic reactions (e.g., anaphylactoid reaction, angioedema, pruritus, urticaria) have been reported during postmarketing surveillance of olanzapine. In addition, a hypersensitivity syndrome consisting of a severe and generalized pruritic eruption, fever, eosinophilia, and toxic hepatitis has been reported in at least one olanzapine-treated patient; the manifestations improved following discontinuance of the drug, and skin and liver biopsy results suggested that the hypersensitivity syndrome was caused by olanzapine. Eruptive xanthomas, which are associated with hyperlipidemia, have occurred in several patients receiving olanzapine therapy. Leukocytoclastic vasculitis also has been reported in a geriatric patient receiving olanzapine and warfarin concurrently; the vasculitis improved following discontinuance of olanzapine in this patient but recurred when the drug was subsequently reintroduced.

Local Effects

Pain at the injection site also has been reported in at least 1% of patients receiving IM olanzapine in controlled clinical trials.

Genitourinary Effects

Urinary incontinence and urinary tract infection both have been reported in approximately 2% and vaginitis has been reported in at least 1% of patients receiving oral olanzapine in short-term controlled clinical trials, although a causal relationship to the drug remains to be established. Abnormal ejaculation, amenorrhea, breast pain, cystitis, decreased menstruation, dysuria, female lactation, glycosuria, gynecomastia, and hematuria have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug.

Impotence, increased menstruation, menorrhagia, metrorrhagia, polyuria, premenstrual syndrome, pyuria, urinary frequency, urinary retention, urinary urgency, impaired urination, enlarged uterine fibroids, and vaginal hemorrhage have been reported in less than 1% of patients receiving oral olanzapine in short-term clinical trials; however, a causal relationship to the drug remains to be established. Albuminuria, breast enlargement, mastitis, and oliguria have been reported in less than 0.1% of patients receiving oral olanzapine; however, these adverse effects have not been definitely attributed to the drug.

Priapism also has been reported in several male patients and at least one case of clitoral priapism has been reported in a female patient. The α-adrenergic blocking effect of olanzapine appears to be responsible for this rare but potentially serious adverse effect requiring immediate medical attention to prevent long-term consequences such as erectile dysfunction.

Musculoskeletal Effects

Joint pain, back pain, and extremity (other than joint) pain have been reported in 5% and joint stiffness and muscle twitching in more than 1% of patients receiving oral olanzapine; muscle twitching also has been reported in less than 1% of patients receiving IM olanzapine in short-term controlled clinical trials. Arthritis, arthrosis, leg cramps, and myasthenia have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug. Bone pain, bursitis, myopathy, osteoporosis, and rheumatoid arthritis have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established. Rhabdomyolysis also has been reported rarely in olanzapine-treated patients and may be seen as one of the clinical features of NMS. (See Neuroleptic Malignant Syndrome in Cautions: Nervous System Effects.)

Ocular and Otic Effects

Amblyopia has been reported in 3% of patients, and conjunctivitis has been reported in at least 1% of patients receiving oral olanzapine in short-term clinical trials; however, a causal relationship to the drug for these effects remains to be established. Accommodation abnormality, blepharitis, cataract, deafness, diplopia, dry eyes, ear pain, eye hemorrhage, eye inflammation, eye pain, ocular muscle abnormality, and tinnitus have been reported in less than 1% of olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug. In addition, corneal lesion, glaucoma, keratoconjunctivitis, macular hyperpigmentation, miosis, mydriasis, and pigment

deposits in the eye lens have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established.

Hematologic Effects

Because of concern about neutropenia associated with other psychotropic agents (e.g., clozapine) and the finding of leukopenia associated with the administration of olanzapine in several animal models, hematologic parameters were carefully evaluated during premarketing clinical trials with olanzapine. There was no indication of a risk of clinically important neutropenia in olanzapine-treated patients in the premarketing database for the drug.

Ecchymosis has been reported in 5% of patients receiving oral olanzapine in short-term clinical trials; however, a causal relationship to the drug remains to be established. Anemia has been reported in less than 1% of patients receiving oral or IM olanzapine; this adverse effect has not been definitely attributed to the drug. Cyanosis, leukocytosis, leukopenia, lymphadenopathy, and thrombocytopenia have been reported in less than 1% of patients receiving oral olanzapine; however, a causal relationship to the drug remains to be established.

During premarketing clinical trials, asymptomatic elevation of the eosinophil count was reported in approximately 0.3% of patients receiving oral olanzapine. In addition, normocytic anemia and thrombocythemia have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established.

Other Adverse Effects

Accidental injury has been reported in approximately 12% of patients receiving oral olanzapine in short-term controlled trials. Fever has been reported in approximately 6% of patients receiving oral olanzapine and in less than 1% of patients receiving IM olanzapine in short-term clinical trials. Dental pain and flu syndrome have been reported in at least 1% of patients receiving oral olanzapine in short-term clinical trials; however, a causal relationship to the drug remains to be established. Enlarged abdomen, chills, facial edema, intentional injury, malaise, moniliasis, neck pain, neck rigidity, pelvic pain, and taste perversion have been reported in less than 1% of oral olanzapine-treated patients; these adverse effects have not been definitely attributed to the drug. In addition, chills accompanied by fever, hangover effect, and sudden death have been reported in less than 0.1% of patients receiving oral olanzapine; however, a causal relationship to the drug has not been clearly established.

Pancreatitis, which has been fatal in some cases, has occurred rarely in patients receiving atypical antipsychotic agents, including olanzapine, clozapine, and risperidone. In most of these cases, pancreatitis developed within 6 months of initiation of atypical antipsychotic therapy. Although the precise mechanism for this effect remains to be established, it has been suggested that it may be due at least in part to the adverse metabolic effects associated with these drugs.

■ Precautions and Contraindications

Pending revision, the material in this section should be considered in light of more recently available information in the MedWatch notification at the beginning of this monograph.

Olanzapine shares many of the toxic potentials of other antipsychotic agents (e.g., other atypical antipsychotic agents, phenothiazines), and the usual precautions associated with therapy with these agents should be observed. (See Cautions, in the Phenothiazines General Statement 28:16.08.24.)

When olanzapine is used in fixed combination with fluoxetine, the usual cautions, precautions, and contraindications associated with fluoxetine must be considered in addition to those associated with olanzapine.

Somnolence

Dose-related somnolence occurred in 26% of patients receiving oral olanzapine compared with 15% of those receiving placebo, and resulted in discontinuance of the drug in 0.4% of the patients in the premarketing database. Because of sedative effects of the drug and because it potentially may impair judgment, thinking, and motor skills, patients should be cautioned that olanzapine may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery, driving a motor vehicle) until they are reasonably certain that olanzapine does not adversely affect them.

Seizures

Although seizures occurred in about 0.9% of patients receiving oral olanzapine in controlled clinical trials during premarketing testing, it should be noted that confounding factors that may have contributed to the occurrence of seizures were present in many of these cases. Olanzapine should be administered with caution to patients with a history of seizures, patients with conditions known to lower the seizure threshold (e.g., Alzheimer's disease, geriatric patients), and during concurrent therapy with drugs that may lower the seizure threshold.

Body Temperature Regulation

Because disruption of the body's ability to reduce core body temperature has been associated with the use of antipsychotic agents, caution is advised when olanzapine is administered in patients exposed to conditions that may contribute to an elevation in core body temperature. Such conditions include strenuous exercise, exposure to extreme heat, concomitant use of drugs with anticholinergic activity, or dehydration. Patients receiving olanzapine should be advised to avoid overheating and dehydration.

Hepatic Effects

Because clinically important serum ALT elevations (3 or more times the upper limit of the normal range) were observed in about 2% of patients exposed to oral olanzapine in placebo-controlled clinical studies, the manufacturer states that olanzapine should be used with caution in patients with signs and symptoms of hepatic impairment, in patients with preexisting conditions associated with limited hepatic functional reserve, and in patients who are being treated concurrently with potentially hepatotoxic drugs. In addition, periodic assessment of transaminases is recommended in patients with clinically important hepatic disease.

Individuals with Phenylketonuria

Individuals with phenylketonuria (i.e., homozygous genetic deficiency of phenylalanine hydroxylase) and other individuals who must restrict their intake of phenylalanine should be warned that olanzapine 5, 10, 15, or 20 mg orally disintegrating tablets contain aspartame (e.g., NutraSweet®), which is metabolized in the GI tract to provide about 0.34, 0.45, 0.67, or 0.9 mg of phenylalanine, respectively, following oral administration.

Dysphagia

Because esophageal dysmotility and aspiration sometimes resulting in death have been associated with the use of antipsychotic agents, olanzapine and other antipsychotic agents should be used with caution in patients at risk for aspiration pneumonia. Aspiration pneumonia is a common cause of morbidity and mortality in patients with advanced Alzheimer's disease.

Suicide

Because the possibility of a suicide attempt is inherent in patients with schizophrenia and bipolar disorder, close supervision of high-risk patients is recommended during olanzapine therapy. The manufacturer recommends that the drug be prescribed in the smallest quantity consistent with good patient management to reduce the risk of overdosage.

Patients with Concomitant Illness

Clinical experience with olanzapine in patients with certain concurrent systemic diseases is limited. Olanzapine has demonstrated anticholinergic activity in vitro and constipation, dryness of the mouth, and tachycardia, possibly related to the drug's anticholinergic effects, have occurred in premarketing clinical trials. Although these adverse effects did not often result in drug discontinuance, the manufacturer states that olanzapine should be used with caution in patients with clinically important prostatic hypertrophy, angle-closure glaucoma, or a history of paralytic ileus.

Olanzapine has not been adequately evaluated in patients with a recent history of myocardial infarction or unstable cardiovascular disease to date and patients with these conditions were excluded from premarketing clinical trials. Because of the risk of orthostatic hypotension associated with olanzapine, the manufacturer states that the drug should be used with caution in patients with cardiovascular disease. (See Cautions: Cardiovascular Effects.)

Concomitant Medication or Alcohol Use

Because of the potential for adverse drug interactions, the manufacturer recommends that patients receiving olanzapine be advised to notify their clinician if they are taking or plan to take any prescription or nonprescription (over-the-counter) medications. The manufacturer also recommends that patients be advised to avoid alcohol while receiving the drug. (See Drug Interactions.)

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), a potentially fatal syndrome requiring immediate discontinuance of the drug and intensive symptomatic treatment, has been reported in patients receiving antipsychotic agents, including olanzapine. If a patient requires antipsychotic therapy following recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. If antipsychotic therapy is reintroduced, the dosage generally should be increased gradually, and an antipsychotic agent other than the agent believed to have precipitated NMS generally should be chosen. In addition, such patients should be carefully monitored since recurrences of NMS have been reported in some patients. (See Neuroleptic Malignant Syndrome in Cautions: Nervous System Effects.)

Tardive Dyskinesia

Because use of antipsychotic agents may be associated with tardive dyskinesia, a syndrome of potentially irreversible, involuntary, dyskinetic movements, olanzapine should be prescribed in a manner that is most likely to minimize the occurrence of this syndrome. Chronic antipsychotic treatment generally should be reserved for patients who suffer from a chronic illness that is known to respond to antipsychotic agents, and for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought, and the need for continued treatment should be reassessed periodically.

The APA currently recommends that patients receiving second-generation antipsychotic agents be assessed clinically for abnormal involuntary movements every 12 months and that patients considered to be at increased risk for tardive dyskinesia be assessed every 6 months. (See Tardive Dyskinesia in Cautions: Nervous System Effects.)

Dispensing and Administration Precautions

Because of similarities in spelling, dosage intervals (once daily), and tablet strengths (5 and 10 mg) of Zyprexa® (the trade name for olanzapine) and Zyrtec® (the trade name for cetirizine hydrochloride, an antihistamine), several dispensing or prescribing errors

have been reported to the manufacturer of Zyprexa®. These medication errors may result in unnecessary adverse events or a potential relapse in patients with schizophrenia or bipolar disorder. Therefore, the manufacturer of Zyprexa® cautions that extra care should be exercised in ensuring the accuracy of written prescriptions for Zyprexa® and Zyrtec® such as printing both the proprietary (brand) and nonproprietary (generic) names on all prescriptions for these drugs. The manufacturer also recommends that pharmacists assess various measures of avoiding dispensing errors and implement them as appropriate (e.g., placing drugs with similar names apart from one another on pharmacy shelves, patient counseling).

Cardiovascular Effects

Orthostatic hypotension associated with dizziness, tachycardia, and/or syncope, particularly during the initial dosage titration period, has been reported in patients receiving oral olanzapine therapy. The risk of orthostatic hypotension and syncope may be minimized by initiating therapy with a dosage of 5 mg orally once daily. A more gradual titration to the target dose should be considered if hypotension occurs. Patients should be cautioned about the risk of orthostatic hypotension, particularly during the initial dosage titration period and if the drug is given concurrently with drugs that may potentiate the orthostatic effect of olanzapine, including diazepam, or alcohol.

Hypotension, bradycardia with or without hypotension, tachycardia, and syncope have been reported in patients receiving IM olanzapine. The use of maximum recommended dosages of IM olanzapine (i.e., 3 doses of 10 mg each given IM 2–4 hours apart) may be associated with a substantial risk of clinically important orthostatic hypotension. Patients who experience drowsiness or dizziness after the IM injection should remain recumbent until an examination indicates that they are not experiencing orthostatic hypotension, bradycardia, and/or hypoventilation. Patients requiring additional IM injections of olanzapine should be assessed for orthostatic hypotension prior to administration of any subsequent doses. Administration of additional IM doses to patients with clinically important postural change in blood pressure is not recommended.

The manufacturer states that olanzapine should be used with caution in patients with known cardiovascular disease (e.g., history of myocardial infarction or ischemia, heart failure, conduction abnormalities), cerebrovascular disease, and/or other conditions that would predispose patients to hypotension (e.g., dehydration, hypovolemia, concomitant antihypertensive therapy) where the occurrence of syncope, hypotension, and/or bradycardia might put the patient at increased risk. The manufacturer also states that the drug should be used with caution in patients receiving other drugs that can induce hypotension, bradycardia, or respiratory and CNS depression. (See Drug Interactions.) Concurrent administration of IM olanzapine and parenteral benzodiazepines has not been well studied; therefore, combined use of these drugs is not recommended. If use of IM olanzapine in combination with parenteral benzodiazepine therapy is considered, careful evaluation of the patient's clinical status for excessive sedation and cardiorespiratory depression is recommended.

Hyperglycemia and Diabetes Mellitus

Because severe hyperglycemia, sometimes associated with ketoacidosis, hyperosmolar coma, or death, has been reported in patients receiving certain atypical antipsychotic agents, including olanzapine, the manufacturers state that patients with preexisting diabetes mellitus in whom therapy with an atypical antipsychotic is initiated should be closely monitored for worsening of glucose control; those with risk factors for diabetes (e.g., obesity, family history of diabetes) should undergo fasting blood glucose testing upon therapy initiation and periodically throughout treatment. Any patient who develops manifestations of hyperglycemia (e.g., polydipsia, polyphagia, polyuria, weakness) during treatment with an atypical antipsychotic should undergo fasting blood glucose testing. In some cases, patients who developed hyperglycemia while receiving an atypical antipsychotic have required continuance of antidiabetic treatment despite discontinuance of the suspect drug; in other cases, hyperglycemia resolved with discontinuance of the antipsychotic or with continuance of both the suspect drug and initiation of antidiabetic treatment.

Various experts have developed additional recommendations for the management of diabetes risks in patients receiving atypical antipsychotics; these include initial screening measures and regular monitoring (e.g., determination of diabetes risk factors; BMI determination using weight and height; waist circumference; blood pressure; fasting blood glucose; hemoglobin A_{1c} [HbA_{1c}]; fasting lipid profile), as well as provision of patient education and referral to clinicians experienced in the treatment of diabetes, when appropriate. Although some clinicians state that a switch from one atypical antipsychotic agent to another that has not been associated with substantial weight gain or diabetes should be considered in patients who experience weight gain (equal to or exceeding 5% of baseline body weight) or develop worsening glycemia or dyslipidemia at any time during therapy, such recommendations are controversial because differences in risk of developing diabetes associated with use of the different atypical antipsychotics remain to be fully established. Many clinicians consider antipsychotic efficacy the most important factor when making treatment decisions and suggest that detrimental effects of switching from a beneficial treatment regimen also should be considered in addition to any potential for exacerbation or development of medical conditions (e.g., diabetes). Decisions to alter drug therapy should be made on an individual basis, weighing the potential risks and benefits of the particular drug in each patient.

Contraindications

Olanzapine is contraindicated in patients with a known hypersensitivity to the drug. (See Cautions: Dermatologic and Sensitivity Reactions.)

■ Pediatric Precautions

Pending revision, the material in this section should be considered in light of more recently available information in the MedWatch notification at the beginning of this monograph.

The manufacturer states that safety and efficacy of olanzapine in children and adolescents younger than 18 years of age have not been established. However, the drug has been used in a limited number of children and adolescents with childhood-onset schizophrenia (see Pediatric Considerations under Psychotic Disorders: Schizophrenia, in Uses). In a double-blind, placebo-controlled trial of 6 weeks' duration conducted in 107 adolescents 13–17 years of age with schizophrenia, olanzapine was effective in the management of schizophrenia, but results indicated that the drug's effects on weight and prolactin concentrations may be greater in adolescents.

Olanzapine also has been effective and well tolerated in a limited number of children and adolescents with bipolar disorder (see Pediatric Considerations under Bipolar Disorder, in Uses) and pervasive developmental disorder, including autistic disorder. In a double-blind, placebo-controlled, 3-week study in 107 adolescents 13–17 years of age with bipolar disorder, olanzapine was found to be effective in the treatment of acute manic or mixed episodes; however, weight gain and hyperprolactinemia occurred more often in patients receiving olanzapine compared with those receiving placebo. Additional controlled and longer-term studies are needed to confirm these initial findings and to evaluate the relative benefits and risks of olanzapine therapy in pediatric patients.

As in adults, olanzapine therapy may be associated with weight gain in pediatric patients (see Cautions: Endocrine and Metabolic Effects). The American Academy of Child and Adolescent Psychiatry (AACAP) currently recommends that pediatric patients who experience weight gain associated with olanzapine or other agents be monitored closely for potential medical consequences associated with weight gain (e.g., diabetes mellitus, hyperlipidemia, elevations in serum transaminase concentrations) and be referred for exercise and nutritional counseling. (See Hyperglycemia and Diabetes Mellitus under Cautions: Precautions and Contraindications.)

■ Geriatric Precautions

Although clinical experience in patients with schizophrenia generally has not revealed age-related differences in safety of olanzapine, lower initial dosages and slower titration during the initial dosing period may be advisable in some geriatric patients.

The first phase of the large-scale Clinical Antipsychotic Trials of Intervention Effectiveness—Alzheimer's Disease (CATIE-AD) trial was designed to evaluate the overall effectiveness of atypical antipsychotic agents in the treatment of psychosis, aggression, and agitation associated with Alzheimer's disease. Patients in this multicenter, double-blind, placebo-controlled trial were randomized to receive either olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks; the principal outcomes were the time from initial treatment until discontinuance of treatment for any reason and the number of patients with at least minimum improvement on the Clinical Global Impression of Change (CGIC) Scale at 12 weeks. No statistically significant differences were found among the 4 groups with regard to the time until discontinuation of treatment for any reason; patients remained on olanzapine, quetiapine, risperidone, and placebo for median times of approximately 8, 5, 7, and 8 weeks, respectively. In addition, no significant differences in CGIC Scale improvements were noted. However, patients receiving atypical antipsychotic therapy reportedly experienced more frequent adverse effects (e.g., drowsiness, weight gain, adverse extrapyramidal effects, confusion, and psychotic symptoms) compared with those receiving placebo. The authors stated that these results indicate that the overall therapeutic benefit of atypical antipsychotics in patients with Alzheimer's disease may be offset by the potential risk of adverse effects.

Studies in patients with dementia-related psychosis have suggested that there may be a different tolerability profile in patients 65 years of age or older with this condition compared with younger patients with schizophrenia. Geriatric patients with dementia-related psychosis receiving atypical antipsychotics including olanzapine appear to be at an increased risk of death compared with that among patients receiving placebo. Analyses of 17 placebo-controlled trials (average duration of 10 weeks) revealed an approximate 1.6- to 1.7-fold increase in mortality among geriatric patients receiving atypical antipsychotic drugs (i.e., olanzapine, aripiprazole, quetiapine, risperidone) compared with that in patients receiving placebo. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5% compared with a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature.

In placebo-controlled trials with olanzapine in geriatric individuals with dementia-related psychosis, an increased incidence of death also was observed; the incidence of death in olanzapine-treated patients was significantly higher than in patients receiving placebo (3.5% and 1.5%, respectively). In addition, a significantly higher incidence of adverse cerebrovascular effects (e.g., stroke, transient ischemic attack), including fatalities, was observed in patients receiving olanzapine compared with those receiving placebo in these trials. In 5 placebo-controlled studies of olanzapine in geriatric individuals with dementia-related psychosis, certain treatment-emergent adverse effects, including falls, somnolence, peripheral edema, abnormal gait, urinary incontinence, lethargy, increased weight, asthenia, pyrexia, pneumonia, dry mouth, and visual hallucinations, occurred in at least 2% of the patients and the incidence was significantly

higher than in patients receiving placebo. Discontinuance of therapy because of adverse effects occurred in a significantly higher number of olanzapine-treated patients than in those receiving placebo (13% and 7%, respectively) in these studies.

The manufacturer states that olanzapine is *not* approved for the treatment of patients with dementia-related psychosis. Some clinicians recommend that the potential risks, therapeutic benefits, and individual needs of patients be carefully considered prior to prescribing olanzapine and other atypical antipsychotic agents for the management of behavioral problems associated with Alzheimer's disease. If a clinician decides to treat geriatric patients with dementia-related psychosis with olanzapine, the manufacturer recommends that caution be exercised. For additional information on the use of antipsychotic agents in the management of dementia-related psychosis, see Geriatric Considerations under Uses: Psychotic Disorders, in the Phenothiazines General Statement 28:16.08.24.

■ Mutagenicity and Carcinogenicity

Olanzapine did not exhibit mutagenic potential in the Ames reverse mutation test, in vivo micronucleus mutation test in mice, the chromosomal aberration test in Chinese hamster ovary cells, unscheduled DNA synthesis test in rat hepatocytes, induction of forward mutation test in mouse lymphoma cells, or in vivo sister chromatid exchange test in bone marrow of Chinese hamsters.

In oral carcinogenicity studies conducted in mice, olanzapine was administered in 2 studies of 78-weeks' duration at dosages of 3, 10, and 30 mg/kg (later reduced to 20 mg/kg) initially then reduced to 20 mg/kg daily (equivalent to 0.8–5 times the maximum recommended human daily oral dosage on a mg/m^2 basis) and 0.25, 2, and 8 mg/kg daily (equivalent to 0.06–2 times the maximum recommended human daily oral dosage on a mg/m^2 basis). In oral carcinogenicity studies conducted in rats, olanzapine was administered for 2 years at dosages of 0.25, 1, 2.5, and 4 mg/kg daily in males (equivalent to 0.13–2 times the maximum recommended human daily oral dosage on a mg/m^2 basis) and 0.25, 1, 4, and 8 mg/kg daily in females (equivalent to 0.13–4 times the maximum recommended human daily oral dosage on a mg/m^2 basis). A is increased incidence of liver hemangiomas and hemangiosarcomas was observed in one mouse study in female mice receiving 8 mg/kg of the drug daily (equivalent to 2 times the maximum recommended human daily oral dosage on a mg/m^2 basis). The incidence of these tumors was not increased in another study in female mice receiving 10 or 30 mg/kg (later reduced to 20 mg/kg) of olanzapine daily (equivalent to 2–5 times the maximum recommended human daily oral dosage on a mg/m^2 basis); in this study, there was a high incidence of early mortalities in males in the 30 mg/kg (later reduced to 20 mg/kg) daily group. The incidence of mammary gland adenomas and adenocarcinomas was increased in female mice receiving 2 mg/kg or more of olanzapine daily and in female rats receiving 4 mg/kg or more of the drug daily (equivalent to 0.5 and 2 times the maximum recommended human daily oral dosage on a mg/m^2 basis, respectively).

Antipsychotic agents have been shown to chronically elevate prolactin concentrations in rodents. Serum prolactin concentrations were not measured during the olanzapine carcinogenicity studies; however, measurements during subchronic toxicity studies demonstrated that olanzapine administration produced up to a fourfold increase in serum prolactin concentrations in rats receiving the same dosages used in the carcinogenicity study. In addition, an increase in mammary gland neoplasms has been observed in rodents following chronic administration of other antipsychotic agents and generally is considered to be prolactin-mediated. However, the clinical importance in humans of this finding of prolactin-mediated endocrine tumors in rodents is unknown.

■ Pregnancy, Fertility, and Lactation

Pregnancy

Limited experience to date with olanzapine administration during pregnancy has been encouraging and has not revealed evidence of any obvious teratogenic risks; however, additional cases of olanzapine exposure during pregnancy need to be evaluated to more fully determine the relative safety of olanzapine and other antipsychotic agents when administered during pregnancy. The manufacturer states that there have been 7 pregnancies reported during clinical trials with olanzapine, including 2 resulting in normal births, one resulting in neonatal death due to a cardiovascular defect, 3 therapeutic abortions, and one spontaneous abortion. In a separate compilation of pregnancy exposures to olanzapine reported to the manufacturer during clinical trials and from spontaneous reports worldwide, outcomes were available from 23 prospectively-collected olanzapine-exposed pregnancies. Spontaneous abortion occurred in 13% of these pregnancies, stillbirth in 5%, major malformations in 0%, and prematurity in 5%; these rates were all within the range of normal historical control rates. In 11 retrospectively collected, olanzapine-exposed pregnancies, there was one case of dysplastic kidney, one case of Down's syndrome, and one case of heart murmur and sudden infant death syndrome at 2 months of age. In another study, the majority of women with schizophrenia receiving atypical antipsychotic agents were found to be overweight and to have reduced folate intake and low serum folate concentrations, which may increase the potential risk of neural tube defects. In a prospective, comparative trial assessing pregnancy outcome in women receiving atypical antipsychotic agents (olanzapine, clozapine, risperidone, and quetiapine) during pregnancy, atypical antipsychotics did not appear to be associated with an increased risk of major congenital malformations. In addition, several case reports have described healthy infants born to women without complications despite prenatal exposure to olanzapine.

The manufacturer and some clinicians state that there are no adequate and well-controlled studies to date using olanzapine in pregnant women, and the drug should be used during pregnancy only when the potential benefits justify the potential risks to the fetus. Women should be advised to notify their clinician if they become pregnant or plan to become pregnant during therapy with the drug.

Parturition in rats was not affected by olanzapine. The effect of olanzapine on labor and delivery is unknown.

In oral reproduction studies in rats receiving dosages of up to 18 mg/kg daily and in rabbits at dosages of up to 30 mg/kg daily (equivalent to 9 and 30 times the maximum recommended human daily oral dosage on a mg/m^2 basis, respectively), no evidence of teratogenicity was observed. In an oral rat teratology study, early resorptions and increased numbers of nonviable fetuses were observed at a dosage of 18 mg/kg daily (9 times the maximum recommended human daily oral dosage on a mg/m^2 basis), and gestation was prolonged at a dosage of 10 mg/kg daily (equivalent to 5 times the maximum recommended human daily oral dosage on a mg/m^2 basis). In an oral rabbit teratology study, fetal toxicity, which was manifested as increased resorptions and decreased fetal weight, occurred at a maternally toxic dosage of 30 mg/kg daily (equivalent to 30 times the maximum recommended human daily oral dosage on a mg/m^2 basis).

Fertility

In an oral fertility and reproductive performance study in rats, male mating performance, but not fertility, was impaired at an olanzapine dosage of 22.4 mg/kg daily, and female fertility was decreased at a dosage of 3 mg/kg daily (equivalent to 11 and 1.5 times the maximum recommended human daily oral dosage on a mg/m^2 basis, respectively). Discontinuance of olanzapine administration reversed the effects on male mating performance. In a female rat fertility study, the precoital period was increased, and the mating index reduced at a dosage of 5 mg/kg daily (equivalent to 2.5 times the maximum recommended human daily oral dosage on a mg/m^2 basis). Diestrus was prolonged and estrus was delayed at a dosage of 1.1 mg/kg daily (equivalent to 0.6 times the maximum recommended human daily oral dosage on a mg/m^2 basis).

Lactation

Olanzapine is distributed into milk. The mean dosage received by an infant at steady state is estimated to be about 1.8% of the maternal dosage. The manufacturer recommends that women receiving olanzapine not breast-feed.

Drug Interactions

■ Drugs Affecting Hepatic Microsomal Enzymes

Olanzapine is a substrate for cytochrome P-450 (CYP) isoenzyme 1A2 and concomitant administration of drugs that induce CYP1A2 or glucuronyl transferase enzymes (e.g., carbamazepine, omeprazole, rifampin) may cause an increase in olanzapine clearance. Inhibitors of CYP1A2 (e.g., fluvoxamine) could potentially inhibit olanzapine clearance. Although olanzapine is metabolized by multiple enzyme systems, induction or inhibition of a single enzyme may appreciably alter olanzapine clearance. Therefore, an increase or decrease in olanzapine dosage may be necessary during concomitant administration of olanzapine with specific drugs that induce or inhibit olanzapine metabolism, respectively.

Carbamazepine

Carbamazepine therapy (200 mg twice daily for 2 weeks) causes an approximately 50% increase in the clearance of a single, 10-mg dose of olanzapine. The manufacturer of olanzapine states that higher dosages of carbamazepine may cause an even greater increase in olanzapine clearance. Increased clearance of olanzapine probably is caused by carbamazepine-induced induction of CYP1A2 activity.

Selective Serotonin-reuptake Inhibitors

Concomitant administration of fluoxetine (60 mg as a single dose or 60 mg daily for 8 days) with a single 5-mg dose of oral olanzapine caused a small increase in peak plasma olanzapine concentrations (averaging 16%) and a small decrease (averaging 16%) in olanzapine clearance; the elimination half-life was not substantially affected. Fluoxetine is an inhibitor of CYP2D6, and thereby may affect a minor metabolic pathway for olanzapine. Although the changes in pharmacokinetics are statistically significant when olanzapine and fluoxetine are given concurrently, the changes are unlikely to be clinically important in comparison to the overall variability observed between individuals; therefore, routine dosage adjustment is not recommended.

Fluvoxamine, a CYP1A2 inhibitor, has been shown to decrease the clearance of olanzapine, which is metabolized by CYP1A2; there is some evidence that fluvoxamine-induced CYP1A2 inhibition is dose dependent. In one pharmacokinetic study, peak plasma olanzapine concentrations increased by an average of 54 and 77% and area under the plasma concentration-time curve (AUC) increased by an average of 52 and 108% in female nonsmokers and male smokers, respectively, when fluvoxamine and olanzapine were administered concomitantly. Symptoms of olanzapine toxicity also have been reported in at least one patient during combined therapy. The manufacturer and some clinicians state that a lower olanzapine dosage should therefore be considered in patients receiving concomitant treatment with fluvoxamine. Preliminary data indicate that concurrent fluvoxamine administration may potentially be used to therapeutic advantage by reducing the daily dosage of olanzapine and thereby the cost of therapy; further controlled studies are needed to more fully evaluate this approach. Although

combined therapy with olanzapine and fluvoxamine generally has been well tolerated and may be associated with clinical benefit, some clinicians recommend that caution be exercised and monitoring of plasma olanzapine concentrations be considered in patients receiving these drugs concurrently.

Preliminary results from a therapeutic drug monitoring service suggest that concurrent administration of sertraline and olanzapine does not substantially affect the pharmacokinetics of olanzapine.

Warfarin

Concomitant administration of a single 20-mg dose of warfarin (which has a potential CYP2C9 interaction) and a single oral 10-mg dose of olanzapine did not substantially alter the pharmacokinetics of olanzapine.

■ Drugs Metabolized by Hepatic Microsomal Enzymes

In vitro studies utilizing human liver microsomes suggest that olanzapine has little potential to inhibit metabolism of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A substrates. Therefore, clinically important drug interactions between olanzapine and drugs metabolized by these isoenzymes are considered unlikely.

■ Levodopa and Dopamine Agonists

Olanzapine may antagonize the effects of levodopa and dopamine agonists.

■ Lamotrigine

In a multiple-dose study in healthy individuals, the pharmacokinetics of olanzapine and lamotrigine were not substantially affected when the drugs were administered concomitantly. In another multiple-dose study conducted in healthy volunteers, olanzapine did not substantially alter lamotrigine pharmacokinetics when the drugs were administered concurrently. However, the time to reach maximal plasma concentrations of lamotrigine was substantially prolonged in this study, possibly because of olanzapine's anticholinergic activity. The tolerability of this combination was found to be similar to that of olanzapine alone, with mild sedative effects reported in some patients receiving the drugs concurrently. Although routine dosage adjustment does not appear to be necessary when olanzapine and lamotrigine are given concurrently, adjustment in lamotrigine dosage may be necessary in some patients for therapeutic reasons when olanzapine therapy is initiated or discontinued. In addition, careful monitoring of patients receiving high dosages of olanzapine and lamotrigine has been recommended by some clinicians.

■ Other CNS-Active Agents and Alcohol

Because of the prominent CNS actions of olanzapine, the manufacturer states that caution should be exercised when olanzapine is administered concomitantly with other centrally acting drugs and alcohol. The manufacturer also states that concomitant use of olanzapine with CNS agents that are associated with hypotension (e.g., diazepam) may potentiate the orthostatic hypotension associated with olanzapine.

Benzodiazepines

Because of the prominent CNS actions of olanzapine, the manufacturer states that caution should be exercised when olanzapine is administered concomitantly with benzodiazepines. The manufacturer also states that concomitant use of olanzapine and diazepam or other benzodiazepines that are associated with hypotension may potentiate the orthostatic hypotension associated with olanzapine. However, administration of multiple doses of olanzapine did not substantially alter the pharmacokinetics of diazepam or its active metabolite *N*-desmethyldiazepam.

The pharmacokinetics of olanzapine, unconjugated lorazepam, and total lorazepam were not substantially affected when IM lorazepam (2 mg) was administered 1 hour after IM olanzapine (5 mg); however, increased somnolence was observed with this combination. Hypotension also has been reported when IM olanzapine and IM lorazepam have been administered concurrently. The manufacturer of olanzapine states that concurrent use of IM olanzapine in conjunction with parenteral benzodiazepines has not been adequately studied to date and therefore is not recommended. If therapy with IM olanzapine in conjunction with a parenteral benzodiazepine is considered, the clinical status of the patient should be carefully evaluated for excessive sedation and cardiorespiratory depression.

Tricyclic Antidepressants

Administration of single doses of olanzapine did not substantially affect the pharmacokinetics of imipramine or its active metabolite desipramine.

Lithium

Multiple doses of olanzapine (10 mg for 8 days) did not affect the pharmacokinetics of a single dose of lithium. Although combined olanzapine and lithium therapy generally has been well tolerated in controlled clinical studies, rare cases of apparent lithium toxicity and adverse extrapyramidal effects, including oculogyric crisis, have been reported in patients receiving these drugs concurrently; the mechanism(s) for this potential drug interaction remains to be established. The manufacturer of olanzapine states that lithium dosage adjustment is not necessary during concurrent olanzapine administration.

Valproic Acid

In vitro studies using human liver microsomes indicated that olanzapine has little potential to inhibit the major metabolic pathway (glucuronidation) of valproic acid. In addition, valproic acid has little potential effect on the metabolism of olanzapine in vitro. In a pharmacokinetic study, olanzapine administration (10 mg daily for 2 weeks) did not affect the steady-state plasma concentrations of valproic acid. However, substantially decreased plasma olanzapine concentrations have been reported in several patients following initiation of valproate in patients already receiving olanzapine; it was suggested that induction of the hepatic enzymes responsible for olanzapine's metabolism by valproate may have been responsible for these findings. Further studies are needed to determine whether a pharmacokinetic interaction exists between olanzapine and valproic acid since these drugs are frequently used in combination in clinical practice. The manufacturer of olanzapine currently states that routine dosage adjustment of valproic acid is not necessary during concurrent olanzapine administration.

Alcohol

In a pharmacokinetic study, concomitant administration of a single dose of alcohol did not substantially alter the steady-state pharmacokinetics of olanzapine (given in dosages of up to 10 mg daily). However, the manufacturer states that concomitant use of olanzapine with alcohol could potentiate the orthostatic hypotension associated with olanzapine and that alcohol should be avoided during olanzapine therapy.

■ Hypotensive Agents

Olanzapine therapy potentially may enhance the effects of certain hypotensive agents during concurrent use. In addition, the administration of dopamine, epinephrine, and/or other sympathomimetic agents with β-agonist activity should be avoided in the treatment of olanzapine-induced hypotension, since such stimulation may worsen hypotension in the presence of olanzapine-induced α-blockade. (See Acute Toxicity: Treatment.)

■ Antacids or Cimetidine

In pharmacokinetic studies, single doses of cimetidine (800 mg) or aluminum- and magnesium-containing antacids (30 mL) did not substantially affect the oral bioavailability of a single, 7.5-mg dose of olanzapine.

■ Activated Charcoal

Concurrent administration of activated charcoal (1 g) reduced peak plasma concentrations and the AUC of a single, 7.5-mg dose of olanzapine by approximately 60%. Since peak plasma concentrations are not usually obtained until about 6 hours after oral administration, activated charcoal may be useful in the management of olanzapine intoxication. (See Acute Toxicity: Treatment.)

■ Smoking

The manufacturer states that the clearance of olanzapine in smokers is approximately 40% higher than in nonsmokers. Therefore, plasma olanzapine concentrations generally are lower in smokers than in nonsmokers receiving the drug. Adverse extrapyramidal effects have been reported in one olanzapine-treated patient after a reduction in cigarette smoking, while worsened delusions, hostility, and aggressive behavior have been reported in another olanzapine-treated patient following a marked increase in smoking (i.e., an increase from 12 up to 80 cigarettes per day). Although the precise mechanism(s) for this interaction has not been clearly established, it has been suggested that induction of the CYP isoenzymes, particularly 1A2, by smoke constituents may be responsible at least in part for the reduced plasma olanzapine concentrations observed in smokers compared with nonsmokers.

Although the manufacturer states that routine dosage adjustment is not recommended in patients who smoke while receiving olanzapine, some clinicians recommend that patients treated with olanzapine should be monitored with regard to their smoking consumption and that dosage adjustment be considered in patients who have reduced or increased their smoking and/or who are not responding adequately or who are experiencing dose-related adverse reactions to the drug. In addition, monitoring of plasma olanzapine concentrations may be helpful in patients who smoke and have other factors associated with substantial alterations in metabolism of olanzapine (e.g., geriatric patients, women, concurrent fluvoxamine administration).

■ Other Drugs

Multiple doses of olanzapine did not substantially alter the pharmacokinetics of theophylline or its metabolites.

Multiple doses of olanzapine did not substantially affect the pharmacokinetics of biperiden.

Acute Toxicity

■ Pathogenesis

The acute lethal dose of olanzapine in humans remains to be established. However, the toxic and lethal doses of olanzapine and other atypical antipsychotic agents appear to be highly variable and depend on concurrent administration of other drugs or toxic substances, patient age and habituation, and the time from exposure until treatment is initiated; pediatric and/or nonhabituated patients appear to be more sensitive to the toxic effects of these drugs. During premarketing clinical trials involving more than 3100 patients and/or healthy individuals, accidental or intentional acute overdosage of olanzapine was identified in 67 patients. In one adult patient who took 300 mg of the drug, the only symptoms reported were drowsiness and slurred speech. In a limited number of patients who were evaluated in hospitals following olanzapine overdosage, no adverse changes in laboratory values or ECG findings were observed. In addition, vital signs usually were within normal limits following these overdosages.

Fatalities have been reported following overdosage of olanzapine alone. In one of these deaths, the amount of olanzapine acutely ingested was possibly as low as 450 mg, while it was estimated to be up to 600 mg in another case; however, in 2 other cases, patients reportedly survived acute ingestions of 1.1 and 1.5 g. The cases of olanzapine intoxication reported to date suggest that overdosages of less than 200 mg of the drug alone in adults generally result in moderate and self-limiting toxicity; however, olanzapine overdosages exceeding 200 mg and/or when taken in combination with

other psychoactive agents or alcohol often were associated with more severe toxicity, including profound CNS depression, mental status changes, and miotic pupils.

■ Manifestations

In postmarketing reports of overdosages with olanzapine alone, manifestations have been reported in the majority of cases. Following acute overdosage of olanzapine or other atypical antipsychotic agents, toxic effects usually begin within 1–2 hours and maximal toxic effects usually are seen 4–6 hours following acute ingestion. In general, overdosage of olanzapine may be expected to produce effects that are extensions of its pharmacologic and adverse effects. The most commonly reported manifestations of olanzapine overdosage and those that have occurred in 10% or more of symptomatic patients following postmarketing overdosage reports of olanzapine alone are agitation and/or aggressiveness, dysarthria, tachycardia, anticholinergic syndrome, miosis, various extrapyramidal symptoms, jerking and myoclonus, hypersalivation, and reduced level of consciousness ranging in severity from sedation to coma. Less commonly reported but potentially medically serious events included aspiration, cardiopulmonary arrest, cardiac arrhythmias (e.g., supraventricular tachycardia), delirium, possible neuroleptic malignant syndrome, respiratory depression and/or arrest, convulsions, hypertension, and hypotension (including orthostatic hypotension); one patient experienced sinus pause with spontaneous resumption of normal rhythm.

In some cases of acute olanzapine intoxication, rapid fluctuation in mental status (i.e., between sedation and agitation or agitation despite sedation) has been reported. In addition, olanzapine overdosage may resemble opiate overdosage because CNS depression and miosis sometimes are observed. Increased creatine kinase (CK, creatine phosphokinase, CPK) concentrations also have occurred following acute olanzapine overdosage. Cardiac arrhythmias, persistent choreoathetosis, nonconvulsive status epilepticus, hypersalivation, and coma occurred in an adult following an intentional ingestion estimated to be 750 mg of olanzapine; both coma and choreoathetosis persisted until the patient's death 8 weeks later.

The toxic effects of olanzapine and other atypical antipsychotic agents in children appear to be similar to those seen in adults. In young children, marked CNS depression and anticholinergic delirium have occurred following ingestion of 7.5–15 mg of olanzapine (equivalent to 0.5–1 mg/kg). In an adolescent who ingested 275 mg of olanzapine and had an extremely high serum olanzapine concentration (1503 ng/mL), somnolence, agitation, and extrapyramidal symptoms developed initially, but the patient recovered without complications. A 400-mg olanzapine overdosage in another adolescent reportedly produced severe respiratory depression requiring intubation and mechanical ventilation; the patient recovered after 3 days. In addition, polyuria and other signs suggesting possible diabetes insipidus, including hypo-osmolar urine, normo-osmolar plasma, and increased serum sodium concentrations, have been reported in one adolescent following an overdosage of olanzapine and prazepam (a benzodiazepine; not commercially available in the US).

■ Treatment

Management of olanzapine overdosage generally involves symptomatic and supportive care, including continuous cardiovascular and respiratory monitoring and ensuring IV access. Cardiovascular monitoring should be initiated immediately and should include continuous ECG monitoring to detect possible arrhythmias. There is no specific antidote for olanzapine intoxication. In managing olanzapine overdosage, the clinician should consider the possibility of multiple drug intoxication.

The manufacturer and many clinicians recommend establishing and maintaining an airway and ensuring adequate ventilation and oxygenation, which may include intubation. Gastric lavage (following intubation, if the patient is unconscious) and/or activated charcoal, which may be used with sorbitol, should be considered. (See Drug Interactions: Activated Charcoal.) The possibility that obtundation, seizures, or dystonic reaction of the head and neck following olanzapine overdosage may create a risk of aspiration with induction of emesis should be considered.

Hypotension and circulatory collapse, if present, should be treated with appropriate measures, such as Trendelenburg's position, IV fluids, and/or sympathomimetic agents (e.g., norepinephrine, phenylephrine). However, dopamine, epinephrine, and/or other sympathomimetic agents with β-adrenergic agonist activity should be avoided, since such stimulation may worsen hypotension in the presence of olanzapine-induced α-adrenergic blockade. Tachycardia associated with olanzapine intoxication usually does not require specific therapy. Atrial and ventricular arrhythmias and conduction disturbances should be treated with appropriate measures; sodium bicarbonate may be helpful if QRS interval prolongation is present. Seizures following olanzapine overdosage may be treated initially with a benzodiazepine followed by barbiturates, if necessary. Acute extrapyramidal reactions should be treated with anticholinergic agents (e.g., diphenhydramine, benztropine).

Physostigmine salicylate or benzodiazepine therapy may be useful in the management of severe agitation and delirium in patients with severe anticholinergic toxicity and a narrow QRS complex on their ECG. Physostigmine has been used successfully in the treatment of anticholinergic toxicity associated with overdosages of olanzapine or clozapine, another atypical antipsychotic agent. However, experience with physostigmine in the management of atypical antipsychotic overdosage is limited, and some clinicians recommend that the drug be used only by experienced clinicians and in cases in which the potential therapeutic benefit outweighs the potential risks.

Resolution of toxic effects following atypical antipsychotic intoxication generally occurs within 12–48 hours following acute overdosage, although it has taken up to 6 days. Patients should remain under close medical supervision and monitoring until fully recovered.

Hemodialysis has not been shown to be useful for enhancing elimination of olanzapine in acute overdosage. Clinical experience with other enhanced elimination techniques, including multiple-dose activated charcoal, hemoperfusion, forced diuresis, and urinary alkalinization, is lacking; however, these treatments also are unlikely to be beneficial following olanzapine overdosage because of the drug's large volume of distribution and extensive protein binding.

Chronic Toxicity

In animal studies prospectively designed to assess abuse and dependence potential, olanzapine was shown to produce acute CNS depressive effects but little or no potential for abuse or physical dependence in rats administered oral doses up to 15 times the maximum recommended human daily oral dosage (20 mg) and rhesus monkeys administered oral doses up to 8 times the maximum recommended human daily oral dosage on a mg/m^2 basis. Olanzapine has not been systematically evaluated in humans to date for its potential for abuse, tolerance, or physical dependence. While clinical trials did not reveal any tendency for drug-seeking behavior, these observations were not systematic, and it is not possible to predict on the basis of this limited experience the extent to which a CNS-active drug will be misused, diverted, and/or abused once marketed. Consequently, patients should be evaluated carefully for a history of drug abuse, and such patients should be observed closely for signs of misuse or abuse of olanzapine (e.g., development of tolerance, increases in dose, drug-seeking behavior).

Pharmacology

Olanzapine is a thienobenzodiazepine-derivative antipsychotic agent. The drug shares some of the pharmacologic actions of other antipsychotic agents and has been described as an atypical or second-generation antipsychotic agent. Like other atypical or second-generation antipsychotics (e.g., aripiprazole, clozapine, quetiapine, risperidone, ziprasidone), olanzapine produces minimal adverse extrapyramidal effects, is unlikely to cause tardive dyskinesia with chronic treatment, and is effective in the treatment of positive, negative, and depressive manifestations of schizophrenia.

■ Nervous System Effects

The exact mechanism of antipsychotic action of olanzapine and other atypical antipsychotic agents has not been fully elucidated but appears to be more complex than that of conventional, first-generation antipsychotic agents and may involve central antagonism at serotonin type 2 (5-hydroxytryptamine [$5\text{-}HT_{2A}$, $5\text{-}HT_{2C}$]), type 3 ($5\text{-}HT_3$), and type 6 ($5\text{-}HT_6$) and dopamine receptors.

The exact mechanism(s) of antimanic action of olanzapine is not fully known. However, it has been suggested that the ability of olanzapine to block and downregulate $5\text{-}HT_{2A}$ receptors may play a role in its antimanic activity. In addition, olanzapine's mood-stabilizing action may be caused at least in part by antagonism of D_2 receptors. Further studies are needed to more clearly elucidate the potential mechanism(s) of the drug's antimanic activity.

Although not clearly established, the efficacy of IM olanzapine in the treatment of acute agitation appears to be due at least in part to its distinct calming effects rather than solely to nonspecific sedation.

Antidopaminergic Effects

The therapeutic effects of antipsychotic drugs are thought to be mediated by dopaminergic blockade in the mesolimbic and mesocortical areas of the CNS, while antidopaminergic effects in the neostriatum appear to be associated with extrapyramidal effects. The relatively low incidence of extrapyramidal effects associated with olanzapine therapy suggests that the drug is more active in the mesolimbic than the neostriatal dopaminergic system.

Several (at least 5) different types or subtypes of dopamine receptors have been identified in animals or humans. The relative densities of these receptors and their distribution and function vary for different neuroanatomical regions, and olanzapine's effects may be secondary to regionally specific receptor interactions and/or other effects on dopaminergic neurons. Current evidence suggests that the clinical potency and antipsychotic efficacy of both typical and atypical antipsychotic drugs generally are related at least in part to their affinity for and blockade of central dopamine D_2 receptors. Some studies suggest that clinically effective dosages of most antipsychotic agents result in occupation of between 60 and 80% of central dopamine D_2 receptors. However, antagonism at D_2 receptors does not appear to account fully for the antipsychotic effects of olanzapine. In vivo and in vitro studies have demonstrated that olanzapine is a comparatively weak antagonist at D_2 receptors. Although their role in eliciting the pharmacologic effects of antipsychotic agents remains to be fully elucidated, dopamine D_3, D_4, and D_5 receptors also have been identified. Olanzapine may have a higher affinity for D_4 receptors than for D_2 or D_3 receptors. K_i values of olanzapine for dopamine $D_{1\text{-}4}$ receptors range from 11–31 nM.

Atypical antipsychotic agents generally have demonstrated relatively loose binding to dopamine D_2 receptors. Compared with typical antipsychotic agents, atypical antipsychotics appear to have faster dissociation rates from and lower affinity for dopamine D_2 receptors, which may result in fewer adverse extrapyramidal effects and less risk of elevated prolactin concentrations; however, further studies are needed to confirm these initial findings.

Serotonergic Effects

It has been suggested that schizophrenia may involve a dysregulation of serotonin- and/or dopamine-mediated neurotransmission, and olanzapine may at least partially restore a normal balance of neurotransmitter function, possibly through serotonergic modulation of dopaminergic tone. Olanzapine blocks serotonin type 2 (5-hydroxytryptamine [5-HT_{2A} and 5-HT_{2C}; K_i of 4 and 11 nM, respectively]), type 3 (5-HT_3; K_i of 57 nM), and type 6 (5-HT_6; K_i of 5 nM) receptors.

Anticholinergic Effects

Olanzapine blocks muscarinic cholinergic receptors and has demonstrated moderate affinity for all 5 muscarinic receptor subtypes (K_i values for M_{1-5} were 73, 96, 132, 32, and 48 nM, respectively). Anticholinergic activity in antipsychotic agents may contribute to certain adverse anticholinergic events associated with these drugs but also may help reduce the risk of adverse extrapyramidal reactions.

Effects on Other Central Neurotransmitters

Antagonism at receptors other than dopamine and 5-HT_2 receptors may produce some of the therapeutic and adverse effects associated with olanzapine. Olanzapine exhibits α_1-adrenergic blocking activity (K_i of 19 nM), which may explain the occasional orthostatic hypotension associated with the drug. In addition, olanzapine blocks histamine H_1 receptors (K_i of 7 nM), which may explain the sedative effects associated with the drug; affinity for H_2 and H_3 receptors appears to be low.

Olanzapine demonstrated weak binding affinity (K_i exceeding 10 μM) for β-adrenergic, γ-aminobutyric acid (GABA), and benzodiazepine receptors; the drug also has little or no affinity for opiate receptors.

Neurophysiologic Effects

In vivo electrophysiologic studies demonstrate different sensitivities of various brain areas to antipsychotic-mediated postsynaptic receptor blockade. While conventional antipsychotics generally reduce spontaneous firing activity in both the mesolimbic (A10) and nigrostriatal regions (A9), chronic administration of atypical antipsychotics generally reduces the number of spontaneously active dopaminergic neurons in the mesolimbic region but not in the nigrostriatal region. Although not clearly established, it has been suggested that the ability to decrease A10 but not A9 neurons is associated clinically with a low potential to cause adverse extrapyramidal reactions and tardive dyskinesia. Olanzapine has demonstrated such mesolimbic selectivity in the in vivo studies conducted to date.

Cognitive Effects in Humans

Clinical experience suggests that second-generation antipsychotics, including olanzapine, improve cognition in patients with schizophrenia and that there may be differences between these drugs in their effects on neurocognitive functioning. In an initial clinical trial evaluating the short-term effects of atypical antipsychotic agents on cognitive function, olanzapine-treated schizophrenic patients demonstrated improved learning and memory, verbal fluency, and executive function. In a controlled clinical trial evaluating the neurocognitive effects of olanzapine, clozapine, risperidone, and haloperidol in patients with treatment-resistant schizophrenia or schizoaffective disorder, global neurocognitive function improved with olanzapine and risperidone treatment, and these improvements were found to be superior to those seen with haloperidol. Patients treated with olanzapine exhibited improvement in the general and attention domains but not more than that observed with the other antipsychotic agents. In another controlled trial, patients with schizophrenia receiving long-term (1 year) therapy with olanzapine demonstrated improved results on a general cognition index compared with those receiving haloperidol and risperidone. Neurocognition also improved in olanzapine- and risperidone-treated schizophrenic and schizoaffective patients receiving the drug for 1 year in another controlled study; improvements in executive function, learning and memory, processing speed, attention and vigilance, verbal working memory, and motor function were reported. The clinical relevance of these cognitive findings in the management of schizophrenia remains to be determined and requires further study.

EEG Effects

Olanzapine may cause EEG changes. In one study, olanzapine-induced EEG slowing to a lesser extent than clozapine in patients with schizophrenia and did not appear to substantially alter epileptiform activity in most of the patients studied; further studies are needed to determine whether olanzapine can affect the seizure threshold. Similarly, a comparative study found that epileptiform activity did not increase during olanzapine therapy; however, EEG slowing and other nonspecific EEG changes did occur more frequently in olanzapine-treated patients than in those receiving certain other antipsychotic agents. In another study that was retrospective in design, EEG changes occurred more frequently in patients receiving olanzapine or clozapine than in those receiving typical antipsychotic agents, quetiapine, or risperidone. In a study in patients with schizophrenia, olanzapine therapy was associated with increased rates of slow waves, sharp waves, and paroxysmal slow wave discharges on EEG recordings in the patients evaluated; however, spike- and sharp-slow-wave complexes that indicate seizure risk were not observed in this study.

Seizures have been reported rarely (0.9% in premarketing clinical trials) in olanzapine-treated patients but confounding factors were present in most of these cases. Further studies and postmarketing surveillance are needed to determine whether olanzapine can affect the seizure threshold and to evaluate the clinical relevance of the observed EEG findings in patients receiving the drug.

Effects on Sleep

The available evidence suggests that atypical antipsychotics, including olanzapine, clozapine, and risperidone, substantially increase total sleep time and stage 2 sleep; both olanzapine and risperidone also have been shown to enhance slow-wave sleep. Olanzapine's beneficial effects on sleep quality are thought to be mediated principally via type 2 serotonergic (5-HT_2) receptors.

In a controlled study, administration of single evening doses of olanzapine (5 or 10 mg orally) in healthy individuals significantly increased slow-wave sleep in a dose-related manner; sleep continuity measures and subjective sleep quality also increased significantly. Single 10-mg doses of the drug also suppressed rapid eye movement (REM) sleep and increased REM sleep latency in this study. In another study in healthy males and females, single 10-mg oral doses of olanzapine also were found to increase slow-wave sleep but preserved the normal structure of sleep; these effects were more prominent in females than in males.

During subchronic administration of olanzapine (15–20 mg) in patients with schizophrenia with predominantly negative symptoms in an uncontrolled study, parameters of sleep efficiency improved and delta sleep and REM sleep increased. Acute olanzapine administration (10 mg orally) in schizophrenic patients improved sleep continuity variables and total sleep time in another study; the principal changes observed in sleep architecture were a reduction in stage 1 sleep, a significant enhancement in stage 2 and delta sleep, and an increase in REM density. In a study comparing the effect of aging on the improvement of subjective sleep quality in patients with schizophrenia receiving atypical antipsychotic agents, including olanzapine, the proportion of patients experiencing improved subjective sleep quality was significantly higher in geriatric patients than in middle-aged patients.

■ Neuroendocrine Effects

In contrast to conventional (first-generation) antipsychotic agents and similar to many other atypical antipsychotic agents, olanzapine therapy in usual dosages generally produces relatively modest and transient elevations in serum prolactin concentrations in humans. This prolactin-elevating effect appears to be mediated by dopamine blockade. The effect of atypical antipsychotic agents on prolactin generally appears to be transient, possibly because the drugs appear to dissociate from dopamine receptors more rapidly than conventional antipsychotic agents.

Pharmacokinetics

■ Absorption

Olanzapine is well absorbed following oral administration. However, because of extensive first-pass metabolism, only about 60% of an orally administered dose reaches systemic circulation unchanged. Olanzapine exhibits linear and dose-proportional pharmacokinetics when given orally within the clinical dosage range. Food does not appear to affect the rate or the extent of GI absorption of the drug. The relative oral bioavailability of olanzapine has been shown to be equivalent following administration of the conventional and orally disintegrating tablets of the drug. When olanzapine and fluoxetine hydrochloride are administered as the fixed-combination oral capsules, the pharmacokinetic characteristics of the drugs are expected to resemble those of the individual components; olanzapine pharmacokinetics are slightly altered when administered with fluoxetine, but the effects were not deemed to be clinically important. (See Selective Serotonin-reuptake Inhibitors under Drug Interactions: Drugs Affecting Hepatic Microsomal Enzymes.)

Following oral administration, peak plasma olanzapine concentrations occur in approximately 6 hours (range: 5–8 hours). Steady-state plasma concentrations of olanzapine are achieved after approximately 7 days of continuous dosing and are approximately twice those observed following single-dose administration.

Following IM administration, olanzapine is rapidly absorbed with peak plasma olanzapine concentrations occurring within 15–45 minutes. In one pharmacokinetic study performed in healthy individuals, a single 5-mg IM dose of olanzapine produced peak plasma concentrations that were an average of fivefold higher than the peak plasma concentrations produced following a single 5-mg oral dose of the drug. In this study, the areas under the plasma concentration-time curve (AUCs) achieved following IM and oral administration of the same dose of the drug were similar. Olanzapine exhibits linear pharmacokinetics when given IM within the clinical dosage range. Preliminary evidence suggests that the onset of antipsychotic action following IM administration of the drug is evident within 24 hours but may be observed as early as 2 hours after IM administration.

Plasma olanzapine concentrations may vary between individuals according to gender, smoking status, and age. There is limited evidence that gender may affect plasma olanzapine concentrations, with concentrations being somewhat higher, perhaps by as much as 30–40%, in females compared with males. Plasma concentrations of olanzapine also may be increased in geriatric individuals compared with younger individuals, possibly as a result of age-related decreases in hepatic elimination of the drug. Data from one limited study in children and adolescents 10–18 years of age with schizophrenia found that plasma olanzapine concentrations among adolescents were within the range reported in nonsmoking adult patients with schizophrenia. In vivo studies have shown that exposures to olanzapine are similar among Japanese, Chinese, and Caucasian individuals, particularly after normalization for body weight differences.

The therapeutic range for plasma olanzapine concentrations and the relationship of plasma concentration to clinical response and toxicity have not been clearly established; however, acutely ill schizophrenic patients with 24-hour post-dose plasma olanzapine concentrations of 9.3 ng/mL or higher in one study or 12-hour post-dose concentrations

of 23.2 ng/mL or higher in another study appeared to have a better clinical response to therapy than patients with lower plasma concentrations.

■ Distribution

Distribution of olanzapine, a highly lipophilic drug, into human body tissues is extensive.

The manufacturer states that the volume of distribution of olanzapine has been reported to be approximately 1000 L. In pharmacokinetic studies in healthy individuals, the apparent volume of distribution of the drug averaged 1150 L and ranged from 660 to 1790 L for the fifth to 95th percentiles. Olanzapine is 93% bound to plasma proteins over the concentration range of 7–1100 ng/mL, principally to albumin and α_1-acid glycoprotein.

Olanzapine and its glucuronide metabolite have been shown to cross the placenta in humans. Placental transfer of olanzapine also has been shown to occur in rat pups.

Olanzapine is distributed into milk. The manufacturer states that in a study in lactating, healthy women, the average infant dose of olanzapine at steady-state was estimated to be approximately 1.8% of the maternal olanzapine dose. In a separate study that evaluated the extent of infant exposure to olanzapine in 7 breastfeeding women who had been receiving 5–20 mg of olanzapine daily for periods ranging from 19–395 days, median and maximum relative infant doses of 1 and 1.2%, respectively, were observed. Olanzapine was not detected in the plasma of the breastfed infants, and adverse effects possibly related to olanzapine exposure were not reported in the infants in this study. In addition, peak milk concentrations were achieved a median of 5.2 hours later than the corresponding maximal maternal plasma concentrations. In a case report, a relative infant dose of approximately 4% was estimated in one woman after 4 and 10 days (estimated to be at steady state) of olanzapine therapy at a dosage of 20 mg daily based on measurements of drug concentration in serum and in expressed breast milk. (See Cautions: Pregnancy, Fertility, and Lactation.)

■ Elimination

Although the exact metabolic fate has not been clearly established, it appears that olanzapine is extensively metabolized. Following a single oral dose of radiolabeled olanzapine, 7% of the dose was recovered in urine as unchanged drug. Approximately 57 and 30% of the dose was recovered in the urine and feces, respectively. In plasma, olanzapine accounted for only 12% of the AUC for total radioactivity, suggesting substantial exposure to metabolites. After multiple doses of olanzapine, the principal circulating metabolites are the 10-*N*-glucoronide, which is present at steady state at 44% of the plasma concentration of the parent drug, and 4′-*N*-desmethyl olanzapine, which is present at steady state at 31% of the plasma concentration of olanzapine. Both of these metabolites lack pharmacologic activity at the concentrations observed.

Direct glucuronidation and cytochrome P-450 (CYP)-mediated oxidation are the principal pathways for olanzapine metabolism. In vitro studies suggest that the CYP isoenzymes 1A2 and 2D6 and the flavin-containing monooxygenase system are involved in the oxidation of olanzapine. However, CYP2D6-mediated oxidation appears to be a minor metabolic pathway for olanzapine in vivo since the clearance of the drug is not reduced in individuals deficient in this enzyme.

Following oral administration, olanzapine has an elimination half-life ranging from 21 to 54 hours for the fifth to 95th percentiles of individual values with a mean of 30 hours. Following IM administration, the half-life and metabolic profile of olanzapine were similar to those observed with oral administration. The apparent plasma clearance of olanzapine ranges from 12 to 47 L/hr (mean: 25 L/hour).

The clearance of olanzapine in smokers is approximately 40% higher than in nonsmokers. (See Drug Interactions: Smoking.)

The clearance of olanzapine in females may be reduced by approximately 30% compared with males.

In a single-dose pharmacokinetic study, the elimination half-life of olanzapine was 1.5 times longer in healthy geriatric individuals 65 years of age or older than in healthy younger adults. (See Dosage and Administration: Dosage and see also Cautions: Geriatric Precautions.)

In one pharmacokinetic study conducted in a limited number of children and adolescents 10–18 years of age with schizophrenia who were treated with oral olanzapine, the apparent plasma clearance at steady-state averaged 9.6 L/hr, which was approximately half of the clearance values reported in adult studies but similar to clearance values reported in nonsmoking male and female schizophrenic patients. The elimination half-life averaged 37.2 hours in this same study. (See Dosage and Administration: Dosage and see also Cautions: Pediatric Precautions.)

The combined effects of age, smoking, and gender could result in substantial pharmacokinetic differences in populations. The clearance in younger, smoking adult male patients may be 3 times higher than that in geriatric, nonsmoking females. Dosage adjustment may be necessary in patients who exhibit a combination of factors that may result in slower metabolism of olanzapine. (See Dosage and Administration: Dosage.)

Because olanzapine is extensively metabolized before excretion and only 7% of the drug is excreted unchanged, renal impairment alone is unlikely to substantially alter the pharmacokinetics of olanzapine. The pharmacokinetics of olanzapine were similar in patients with severe renal impairment and healthy individuals, suggesting that dosage adjustment based upon the degree of renal impairment is not necessary. The effect of renal impairment on the elimination of olanzapine's metabolites has not been evaluated to date.

Although the presence of hepatic impairment would be expected to reduce the clearance of olanzapine, a pharmacokinetic study evaluating the effect of impaired hepatic function in individuals with clinically important cirrhosis (Childs Pugh Classification A and B) revealed little effect on the pharmacokinetics of olanzapine.

Olanzapine is not appreciably removed by hemodialysis, probably due to its large volume of distribution and extensive protein binding. Clinical experience with other enhanced elimination techniques, including multiple-dose activated charcoal, hemoperfusion, forced diuresis, and urinary alkalinization, is lacking; however, these treatments are unlikely to be beneficial following olanzapine overdosage because of the drug's large volume of distribution and extensive protein binding.

Chemistry and Stability

■ Chemistry

Olanzapine is a thienobenzodiazepine-derivative antipsychotic agent. The drug is structurally similar to clozapine.

Olanzapine occurs as a yellow crystalline solid that is practically insoluble in water.

Olanzapine for injection contains lactose monohydrate and tartaric acid; hydrochloric acid and/or sodium hydroxide may have been added to adjust pH. When olanzapine for injection is reconstituted as directed, the resulting solution should appear clear and yellow.

■ Stability

Commercially available olanzapine conventional tablets, orally disintegrating tablets, and olanzapine for IM injection should be stored at a controlled room temperature of 20–25°C but may be exposed to temperatures ranging from 15–30°C. Olanzapine orally disintegrating tablets should be stored in their original sealed blister. The conventional and orally disintegrating tablets should be protected from light and moisture and olanzapine for injection should be protected from light and freezing.

Following reconstitution, olanzapine for injection may be stored at a controlled room temperature of 20–25°C for up to 1 hour if necessary, but immediate use is preferred. Lorazepam injection should not be used to reconstitute olanzapine for injection since this delays reconstitution time.

Olanzapine orally disintegrating tablets contain aspartame (e.g., NutraSweet®). (See Individuals with Phenylketonuria, under Cautions: Precautions and Contraindications.)

Olanzapine for IM injection should not be combined with diazepam injection in a syringe because precipitation occurs when these drugs are mixed. Olanzapine for injection should not be combined in a syringe with haloperidol injection because the resulting pH has been shown to degrade olanzapine over time. Specialized references should be consulted for additional specific compatibility information.

Preparations

Excipients in commercially available drug preparations may have clinically important effects in some individuals; consult specific product labeling for details.

ARIPIPRAZOLE

0.0 Overview

1) Class
- **a)** This drug is a member of the following class(es):
  Antipsychotic

2) Dosing Information
- **a)** Adult
  - **1)** oral solution may be substituted for the tablet dosages on a mg-per-mg basis for up to a 25 mg dose; patients oral solution (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008)
    - **a)** Bipolar disorder - Psychomotor agitation
      - **1)** initial, 9.75 mg IM (dose range 5.25 mg to 15 mg); cumulative doses up to a total of 30 mg/day may b dose required, wait at least 2 h after initial dose; for ongoing therapy, oral aripiprazole in a range of 10 m injection as soon as possible (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM
    - **b)** Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes
      - **1)** initial and target dose, 15 mg ORALLY once a day; may increase to MAX dose of 30 mg ORALLY on solution, orally disintegrating tablets, IM injection, 2008)
    - **c)** Bipolar I disorder, Monotherapy, manic or mixed episodes
      - **1)** initial and target dose, 15 mg ORALLY once a day; may increase up to MAX dose of 30 mg ORALLY solution, orally disintegrating tablets, IM injection, 2008)
    - **d)** Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants
      - **1)** initial, 2 mg to 5 mg ORALLY once daily; dose adjust in up to 5 mg/day increments at intervals of 1 w (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008)
    - **e)** Psychomotor agitation - Schizophrenia
      - **1)** initial, 9.75 mg IM (dose range 5.25 mg to 15 mg); cumulative doses up to a total of 30 mg/day may b dose required, wait at least 2 hr after initial dose; for ongoing therapy, oral aripiprazole in a range of 10 n injection as soon as possible (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM
    - **f)** Schizophrenia
      - **1)** initial, 10 to 15 mg ORALLY once daily (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrati
      - **2)** maintenance, MAX daily dosage is 30 mg/day ORALLY; increase dose only after 2 weeks at each do greater with doses higher than 10 to 15 mg/day (Prod Info ABILIFY(R) oral tablets, solution, orally disinte
- **b)** Pediatric
  - **1)** safety and efficacy not established in pediatric patients with major depressive disorder or agitation associated less than 13 years of age with schizophrenia, or patients less than age 10 years with bipolar I disorder (Prod Info disintegrating tablets, IM injection, 2008)
  - **2)** oral solution may be substituted for the tablet dosages on a mg-per-mg basis for up to a 25 mg dose; patients oral solution (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008)
    - **a)** Bipolar I disorder, Monotherapy, manic or mixed episodes
      - **1)** 10 yr and older, oral tablets, initial, 2 mg ORALLY once a day for 2 days, then 5 mg ORALLY once a ORALLY once a day; MAX dose 30 mg ORALLY once a day, titrated in 5 mg per day increments (Prod I disintegrating tablets, IM injection, 2008)
    - **b)** Schizophrenia
      - **1)** initial, oral tablets, 2 mg ORALLY once daily; increase to 5 mg after 2 days and to 10 mg (target dose mg; efficacy not greater at 30 mg/day compared to 10 mg/day (Prod Info ABILIFY(R) oral tablets, solutio 2008)

3) Contraindications
- **a)** hypersensitivity to aripiprazole or any component of the product (Prod Info ABILIFY(R) oral tablets, oral solution, IM disintegrating tablets, 2008)

4) Serious Adverse Effects
- **a)** At risk for suicide
- **b)** Cerebrovascular accident
- **c)** Death
- **d)** Diabetic ketoacidosis
- **e)** Immune hypersensitivity reaction
- **f)** Leukopenia
- **g)** Neuroleptic malignant syndrome
- **h)** Prolonged QT interval
- **i)** Seizure
- **j)** Suicidal behavior
- **k)** Tardive dyskinesia
- **l)** Transient ischemic attack

5) Clinical Applications
- **a)** FDA Approved Indications

1) Bipolar disorder - Psychomotor agitation
2) Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes
3) Bipolar I disorder, Monotherapy, manic or mixed episodes
4) Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants
5) Psychomotor agitation - Schizophrenia
6) Schizophrenia

Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes

Bipolar I disorder, Monotherapy, manic or mixed episodes

Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants

Schizophrenia

1.3.1.B.1 Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed ep

a) As adjunctive therapy with lithium or valproate, the recommended initial and target dose is aripiprazol
Depending on clinical response, the dose may be increased to 30 mg orally once a day. There have bee
safety of daily doses greater than 30 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating

b) Concomitant CYP3A4 Inhibitors

1) The dosage of aripiprazole should be reduced to one-half the usual dose when administered con
as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose
oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

c) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

d) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM

1.3.1.B.2 Bipolar I disorder, Monotherapy, manic or mixed episodes

a) The recommended starting and target dose is aripiprazole 15 milligrams (mg) orally once a day. Depe increased to 30 mg orally once a day. There have been no clinical trials performed evaluating the safety ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

b) Maintenance Therapy

1) Aripiprazole has been effective for stabilizing and maintaining patients with a recent manic or mix 2006). However, it is unclear how long a patient should remain on aripiprazole therapy. Patients who aripiprazole monotherapy for at least 6 weeks demonstrated a benefit from maintenance treatment. beyond 6 weeks should be reassessed at regular intervals to determine the need for ongoing treatm solution, orally disintegrating tablets, IM injection, 2008).

c) Concomitant CYP3A4 Inhibitors

1) The dosage of aripiprazole should be reduced to one-half the usual dose when administered con as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

d) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

e) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM

1.3.1.B.3 Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants

a) The recommended initial dose of aripiprazole as adjunctive treatment in patients with major depressiv 2 to 5 milligrams (mg) orally once daily. The aripiprazole dose may be gradually adjusted by 5 mg/day in patient tolerability and efficacy. In two 6-week, placebo-controlled trials, the aripiprazole dose ranged fro CYP2D6 inhibitors (eg, fluoxetine, paroxetine) and 2 to 20 mg/day in patients not on potential CYP2D6 in established; reassess periodically to evaluate the need for maintenance therapy (Prod Info ABILIFY(R) o tablets, IM injection, 2008).

1.3.1.B.4 Schizophrenia

a) The recommended initial and target oral dose of aripiprazole for the treatment of schizophrenia is 10 daily, with or without meals (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM in daily have been effective in patients with acutely relapsed schizophrenia or schizoaffective disorder (Kan Petrie et al, 1998a). However, in clinical trials efficacy has not been significantly greater with doses highe not should be made before 2 weeks at each dose strength (Prod Info ABILIFY(R) oral tablets, solution, o

b) Doses of 30 mg daily could be administered without dose titration in one study (Petrie et al, 1998a).

c) Maintenance Therapy

1) It is unclear how long a patient should remain on aripiprazole therapy; however, patients who had antipsychotic mediations for at least 3 months and were discontinued from those medication and giv weeks did demonstrate a benefit from maintenance treatment. Patients should be reassessed at reg ongoing treatment (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM inject

d) Switching from Other Antipsychotics

1) Data are not available to recommend guidelines for switching from other antipsychotics to aripipr other antipsychotics. The previous antipsychotic treatment may be immediately discontinued or mor individual patient. However, in all cases, duration of antipsychotic administration overlap should kep tablets, solution, orally disintegrating tablets, IM injection, 2008).

e) Concomitant CYP3A4 Inhibitors

1) The dosage of aripiprazole should be reduced to one-half the usual dose when administered con as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

f) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

g) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM

1.3.1.B.5 Oral Solution

a) Doses of the aripiprazole oral solution may be substituted for the tablet dosages on a milligram (mg)-
receiving 30 mg tablets should receive 25 mg of the oral solution (Prod Info ABILIFY(R) oral tablets, solu
2008).

b) Patients using the oral solution should be advised that every milliliter of aripiprazole oral solution cont
200 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

1.3.1.B.6 Orally Disintegrating Tablet

a) Dosing with orally disintegrating tablets is the same as for the oral tablets (Prod Info ABILIFY(R) oral
IM injection, 2008)

b) Abilify Discmelt(R) 10 milligram (mg) orally disintegrating tablets contain 1.12 mg of phenylalanine, a
phenylalanine (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008

1.3.2 Dosage in Renal Failure

A) Dosage adjustment is not necessary in patients with renal impairment (Prod Info ABILIFY(R) oral tablets, solu
2008).

1.3.3 Dosage in Hepatic Insufficiency

A) Dosage adjustment is not necessary in patients with hepatic impairment (Prod Info ABILIFY(R) oral tablets, so
injection, 2008).

1.3.4 Dosage in Geriatric Patients

A) Dosage adjustment is not necessary for elderly patients (Prod Info ABILIFY(R) oral tablets, solution, orally disi

1.4 Pediatric Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

1.4.1 Normal Dosage

1.4.1.A Oral route

Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes

Bipolar I disorder, Monotherapy, manic or mixed episodes

Schizophrenia

1.4.1.A.1 Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed ep

a) As adjunctive therapy with lithium or valproate, the recommended starting dose of oral tablets in pedi
aripiprazole 2 milligrams (mg) orally once a day for 2 days, then titrated to 5 mg orally once a day for 2 d
orally once a day. Depending on clinical response, the dose may be increased in 5 mg per day incremen
performed evaluating the safety of daily doses greater than 30 mg (Prod Info ABILIFY(R) oral tablets, so
2008).

b) Maintenance Therapy

1) The efficacy of aripiprazole for the maintenance treatment of bipolar I disorder in pediatric patien
maintenance therapy can be extrapolated from adult data. It is recommended that responding pedia
acute response, but at the lowest dose needed to maintain remission with periodic reassessments p
solution, orally disintegrating tablets, IM injection, 2008).

c) Concomitant CYP3A4 Inhibitors

1) The dosage of aripiprazole should be reduced to one-half the usual dose when administered con
as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose
oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

d) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C
dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is
reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

e) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe

inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr
dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, II

1.4.1.A.2 Bipolar I disorder, Monotherapy, manic or mixed episodes

a) The recommended starting dose of oral tablets in pediatric patients age 10 years and older is aripipra
days, then titrated to 5 mg orally once a day for 2 days, and titrated to the target dose of 10 mg orally on
dose may be titrated in 5 mg per day increments. There have been no clinical trials performed evaluating
(Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

b) Maintenance Therapy

1) The efficacy of aripiprazole for the maintenance treatment of Bipolar I Disorder in pediatric patier
maintenance can be extrapolated from adult data. It is recommended that responding pediatric patie
response, but at the lowest dose needed to maintain remission with periodic reassessments perform
solution, orally disintegrating tablets, IM injection, 2008).

c) Concomitant CYP3A4 Inhibitors

1) The dosage of aripiprazole should be reduced to one-half the usual dose when administered con
as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose
oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

d) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C
dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is
reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

e) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe
inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr
dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, II

1.4.1.A.3 Schizophrenia

a) The recommended target dose for the treatment of schizophrenia in adolescents aged 13 to 17 years
tablets at 2 mg/day and increase the dose to 5 mg after 2 days and then to 10 mg after an additional 2 d
should be done in 5-mg increments. However, no additional benefit has been seen with the 30 mg dose
orally disintegrating tablets, IM injection, 2008).

b) Maintenance Therapy

1) The efficacy of aripiprazole for the maintenance treatment of schizophrenia in pediatric patients h
of maintenance can be extrapolated from adult data. It is recommended that responding pediatric pa
response, but at the lowest dose needed to maintain remission with periodic reassessments perform
solution, orally disintegrating tablets, IM injection, 2008).

c) Switching from Other Antipsychotics

1) Data are not available to recommend guidelines for switching from other antipsychotics to aripipr
other antipsychotics. The previous antipsychotic treatment may be immediately discontinued or mor
individual patient. However, in all cases, duration of antipsychotic administration overlap should kep
tablets, solution, orally disintegrating tablets, IM injection, 2008)

d) Concomitant CYP3A4 Inhibitors

as ketoconazole or clarithromycin. When the CYP3A4 inhibitor is discontinued, the aripiprazole dose
oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

e) Concomitant CYP3A4 Inducers

1) The dosage of aripiprazole should be doubled when administered concurrently with a potential C
dose may be further increased if needed based on clinical evaluation. When the CYP3A4 inducer is
reduced to 10 to 15 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM i

f) Concomitant CYP2D6 Inhibitors

1) The dosage of aripiprazole should be reduced to at least one-half the usual dose when administe
inhibitors, such as quinidine, fluoxetine, or paroxetine. When the CYP2D6 inhibitor is discontinued fr
dose should be increased (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, II

4) The safety and efficacy of aripiprazole have not been established in pediatric patients with major depressi
schizophrenia or bipolar mania, patients less than 13 years of age with schizophrenia, or patients less than a
ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

1.4.1.A.5 Oral Solution

a) Doses of the aripiprazole oral solution may be substituted for the tablet dosages on a milligram (mg)-
receiving 30 mg tablets should receive 25 mg of the oral solution (Prod Info ABILIFY(R) oral tablets, solu
2008).

b) Patients using the oral solution should be advised that every milliliter of aripiprazole oral solution con
200 mg (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

1.4.1.A.6 Orally Disintegrating Tablets

a) Dosing with orally disintegrating tablets is the same as for the oral tablets (Prod Info ABILIFY(R) oral
IM injection, 2008)

b) Abilify Discmelt(R) 10 milligram (mg) orally disintegrating tablets contains 1.12 mg of phenylalanine a
phenylalanine (Prod Info ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008

1.4.2 Dosage in Renal Failure

A) Dosage adjustment is not necessary in patients with renal impairment (Prod Info ABILIFY(R) oral tablets, solu 2008).

1.4.3 Dosage in Hepatic Insufficiency

A) Dosage adjustment is not necessary in patients with hepatic impairment (Prod Info ABILIFY(R) oral tablets, sc injection, 2008).

2.0 Pharmacokinetics

Onset and Duration

Drug Concentration Levels

ADME

2.1 Onset and Duration

A) Onset

1) Initial Response

a) SCHIZOPHRENIA, ORAL: 1 week (10 to 30 mg daily) (Petrie et al, 1998b; Anon, 2000b).

1) In phase II studies involving hospitalized schizophrenic patients, significant improvement (including n of therapy with aripiprazole 30 mg daily. With lower doses (2 or 10 mg daily), symptom improvement was less substantial (Petrie et al, 1998b).

2.2 Drug Concentration Levels

A) Therapeutic Drug Concentration

1) Not established.

B) Peak Concentration

1) Following an intramuscular dose, the geometric mean maximum concentration (Cmax) was on average 19% h administration (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM injection, 2006).

C) Time to Peak Concentration

1) Oral: 3 to 5 hours (Anon, 2000b; Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, I

2) Intramuscular: 1 to 3 hours (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM inj

a) In healthy subjects receiving once-daily doses of 5 and 20 mg, mean peak plasma levels on day 14 were in 3 to 5 hours (Anon, 2000b).

b) With a titrated dosing schedule of 10 mg daily for 2 days, then 20 mg daily for 2 days, and finally 30 mg da concentration on day 14 was 452 ng/mL (3 hours) (Anon, 2000b).

c) In 2 studies of healthy subjects, the median times to peak plasma concentrations following intramuscular a hours (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM injection, 2006).

D) Area Under the Curve

1) The aripiprazole area under the curve (AUC) in the first 2 hours after an intramuscular injection was 90% great tablet; however, both routes had similar systemic exposure over 24 hours. When intramuscular aripiprazole doses schizophrenia or schizoaffective disorder, the pharmacokinetics of aripiprazole were linear over a dose range of 1 orally-disintegrating tablets, oral solution, IM injection, 2006).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

2.3.1 Absorption

A) Bioavailability

1) Oral: tablet, 87%; solution, well-absorbed (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets,

2) Intramuscular: 100% after a 5-mg intramuscular injection (Prod Info ABILIFY(R) oral tablets, orally-disinte

2006).

a) A comparative bioavailability study which compared the pharmacokinetics of a 30 milligram aripiprazo found that plasma concentrations of aripiprazole were higher with the solution than with the tablet. In hea concentration and area under the curve values were 22% and 14% higher with the solution as compared (R) oral tablets, orally-disintegrating tablets, oral solution, IM injection, 2006).

b) Pharmacokinetic studies with the orally disintegrating aripiprazole tablet indicate that they are bioequ ABILIFY(R) DISCMELT(TM) orally disintegrating tablets, 2006).

B) Effects of Food

1) Absorption unaffected (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM inje

a) Peak serum levels and AUC of aripiprazole and dehydroaripiprazole are not significantly affected whe peak serum levels is delayed (by 3 hours for aripiprazole and by 12 hours for dehydroaripiprazole) (Prod disintegrating tablets, oral solution, IM injection, 2006).

2.3.2 Distribution

A) Distribution Sites

1) Protein Binding

a) greater than 99% (aripiprazole and dehydroaripiprazole) (Prod Info ABILIFY(R) oral tablets, orally-dis 2006).

B) Distribution Kinetics

1) Volume of Distribution

a) 404 L or 4.9 L/kg (intravenous) (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral so

2.3.3 Metabolism

A) Metabolism Sites and Kinetics

1) Liver, extent unknown (Lawler et al, 1999).

a) Metabolic pathways include dehydrogenation and hydroxylation (via cytochrome P450 (CYP)-3A4 an CYP-3A4 . Aripiprazole is the primary compound in plasma. Aripiprazole does not inhibit or induce the C tablets, orally-disintegrating tablets, oral solution, IM injection, 2006).

b) Poor metabolizers (CYP-2D6) have been identified (speculated as 8% of population); these patients l active compounds (aripiprazole and dehydroaripiprazole) . Inhibitors of CYP-2D6 are capable of increasi (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM injection, 2006).

B) Metabolites

1) Dehydroaripiprazole (active) (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution,

a) Major metabolite, representing about 40% of aripiprazole AUC in plasma. This metabolite has affinitie compound and appears to contribute to pharmacologic activity (Prod Info ABILIFY(R) oral tablets, orally- injection, 2006).

2.3.4 Excretion

A) Kidney

1) Renal Excretion (%)

a) 25% of dose (less than 1% unchanged aripiprazole) (Prod Info ABILIFY(R) oral tablets, orally-disinteg 2006).

B) Feces

1) FECES, 55% of a dose (about 18% unchanged aripiprazole) (Prod Info ABILIFY(R) oral tablets, orally-disi 2006).

2.3.5 Elimination Half-life

A) Parent Compound

1) ELIMINATION HALF-LIFE

a) 75 hours (extensive metabolizers) (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, ora

1) An elimination half-life of 146 hours has been reported in poor metabolizers (Prod Info ABILIFY(R solution, IM injection, 2006).

B) Metabolites

1) Dehydroaripiprazole, 94 hours (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solutio

Drug Interactions

3.0.A Black Box WARNING

1) Oral (Tablet; Tablet, Disintegrating; Solution)

Increased Mortality In Elderly Patients With Dementia-Related Psychosis

Elderly patients with dementia-related psychosis treated with antipsychotic drugs are at an increased risk of d controlled trials (modal duration of 10 weeks), largely in patients taking atypical antipsychotic drugs, revealed between 1.6 to 1.7 times the risk of death in placebo-treated patients. Over the course of a typical 10-week c patients was about 4.5%, compared to a rate of about 2.6% in the placebo group. Although the causes of dea to be either cardiovascular (eg, heart failure, sudden death) or infectious (eg, pneumonia) in nature. Observa antipsychotic drugs, treatment with conventional antipsychotic drugs may increase mortality. The extent to wh observational studies may be attributed to the antipsychotic drug as opposed to some characteristic(s) of the approved for the treatment of patients with dementia-related psychosis.

Suicidality and Antidepressant Drugs

Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in child term studies of Major Depressive Disorder (MDD) and other psychiatric disorders. Anyone considering the us antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term suicidality with antidepressants compared to placebo in adults beyond age 24; there was a reduction in risk w adults aged 65 and older. Depression and certain other psychiatric disorders are themselves associated with ages who are started on antidepressant therapy should be monitored appropriately and observed closely for changes in behavior. Families and caregivers should be advised of the need for close observation and comm not approved for use in pediatric patients with depression (Prod Info ABILIFY(R) oral tablets, oral solution, IM disintegrating tablets, 2008).

2) Intramuscular (Solution)

Increased Mortality In Elderly Patients With Dementia-Related Psychosis

3.3.1 Cardiovascular Effects

Orthostatic hypotension

Prolonged QT interval

Summary

Tachycardia

3.3.1.A Orthostatic hypotension

1) Incidence: 0.6% to 4% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(
2) Compared with placebo, aripiprazole therapy resulted in a higher incidence of orthostatic hypotension am
(1% vs 0.3%; n=2467), pediatric patients 10 to 17 years of age receiving oral aripiprazole (1% vs 0%; n=399)

(0.6% vs 0%; n=501) during short-term trials. Aripiprazole should be used cautiously in patients with preexisti
would predispose patients to hypotension (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILI
2008).
3) The frequency of a significant orthostatic change in blood pressure (ie, a decrease of at least 20 mmHg in
increase in heart rate of 25 or greater when changing from a supine to standing position) was not significantly
compared with those treated with placebo in the placebo controlled trials of adult patients (4% aripiprazole, 2
years (0%, 0.5%), or in aripiprazole injection-treated patients (3%, 2%) (Prod Info ABILIFY(R) oral tablets, ora
(R) orally disintegrating tablets, 2008).

3.3.1.B Prolonged QT interval

1) Incidence: 0.1% to 1% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(
2) Prolongation of the QT-interval has been observed during clinical trials with a frequency between 1/1000 a
doses of aripiprazole at least 2 mg day. Aripiprazole should be used cautiously in patients with preexisting ca
abnormalities (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally dis

3.3.1.C Summary

1) Because orthostatic hypotension, prolonged QT interval, and tachycardia have been reported with aripipra
caution in patients with known cardiovascular disease or conduction abnormalities, or conditions which would
ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

3.3.1.D Tachycardia

1) Incidence: 2% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar
intramuscularly 5.25 mg/day or greater (n=501) or placebo (n=220), tachycardia was reported in 2% of patien
than 1% of patients receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY
2008).

3.3.2 Dermatologic Effects

Acneiform drug eruption

Rash

3.3.2.A Acneiform drug eruption

1) Incidence: rare
2) A 23-year-old man developed acneiform drug eruptions 10 days after starting aripiprazole treatment for pa
year history of symptoms suggestive of paranoid schizophrenia. In the past had received an adequate trial of
treated with aripiprazole 20 mg/day with a good response. After 1 month of treatment with aripiprazole, the pa
remained symptomatic for 1 year. The patient was readmitted for aggravation of symptoms and upon admiss
hemogram, serum electrolytes, renal function and liver function. For acute control of his aggression, the patie
haloperidol 10 mg and promethazine 25 mg intramuscularly twice daily for 4 days. The patient was restarted
mg/day over 4 days. After 10 days of aripiprazole treatment, the patient developed papulopustular eruptions
worsened with sunlight exposure) The patient had no past history of the eruptions or aripiprazole exposure in
with aripiprazole-induced acneiform eruptions. Aripiprazole was discontinued and the patient was switched to
response. Consequently, the affected regions were treated with topical retinoic acid 0.25 mg ointment. Within
there was complete resolution of the acneiform eruptions with mild scarring. Because the patient was previou
rapid development of the acneiform lesions, the acneiform drug eruption may have been mediated through a
clinical signs of allergy were noted (Mishra et al, 2008).

3.3.2.B Rash

1) Incidence: 2% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), rash was reported in 2% of patients receiving aripiprazole co
(Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

3.3.3 Endocrine/Metabolic Effects

Blood glucose level - finding

Diabetes mellitus

Diabetic ketoacidosis

Hyperglycemia

Hyponatremia

Increased body temperature

Increased prolactin level

Metabolic syndrome

Summary

Triglyceride level - finding

Weight increased

3.3.3.A Blood glucose level - finding

1) Incidence: rare (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall

2) Blood glucose fluctuation has been observed rarely in postmarketing surveillance of aripiprazole (Prod Inf injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.3.B Diabetes mellitus

See Drug Consult reference: ATYPICAL ANTIPSYCHOTIC AGENTS - EFFECT ON GLUCOSE AND RISK C

3.3.3.C Diabetic ketoacidosis

1) A 44-year-old, obese, African-American man developed new-onset diabetes and diabetic ketoacidosis (DK treatment for schizoaffective disorder. The patient's medical history included a 16-year diagnosis of schizoaff upon admission was 43.3 kg/m(2)), and he had no personal or family history of diabetes and no current medi prior for schizoaffective disorder with a good clinical response to fluphenazine and valproic acid. Upon admis exacerbation of schizoaffective disorder symptoms (auditory hallucinations), treatment with fluphenazine 5 m fluphenazine was increased to 5 mg twice daily and valproic acid 1750 mg/day was added. By day 27, the pa hallucinations and aripiprazole 15 mg/day was initiated. Additionally, the patient was receiving fluphenazine, atorvastatin for hyperlipidemia. On day 28 the aripiprazole was increased to 30 mg/day. On day 43, after 16 d experienced a episode of urinary incontinence. On day 44, the patient refused to eat, experienced somnolenc ability to take his medication or drink fluids without assistance. The patient was treated with intravenous fluids sinus tachycardia. On day 45, the patient was lethargic, stopped communicating, had difficulty walking and ha hours. Laboratory analysis revealed hyperglycemia (glucose, 813 mg/dL), metabolic acidosis (bicarbonate, 9 gases pH, 7.2), moderate serum ketone levels, elevated serum creatinine (2.7 mg/dL), bilirubinemia (2.6 mg/ 14.9%. The patient was diagnosed with DKA, transferred to the medical intensive care unit where all psychiat patient was given intravenous insulin and fluids. The psychiatric team recommended fluphenazine, benztropi metabolic acidosis and azotemia resolved, and the intravenous insulin was changed to subQ long-acting insu back to the psychiatric service after the serum glucose had stabilized. The patient's discharge medications in aspart in addition to benztropine, fluphenazine, divalproex sodium, and escitalopram. Within 4 months after h insulin. According to the Naranjo scale (score of 5), aripiprazole was the probable catalyst triggering DKA. Th associated DKA may be attributed to preexisting glucose impairment (evidenced by the strong correlation bet (Makhzoumi et al, 2008).

2) A case of new-onset diabetes and diabetic ketoacidosis with elevated lipase was described in a 33-year-o following treatment with aripiprazole. Prior to current presentation, the patient had been on aripiprazole thera had a body mass index (BMI) was 32 kg/m(2) prior to taking aripiprazole. At the time of presentation, the pati epigastric abdominal pain. The patient had progressively gained weight since initiating aripiprazole treatment Laboratory tests indicated hyperglycemia (blood glucose of 1769 mg/dL), diabetic ketoacidosis (anion gap of milliosmoles/kg, CO2 of 6 mmol/L), and hyperlipasemia (lipase of 4068 International Units/L). An abdominal u pancreatitis and gallstones, and thyroid function tests were normal. The patient did not have a prior medical h Aripiprazole was discontinued and the patient was treated with intravenous fluids and insulin. A diagnosis of a lipase, secondary to diabetic ketoacidosis, was made and the patient was discharged home with haloperidol discontinuation of aripiprazole, the patient's BMI had decreased to 33 kg/m(2) and, while still diabetic, his insu proposed that patient's weight and blood glucose may need be monitored during aripiprazole therapy (Reddy

3.3.3.D Hyperglycemia

1) Hyperglycemia has been reported in patients treated with atypical antipsychotics; and in some instances, ketoacidosis, hyperosmolar coma, or death. There have been few reports of hyperglycemia in patients treate atypical antipsychotic use and hyperglycemia-related adverse events is not completely understood. However risk of treatment-emergent hyperglycemia-related adverse events in patients treated with atypical antipsychot the time these studies were conducted, it is not known if aripiprazole is associated with this increased risk. Pa antipsychotics for symptoms of hyperglycemia including polydipsia, polyuria, polyphagia, and weakness. If sy should undergo fasting blood glucose testing. Although hyperglycemia has resolved when the antipsychotic d

required continued antidiabetic treatment despite antipsychotic discontinuation (Prod Info ABILIFY(R) oral tab DISCMELT(R) orally disintegrating tablets, 2008).

3.3.3.E Hyponatremia

1) Hyponatremia was reported in a 69-year-old man when aripiprazole was added to sodium valproate maint His comorbid conditions included diabetes mellitus treated with metformin and glibenclamide, and hypothyroi While he was treated with a stable dose of sodium valproate 1000 mg/day, he experienced a relapse of mani mg/day was added. The patient developed persistent hiccoughs 2 days later, accompanied by a serum sodiu of 4.5 mEq/L, and urine specific gravity of 1.01; other laboratory and thyroid serology results were unremarka per day of water for the previous 3 weeks. When aripiprazole was withheld and water intake was restricted to mEq/L. However, sodium levels dropped again to 120 mEq/L one day following rechallenge with aripiprazole aripiprazole and was initiated on quetiapine (dose titrated to 400 mg/day over 2 weeks), his sodium levels gra later with spontaneous resolution of hiccoughs. Fluid restriction was then stopped. During the following 8 mor normal sodium levels (Behere et al, 2007).

3.3.3.F Increased body temperature

1) Disruption of the body's ability to reduce core body temperature has been associated with antipsychotic a appropriate care in patients who will be experiencing conditions that may contribute to an elevated core body exposure to extreme heat, or dehydration) (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABIL tablets, 2008).

3.3.3.G Increased prolactin level

1) Serum prolactin levels have been unaffected or increased only slightly by oral aripiprazole (2 to 30 mg dai Petrie et al, 1998; Kane et al, 2000b). Increases in prolactin levels were greater with haloperidol 10 mg daily i Saha et al, 1999a).

3.3.3.H Metabolic syndrome

See Drug Consult reference: ANTIPSYCHOTIC AGENTS - METABOLIC SYNDROME

3.3.3.I Summary

1) Blood glucose fluctuation, diabetic ketoacidosis, and hyperglycemia have been reported with aripiprazole factors for diabetes should be monitored for worsening glucose control and should undergo fasting blood gluc during aripiprazole treatment. Reports of weight gain, increased body temperature, a case report of hyponatr prolactin have been reported with aripiprazole use. Aripiprazole should be used cautiously in patients with the temperatures, dehydration, strenuous exercise, or other conditions which may increase core body temperatu solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.3.J Triglyceride level - finding

1) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), the triglycerides was 5% versus 0%, respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, A tablets, 2008).

3.3.3.K Weight increased

1) Incidence: 2% to 30% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(

2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, increased weight was repo mg/day or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130). Patients receiv aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILI 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371), compared with antidepressant therapy only (n=366), of patients, respectively. Comparing the aripiprazole adjunctive group with the adjunctive placebo group, the respectively, and the percentage of patients gaining 7% or greater of body weight was 5% vs 1%, respectivel solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

4) In 4- to 6-week trials in which adult patients with schizophrenia were treated with either aripiprazole 5 to 3 was observed among patients treated with aripiprazole compared with a weight loss of 0.05 kg observed amo greater gain in body weight from baseline was observed in 8% of the aripiprazole-treated patients compared Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2

5) In 3-week trials in which adult patients with mania were treated with either aripiprazole or placebo, a weigl treated with aripiprazole compared with a weight loss of 0.2 kg observed among patients treated with placebo baseline was observed in 3% of the aripiprazole-treated patients compared with 2% of the placebo-treated pa solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

6) In a 6-week trial in which pediatric patients 13 to 17 years of age with schizophrenia were treated with eith 0.13 kg was observed among patients treated with aripiprazole compared with a weight loss of 0.83 kg obser 7% or greater gain in body weight from baseline was observed in 5% of the aripiprazole-treated patients com (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

7) In one large 4-week study, weight gain of more than 7% was observed in about 11% of patients treated w relationship) and 14% receiving haloperidol 10 mg daily (Saha et al, 1999a).

8) In a 26-week, placebo-controlled trial among patients treated with aripiprazole 15 mg daily for schizophrer greater body weight from baseline were as follows (Prod Info ABILIFY(R) oral tablets, oral solution, IM injecti disintegrating tablets, 2008):

Body-Mass Index (BMI)	Aripiprazole	Placebo
Less than 23	6.8%	3.7%
23 to 27	5.1%	4.2%
Greater than 27	5.7%	4.1%

p values not provided

9) In a 52-week, active-controlled trial with aripiprazole for schizophrenia, weight changes from baseline wer tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008):

Body-Mass Index (BMI)	Mean weight change from baseline (kg)	Weight gain
Less than 23	2.6	
23 to 27	1.4	
Greater than 27	-1.2	

p values not provided

3.3.4 Gastrointestinal Effects

Constipation

Diarrhea

Dysphagia

Excessive salivation

Increased appetite

Nausea

Summary

Vomiting

Xerostomia

3.3.4.A Constipation

1) Incidence: 5% to 11% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(I
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy only (n=366), const respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin
3) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), constipation was reported in 11% of patients receiving aripiprazole compared with 7% c ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

3.3.4.B Diarrhea

1) Incidence: 3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), diarrhea was reported in 3% of patients receiving aripiprazole placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.4.C Dysphagia

1) Esophageal dysmotility and aspiration have occurred with aripiprazole use. Dysphagia was reported infrec premarketing clinical trials. Nonetheless, like other antipsychotic drugs, aripiprazole should be used cautiousl (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

3.3.4.D Excessive salivation

1) Incidence: 3.1% to 8.1% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMEL
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, salivary hypersecretion wa aripiprazole 15 mg/day or 30 mg/day orally (n=253) compared with 2% of patients receiving placebo (n=130).

in addition to aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM inj disintegrating tablets, 2008).
3) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, salivary hypersecretion was reported in 8.1% of the aripiprazole 30-mg group and 3.1% of t placebo group (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally dis
4) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), salivary hypersecretion was reported in 4% of patients receiv receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
5) A 27-year-old man with bipolar affective disorder and current-episode mania with mood-congruent psycho gram/day developed sialorrhea 3 months after the institution of aripiprazole 10 mg/day for persistent psychoti any associated sign suggestive of extrapyramidal syndrome. A significant reduction in sialorrhea was noted c mg/day (Praharaj et al, 2009).

3.3.4.E Increased appetite

1) Incidence: 3% to 4% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy only (n=366), increa patients, respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) o
3) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), increased appetite was reported in 4% of patients receiving a receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally

3.3.4.F Nausea

1) Incidence: 8% to 15% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(I
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, nausea was reported in 8% or 30 mg/day orally (n=253) compared with 5% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).
3) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), nausea was reported in 15% of patients receiving aripiprazole compared with 11% of pa (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
4) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM (n=501) or placebo (n=220), nausea was reported in 9% of patients receiving aripiprazo placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr
5) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, nausea was reported in 11% of the aripiprazole group (n=197) compared with 4% of the pla tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
6) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), nausea was reported in 10% of patients receiving aripiprazol placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.4.G Summary

1) Nausea has been reported commonly in adult and pediatric patients treated with oral or injectable aripipra patients treated with oral or injectable aripiprazole. Constipation has been reported in adult patients treated w patients treated with oral aripiprazole have reported dry mouth and salivary hypersecretion. Diarrhea occurre aripiprazole. Although uncommon, dysphagia has been reported in patients treated with aripiprazole. Therefo patients at risk for aspiration pneumonia (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).

3.3.4.H Vomiting

1) Incidence: 3% to 11% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(I
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, vomiting was reported in 4% or 30 mg/day orally (n=253) compared with 0% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).
3) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), vomiting was reported in 11% of patients receiving aripiprazole compared with 6% of pa (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
4) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM (n=501) or placebo (n=220), vomiting was reported in 3% of patients receiving aripiprazo placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.4.I Xerostomia

1) Incidence: 2% to 5% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, dry mouth was reported in mg/day or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130). Patients receiv aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).

3) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari
or placebo (n=1166), dry mouth was reported in 5% of patients receiving aripiprazole compared with 4% of pa
(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
4) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), dry mouth was reported in 2% of patients receiving aripiprazo
placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.5 Hematologic Effects

3.3.5.A Leukopenia

1) A case report described leukopenia in a 32-year-old man following treatment with risperidone and aripipra
paranoid schizophrenia, had been initiated on risperidone 2 mg/day a few years earlier. Although he reported
physical exam were normal, laboratory assessment showed a WBC and absolute neutrophil count (ANC) of 2
Risperidone-induced leukopenia was suspected and the patient agreed to reduce the risperidone dose to 1 m
showed WBC count and ANC at 2.7 x 10(9) and 1.22 x 10(9), respectively. Subsequently, risperidone was dis
aripiprazole 10 mg daily. He was evaluated every 4 weeks and reported no adverse effects. Six months later,
and 0.85 x 10(9), respectively, and aripiprazole was discontinued. Two weeks later, he experienced paranoid
hallucinations for which he was hospitalized. Upon admission, his WBC count and ANC were 6.4 x 10(9) and
after being reinitiated on aripiprazole 10 mg/day. At a follow-up appointment, his WBC count and ANC were a
respectively). It was decided to discontinue aripiprazole and treat the patient with paliperidone 6 mg and lithiu
change, his WBC count and ANC increased to 3.3 x 10(9) and 1.42 x 10(9). A full hematologic workup was p
& Rubin, 2008).

3.3.7 Immunologic Effects

3.3.7.A Immune hypersensitivity reaction

1) Incidence: rare (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall
2) Allergic reactions (ie, anaphylactic reaction, angioedema, laryngospasm, pruritus/urticaria, or oropharynge
postmarketing surveillance of aripiprazole (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILI
2008).

3.3.8 Musculoskeletal Effects

Arthralgia

Myalgia

3.3.8.A Arthralgia

1) Incidence: 2% to 4% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip
in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), arthralgia o
respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin
3) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), arthralgia was reported in 2% of patients receiving aripiprazo
placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.8.B Myalgia

1) Incidence: 3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip
in addition to continued antidepressant therapy (n=371) or antidepressant therapy only (n=366), myalgia occu
(Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

3.3.9 Neurologic Effects

Akathisia

Cerebrovascular accident

Dizziness

Dystonia

Extrapyramidal disease

Headache

Insomnia

Sedated

Seizure

Somnolence

Summary

Tardive dyskinesia

Transient ischemic attack

Tremor

3.3.9.A Akathisia

1) Incidence: 2% to 25% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(

2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, akathisia was reported in 1 mg/day or 30 mg/day orally (n=253) compared with 5% of patients receiving placebo (n=130). Patients receiv aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILI 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy only (n=366), akath respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

4) In a pooled analysis of 3-week, placebo-controlled trials in which adult patients with bipolar mania receive placebo (n=753), akathisia was reported in 13% of aripiprazole-treated patients compared with 4% of placeb tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

5) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), akathisia was reported in 10% of patients receiving aripiprazole compared with 4% of p (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

6) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM injection (n=501) or placebo (n=220), akathisia was reported in 2% of patients receiving receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall

7) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, akathisia was reported in 11.1% of the aripiprazole 30-mg group and 8.2% of the 10-mg gr (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

8) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), akathisia was reported in 9% of patients receiving aripiprazol placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

9) A case series reported dose-dependent akathisia following initiation of aripiprazole therapy in 4 patients (a had a history of schizoaffective disorder. All patients were concurrently receiving SSRI therapy. The patients weeks following aripiprazole initiation. Dose adjustments and/or changes to the patient's psychiatric medicati akathisia subsequently improved or resolved with no further issues (Basu & Brar, 2006).

3.3.9.B Cerebrovascular accident

1) In three, 10-week, placebo-controlled clinical studies (two flexible dose and one fixed dose study) of deme patients (mean age of 84 years; range: 78 to 88 years) were treated with aripiprazole or placebo, cerebrovas ischemic attack), including fatalities, were reported with greater incidence in the aripiprazole-treated patients the fixed-dose study, there was a significant dose response relationship for cerebrovascular adverse events i not approved for the treatment of dementia-related psychosis (Prod Info ABILIFY(R) oral tablets, oral solution disintegrating tablets, 2008).

3.3.9.C Dizziness

1) Incidence: 4% to 10% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(

2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, dizziness was reported in 4 or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILI 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), dizziness o

respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin
4) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ora
placebo (n=1166), dizziness was reported in 10% of patients receiving aripiprazole compared with 7% of pati
oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
5) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar
injection of aripiprazole 5.25 mg/day or greater (n=501) or placebo (n=220), dizziness was reported in 8% of
5% of patients receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISC
6) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re
orally or placebo, dizziness was reported in 5% of the aripiprazole group (n=197) compared with 1% of the pl
oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
7) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), dizziness was reported in 5% of patients receiving aripiprazo
placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.9.D Dystonia

1) Incidence: 2% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), dystonia was reported in 2% of patients receiving aripiprazole
placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr
3) A 25-year-old female with schizophrenia developed characteristics associated with tardive dystonia follow
diagnosed with schizoaffective disorder that included 2 previous psychotic episodes and 3 previous manic ep
changing to various antipsychotic medications due to adverse events which included skin rashes with carban
galactorrhea and severe extrapyramidal symptoms with risperidone , and tremors and drowsiness with valpro
mania with quetiapine, the patient switched to lithium. Lithium was reduced to 450 mg/day because of memo
lithium for 8 months with additional adverse effects. Aripiprazole 10 mg/day was added to lithium therapy due
treatment, aripiprazole was increased to 15 mg/day. After 2 months of lithium and aripiprazole therapy, she p
spasms over the latissimus dorsi, which worsened over time. The patient did not experience any other sympt
facial grimacing, or difficulty in breathing or chewing. However, the Extrapyramidal Symptom Rating Scale (E
from moderate to severe levels of extrapyramidal symptoms. The patient was started on trihexyphenidyl 6 mg
After 2 weeks, her dystonia improved and she had a ESRS score of zero. After 4 weeks, clozapine was adde
to 150 mg/day to treat her mood and psychotic symptoms. She remained symptom free 1 year after stopping
4) A 10-year-old boy with bipolar disorder developed dystonia following aripiprazole treatment. The child was
high energy and violent, impulsive behaviors with aggression toward his family and peers. His current medica
divided three times daily plus guanfacine 0.5 mg three times daily. Divalproex was discontinued and aripiprazo
was initiated the following day. Three days after initial aripiprazole therapy, the patient developed neck pain a
Upon examination, his symptoms were consistent with acute torticollis. His neck symptoms completely resolv
administration and aripiprazole discontinuation. The patient did not have any recurrence of dystonia after he w
times daily with bupropion SR 200 mg daily for mood disorder (Singh et al, 2007).

3.3.9.E Extrapyramidal disease

1) Incidence: 2% to 27.3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, extrapyramidal disorder wa
aripiprazole 15 mg/day or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130).
in addition to aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM inj
disintegrating tablets, 2008).
3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip
in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), extrapyram
patients, respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) o
4) In a pooled analysis of 3-week, placebo-controlled trials in which adult patients with bipolar mania receive
placebo (n=753), extrapyramidal disorder was reported in 5% of aripiprazole-treated patients compared with
ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)
5) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari
or placebo (n=1166), extrapyramidal disorder was reported in 5% of patients receiving aripiprazole compared
Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2
6) In a short-term, placebo-controlled trial in which pediatric patients age 13 to 17 years with schizophrenia r
extrapyramidal disorder was reported in 21.6% of the 30-mg aripiprazole group and 13% of the 10-mg aripipr
group (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrati
7) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re
mg/day or placebo, extrapyramidal disorder was reported in 27.3% of the aripiprazole 30-mg group and 12.2%
the placebo group (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall
8) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m
mg/day or greater) (n=399) or placebo (n=197), extrapyramidal disorder was reported in 19% of patients rece
patients receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT
9) A case report described the development of extrapyramidal symptoms (EPS) in a 56-year-old schizophrer
aripiprazole. The patient, who presented with psychiatric symptoms of paranoid and persecutory delusions, a
was started on aripiprazole 10 mg once daily. The dose was increased to 15 mg once daily the second week
Five weeks after the initiation of aripiprazole, including 3 weeks at the 30 mg dose, the patient developed stiff
mask-like facial expression, and hypersalivation. None of these symptoms had been documented in this patie

patient had not received treatment with any other antipsychotic agents previously. Akathisia was absent, and absence of opisthotonos, torticollis, oculogyric crisis, and the time of onset. Subsequently, the aripiprazole dc procyclidine 5 mg was added, which prompted resolution of the stiffness. However, the patient continued to h not improve. Aripiprazole treatment was stopped 7 days after the onset of EPS and nightly olanzapine therap followed by 5 mg thereafter. The hypersalivation resolved 10 days after discontinuation of aripiprazole and nc the exact mechanism for this adverse event was not elucidated, an idiosyncratic reaction to aripiprazole, rath as a possible cause for this effect (Salmoiraghi & Odiyoor, 2006).

10) Extrapyramidal symptoms have been minimal during oral aripiprazole therapy of schizophrenia in unpubl 1999a; Petrie et al, 1998; Inoue & Nakata, 2001a). In one 4-week study, the overall incidence of extrapyramic daily was similar to that in the placebo group; at least one dose of benztropine was required in 11 to 17% of p compared to 36% assigned to haloperidol 10 mg daily (Kane et al, 2000b). The frequency of extrapyramidal s than haloperidol in a phase II study (Saha et al, 1999a).

See Drug Consult reference: NEUROLEPTIC-INDUCED EXTRAPYRAMIDAL REACTIONS

3.3.9.F Headache

1) Incidence: 12% to 27% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT

2) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), headache was reported in 27% of patients receiving aripiprazole compared with 23% of (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM (n=501) or placebo (n=220), headache was reported in 12% of patients receiving aripip placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

4) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), headache was reported in 16% of patients receiving aripiprazole placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.9.G Insomnia

1) Incidence: 8% to 18% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(

2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, insomnia was reported in 8 or 30 mg/day orally (n=253) compared with 4% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), inso respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

4) In a pooled analysis in which adult patients with schizophrenia or bipolar mania received either aripiprazol placebo (n=1166), insomnia was reported in 18% of patients receiving aripiprazole compared with 3% of patie oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.9.H Sedated

1) Incidence: 1% to 8% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R

2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, sedation was reported in 4 or 30 mg/day orally (n=253) compared with 2% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), sedation oc respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

4) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), sedation was reported in 7% of patients receiving aripiprazole compared with 4% of pat oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

5) In a pooled analysis of 3-week, placebo-controlled trials in which adult patients with bipolar mania receive placebo (n=753), sedation was reported in 8% of aripiprazole-treated patients compared with 3% of placebo- tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

6) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM injection (n=501) or placebo (n=220), sedation was reported in 3% of patients receiving receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally

7) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), sedation was reported in 1% of patients receiving aripiprazol placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.9.I Seizure

1) Incidence: 0.1% to 0.3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMEL

2) Seizures or convulsions have been reported with aripiprazole use. Use aripiprazole with caution in patient lower the seizure threshold (eg, Alzheimer's dementia) (Prod Info ABILIFY(R) oral tablets, oral solution, IM in disintegrating tablets, 2008).

3) In short-term, placebo-controlled trials, seizures or convulsions were reported in 0.1% (3 of 2467) of adult patients (ages 10 to 17 years) who received oral aripiprazole and 0.2% of adult patients (1 of 501) treated wit

oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.9.J Somnolence

1) Incidence: 5% to 26.3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT

2) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, somnolence was reported in 23% of the aripiprazole group (n=197) compared with 3% of th oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), somnolenc respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

4) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), somnolence was reported in 5% of patients receiving aripiprazole compared with 3% of (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

5) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM injection (n=501) or placebo (n=220), somnolence was reported in 7% of patients recei receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall

6) In a short-term, placebo-controlled trial in which pediatric patients age 13 to 17 years with schizophrenia r somnolence was reported in 21.6% of the 30-mg aripiprazole group and 11% of the 10-mg aripiprazole group (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

7) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re mg/day or placebo, somnolence was reported in 26.3% of the 30-mg aripiprazole group and 19.4% of the 10- the placebo group (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall

8) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), somnolence was reported in 20% of patients receiving aripip placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

9) Excessive somnolence requiring hospitalization was observed in a 9-year-old girl weighing 25 kg within 3. 15 mg/day (0.6 mg/kg/day) for the treatment of oppositional defiant disorder. Although optimal dosing in pedia dose is up to three times higher than doses used in a clinical study including children of similar body weight t mg/day) (Davenport et al, 2004).

3.3.9.K Summary

1) Neuroleptic malignant syndrome (NMS), sometimes fatal, has been reported rarely in patients treated with aripiprazole is diagnosed with NMS, management should include immediate discontinuation of aripiprazole fo Cerebrovascular accident, lethargy, and tardive dyskinesia have been reported with aripiprazole use, particul for the treatment of dementia-related psychosis. Akathisia, dystonia, extrapyramidal disorder, insomnia and s should be used with caution in patients with a history of seizures or conditions that may lower the seizure thre somnolence, sedation, and tremor, there is the potential for cognitive and motor impairment. Patients who are use caution while operating machinery, including automobiles, until the effects of the drug are known (Prod In injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.9.L Tardive dyskinesia

1) Tardive dyskinesia may develop in patients treated with antipsychotic drugs, with a higher prevalence in th of developing tardive dyskinesia and the likelihood of it becoming irreversible appear to increase as treatmen drug increase. Although less common, the condition can develop after relatively brief treatment periods at low discontinuation of the antipsychotic drug; however, the antipsychotic drug itself may mask the underlying proc lowest dose and the shortest duration of therapy to produce a satisfactory clinical response to minimize the o receiving aripiprazole therapy develops symptoms of tardive dyskinesia, consideration should be given to dis require aripiprazole treatment regardless of the presence of tardive dyskinesia (Prod Info ABILIFY(R) oral tab DISCMELT(R) orally disintegrating tablets, 2008).

2) Two case reports (involving Taiwanese women, ages 41 and 52 years) suggest a relationship between us first patient was maintained on amisulpiride 200 mg/day no adverse effects. However, she was concerned ov treatment. A combination of amisulpiride 200 mg/day and aripiprazole 10 mg/day was initiated and the patien remained stable. After 11 months of therapy, the patient presented with Parkinsonian symptoms including rab which persisted for 4 months. Amisulpiride was withdrawn and aripiprazole 15 mg/day was given. Dyskinetic amisulpiride discontinuation. However, the patient was reluctant to change medication since her psychotic sy dyskinetic symptoms improved and sustained after 21 months of aripiprazole therapy. The second patient, wh medications (sulpiride 50 to 200 mg/day for 6 years) was admitted due to reoccurring psychotic symptoms. U initiated titrating up to 10 mg/day in one week. She was discharged on this dose. After 2 months of aripiprazo dyskinesia (involuntary chewing and crunching movements). Diphenhydramine 150 mg/day was added to her eventually disappeared within 3 to 4 months (Wang et al, 2009).

3.3.9.M Transient ischemic attack

1) In three, 10-week, placebo-controlled clinical studies (two flexible dose and one fixed dose study) of deme patients (mean age of 84 years; range: 78 to 88 years) were treated with aripiprazole or placebo, cerebrovas ischemic attack), including fatalities, were reported with greater incidence in the aripiprazole-treated patients the fixed-dose study, there was a significant dose response relationship for cerebrovascular adverse events i not approved for the treatment of dementia-related psychosis (Prod Info ABILIFY(R) oral tablets, oral solution disintegrating tablets, 2008).

3.3.9.N Tremor

1) Incidence: 2% to 11.8% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT

2) In a pooled analysis of 3-week, placebo-controlled trials in which adult patients with bipolar mania receive placebo (n=753), tremor was reported in 6% of aripiprazole-treated patients compared with 3% of placebo-tre tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, tremor was reported in 9% 30 mg/day orally (n=253) compared with 6% of patients receiving placebo (n=130). Patients received lithium or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMEL

4) In pooled data of 2 placebo-controlled trials in adult patients with major depressive disorder receiving aripi in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), tremor occu (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab

5) In a pooled analysis of short-term trials in which adult patients with schizophrenia or bipolar mania receive (n=1843) or placebo (n=1166), tremor was reported in 5% of patients receiving aripiprazole compared with 3 ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

6) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), tremor was reported in 5% of patients receiving aripiprazole placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

7) In a short-term, placebo-controlled trial in which pediatric patients age 13 to 17 years with schizophrenia r was reported in 11.8% of the 30-mg aripiprazole group and 2% of the 10-mg aripiprazole group compared wi (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.10 Ophthalmic Effects

3.3.10.A Blurred vision

1) Incidence: 3% to 8% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R

2) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), blurred vision was reported in 3% of patients receiving aripiprazole compared with 1% ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), blur patients, respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) o

4) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, blurred vision was reported in 8% of the aripiprazole group (n=197) compared with 0% of th oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

5) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), blurred vision was reported in 5% of patients receiving aripip placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.12 Psychiatric Effects

Agitation

Anxiety

At risk for suicide

Feeling nervous

Restlessness

Suicidal behavior

3.3.12.A Agitation

1) A case report described severe agitation in a 45-year-old woman after abrupt clozapine discontinuation ar woman, who had a history of psychosis (schizophrenia and chronic paranoid), substance abuse (cocaine and hospitalizations, was transferred to a state psychiatric hospital from a jail facility. Her medical history also incl normal glycemic control. Upon admission, risperidone and haloperidol were stopped due to lack of response included valproic acid and nortriptyline, as well as an albuterol inhaler and ibuprofen as needed. Her clozapin titrated upward. Although her glucose levels remained within normal range, she continued to experience psyc frustration tolerance. Subsequently, haloperidol 10 mg twice daily was reinitiated as adjunctive therapy. Two epigastric pain with emesis, dizziness and lethargy. Because her blood glucose levels were in the range of 4 the patient was sent to an ER at an outside hospital where she was diagnosed with new-onset diabetes with discontinued due to the potential for diabetogenic effects. Aripiprazole 15 mg was then initiated in its place, a

to the psychiatric hospital 7 days after clozapine discontinuation, she was stable with no signs of delusions or she experienced more restlessness, showed emotional distress (crying inconsolably and verbally threatening hallways. These symptoms persisted for several days, resulting in the discontinuation of aripiprazole. She wa titrated upward to 75 mg twice daily while haloperidol was continued. Over the next week, her condition impro and greater cooperation and alertness. The patient remained clinically stable over the next 12 weeks. The au agitation: 1) a withdrawal reaction due to abrupt clozapine withdrawn, and 2) the partial dopamine agonist eff 2009).

3.3.12.B Anxiety

1) Incidence: 4% to 17% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, anxiety was reported in 4% or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130). Patients received lithiu aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).
3) In a pooled analysis of short-term trials in which adult patients with schizophrenia or bipolar mania receive (n=1843) or placebo (n=1166), anxiety was reported in 17% of patients receiving aripiprazole compared with ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

3.3.12.C At risk for suicide

1) In pooled analysis of placebo-controlled trials of adult patients with major depressive disorder, or other psy antidepressant drugs in 77,000 patients, there was a tendency toward an increased risk of suicidality in the y and the absolute risk of suicidality was highest in patients with major depressive disorder. In patients less tha versus placebo, there were 14 additional cases per 1000 patients treated, and in patients age 18 to 24 years patients treated. Patients should be carefully monitored for clinical worsening of depression, suicidality, and u precursors to suicidality, especially if symptoms are severe, abrupt, or unusual. This is especially crucial duri therapy and during dose changes (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DIS
2) Because a suicide attempt is inherently possible in patients with a psychotic illness or bipolar disorder, hig receive close supervision (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R

3.3.12.D Feeling nervous

1) Incidence: 3% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy only (n=366), feelin respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

3.3.12.E Restlessness

1) Incidence: 2% to 12% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R
2) In a short-term study of aripiprazole as adjunctive therapy for bipolar disorder, restlessness was reported mg/day or 30 mg/day orally (n=253) compared with 1% of patients receiving placebo (n=130). Patients receiv aripiprazole or placebo for up to 6 weeks (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIF 2008).
3) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), restlessnes respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin
4) In a pooled analysis of 3-week, placebo-controlled trials in which adult patients with bipolar mania receive placebo (n=753), restlessness was reported in 6% of aripiprazole-treated patients compared with 3% of place tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
5) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), restlessness was reported in 5% of patients receiving aripiprazole compared with 3% of ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008)

3.3.12.F Suicidal behavior

1) Adult and pediatric patients with major depressive disorder may experience unusual changes in behavior Antidepressant therapy may be associated with the emergence of suicidality and inducing worsening of depre treatment phase and in children, adolescents, and young adults ages 18 to 24 years. It is important that famil depressive disorder or other psychiatric and nonpsychiatric disorders be vigilant in monitoring (daily) signs of aggressiveness, impulsivity, akathisia, hypomania, mania, irritability, or any unusual changes in behavior. Ch discontinuing the antidepressant medication may be considered in patients with persistent worsening depress symptoms are abrupt in onset, severe, or were not part of the patient's initial presentation (Prod Info ABILIFY ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

3.3.15 Respiratory Effects

3.3.15.A Upper respiratory infection

1) Incidence: 6% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally
2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving arip in addition to continued antidepressant therapy (n=371), compared with antidepressant therapy only (n=366), 6% versus 4% of patients, respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY

2008).

3.3.16 Other

Death

Extrapyramidal disease

Fatigue

Neuroleptic malignant syndrome

3.3.16.A Death

1) Elderly patients with dementia-related psychosis (unapproved use) treated with aripiprazole had a 1.6 to 1 placebo (4.5% vs 2.6%) in 17 placebo-controlled clinical studies (modal duration 10 weeks). The cause of de cardiovascular events including heart failure, or infectious events including pneumonia (Prod Info ABILIFY(R) ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

2) Results of a population-based, retrospective cohort study demonstrated that the use of conventional antip risk for death than atypical antipsychotics when administered to elderly patients (aged 66 years and older) wi use and conventional versus atypical antipsychotic use pair-wise comparisons were made. A total of 27,259 r dementia cohort was stratified based on place of residence (community versus long-term care facilities). In or status, propensity score matching was used. The primary outcome of the study was all-cause mortality. The r and 180 days after the antipsychotic medications were initially dispensed. There was a statistically significant associated with new use of atypical antipsychotic medications compared with nonuse in both the community- 1.31 (95% confidence interval (CI), 1.02 to 1.70); absolute risk difference, 0.2 percentage point) and long-ter 1.15 to 2.07); absolute risk difference, 1.2 percentage points). For both cohorts, the risk associated with atypi days. The risk for death associated with conventional antipsychotics was even greater than the risk identified adjusted HR for the community-dwelling cohort was 1.55 (95% CI, 1.19 to 2.02) and 1.26 (95% CI, 1.04 to 1.5 difference for both was 1.1 percentage points). The risk appeared to persist to 180 days for both groups. Son unknown or unmeasured confounders may influence the results and cause of death could not be examined (

3) Results of a population-based, retrospective cohort study demonstrated comparable to possibly greater ris conventional antipsychotic medications in the elderly (aged 65 years and older) compared with atypical antips patients with cancer and included only new users of antipsychotic medications. The primary study outcome w potential confounders was measured based on healthcare utilization data within 6 months before the initiatior elderly patients identified, 12,882 and 24,359 received conventional and atypical antipsychotic medications, r conventional drug group within the first 180 days was 14.1% compared with 9.6% in the atypical drug group (confidence interval (CI), 1.39 to 1.56). In the multi-variable analysis which controlled for potential confounders death within 180 days for conventional versus atypical drug therapy was 1.32 (95% CI, 1.23 to 1.42). When tl antipsychotic drugs were compared with risperidone, the mortality ratio associated with haloperidol was 2.14 (95% CI, 1.19 to 1.40), while there was no difference associated with olanzapine. The increased mortality risk was greatest when doses higher (above median) doses were used (mortality ratio 1.67; 95% CI, 1.5 to 1.86) (mortality ratio 1.6; 95% CI, 1.42 to 1.8). Confirmatory analyses consisting of multi-variable Cox regression, p estimation confirmed the results of the study (Schneeweiss et al, 2007).

4) The findings of one meta-analysis suggest that there may be a small increased risk of death associated w the treatment of dementia in elderly patients. The study analysis (n=5110), including 15 randomized, double-l of antipsychotic use (ie, aripiprazole (n=3), olanzapine (n=5), quetiapine (n=3), risperidone (n=5)) in elderly p dementia, found that death occurred more often in patients receiving atypical antipsychotic therapy as compa respectively). The overall odds ratio, as assessed by meta-analysis, for death in elderly patients receiving aty was 1.54 (95% CI, 1.06 to 2.23; p=0.02), and the risk difference was 0.01 (95% CI, 0.004 to 0.02; p=0.01). O antipsychotic use was 1.65 (95% CI, 1.19 to 2.29; p=0.003); however this increased risk was only identified w analyses of individual drugs did not show a statistically significant increased risk. A similar dropout rate was c treated patients (32.2% vs 31.4%, respectively), with no significant difference in dropouts found by meta-anal

5) The results of a retrospective cohort study indicate that conventional antipsychotic agents are at least as l increase the risk of death among elderly patients 65 years of age or older. The study included 9,142 new use years) and 13,748 new users of atypical agents (mean age, 83.5 years). A higher adjusted relative risk of dea conventional antipsychotics as compared with atypical antipsychotics at all time points studied after beginnin 1.27 to 1.49; less than 40 days: RR, 1.56; 95% CI, 1.37 to 1.78; 40 to 79 days: RR, 1.37; 95% CI, 1.19 to 1.5 1.41). In addition, the adjusted risks of death observed in patients with dementia (RR, 1.29; 95% CI, 1.15 to 1 1.30 to 1.63), in a nursing home (RR, 1.26; 95% CI, 1.08 to 1.47), or not in a nursing home (RR, 1.42; 95% C of conventional antipsychotic therapy as compared with atypical antipsychotic use. This risk appeared to be c higher dose (ie, greater than the median) conventional antipsychotics (RR, 1.73; 95% CI, 1.57 to 1.90). Addit optimum care of elderly patients requiring antipsychotic therapy are needed so that appropriate guidance reg provided (Wang et al, 2005).

3.3.16.B Extrapyramidal disease

See Drug Consult reference: NEUROLEPTIC-INDUCED EXTRAPYRAMIDAL REACTIONS

3.3.16.C Fatigue

1) Incidence: 2% to 11% (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(

2) In pooled data of 2 placebo-controlled trials of adult patients with major depressive disorder receiving oral weeks in addition to continued antidepressant therapy (n=371) or antidepressant therapy alone (n=366), fatig respectively (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disin

3) In a pooled analysis of trials in which adult patients with schizophrenia or bipolar mania received either ari or placebo (n=1166), fatigue was reported in 6% of patients receiving aripiprazole compared with 4% of patie schizophrenia received acute therapy up to 6 weeks and patients with bipolar mania received treatment up to oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

4) In a pooled analysis of trials in which adult patients with agitation associated with schizophrenia or bipolar mg/day or greater IM injection (n=501) or placebo (n=220), fatigue was reported in 2% of patients receiving a receiving placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally

5) In a short-term, placebo-controlled trial in which pediatric patients age 10 to 17 years with bipolar mania re orally or placebo, fatigue was reported in 11% of the aripiprazole group (n=197) compared with 4% of the pla tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

6) In a pooled analysis of trials in which pediatric patients age 10 to 17 years with schizophrenia or bipolar m mg/day or greater) (n=399) or placebo (n=197), fatigue was reported in 7% of patients receiving aripiprazole placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegr

3.3.16.D Neuroleptic malignant syndrome

1) Incidence: rare (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orall

2) Neuroleptic malignant syndrome (NMS) has been reported rarely in the worldwide clinical database in pat may include hyperpyrexia, muscle rigidity, altered mental status, evidence of autonomic instability, elevated c (rhabdomyolysis), and acute renal failure. The diagnosis of patients with NMS is complicated; differential diag serious illness and untreated extrapyramidal signs, as well as central anticholinergic toxicity, heat stroke, drug diagnosed, antipsychotic drugs and other concomitant drugs that are not essential should be immediately dis and receive intensive treatment for presenting symptoms and any concomitant serious medical problems. Fo require antipsychotic drug treatment and reintroduction of such therapy should be carefully considered and th recurrence of NMS (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) oral

3) Neuroleptic malignant syndrome (NMS) was reported in a 71-year-old female with pre-hypertension and p to an abrupt change in her baseline mental status, skin flushing, and worsening tardive dyskinesia including g upper extremity choreiform movements. In the previous 9 months, the patient was receiving aripiprazole 15 m buccal oral muscle movement and upper arm athetosis 4 weeks prior to admission. Despite aripiprazole dose hospitalization and a 1-week treatment of benztropine 1 mg/day for extrapyramidal reactions, her clinical con revealed a rectal temperature of 106.5 Fahrenheit, pulse of 137 beats per minute, respiratory rate of 22 breat ranging between 99/54 mmHg and 147/100 mmHg. The patient exhibited distress, marked muscle rigidity, ch worsening slurred speech that became muted. CPK rose from 78 units/L at admission to 103 units/L eight ho leukocytosis, unremarkable metabolic panel, urine analysis, and normal aged-consistent atrophic changes or with NMS and aripiprazole was discontinued. She was given intravenous hydration, supportive cooling therap benztropine 1 mg/day, and lorazepam 1 to 2 mg as needed. Five days later, the patient stabilized aside from to the care of her psychiatrist in a psychiatric hospital (Molina et al, 2007).

4) In a case report, a 14-year-old girl with psychotic depression and mental retardation developed partial neu aripiprazole treatment. The patient had no prior experience with any extrapyramidal symptoms with her past during previous hospitalizations. She did not experience any side effects from quetiapine 300 mg daily which aripiprazole 5 mg daily. Within 48 hours of aripiprazole initiation, the patient presented with tremors, drooling, incontinence, and agitation. The patient was disoriented and had slurred, incoherent speech with fluctuating (rpm) and a pulse of 131 beats per minute (bpm). The patient's serum creatine phosphokinase (CPK) increas myoglobinuria. However, her temperature and blood pressure were within normal parameters. Her white bloo (9300 per millimeter cubed (mm(3)) of blood) and urine toxicology screen was negative. Along with other sup sodium bicarbonate to alkalinize the urine. After 2 days, the patients CPK decreased to 6157 international un every 4 hours was administered to treat the tremors and agitation. The patient eventually recovered and retu

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info Abilify(TM), 2002) (All Trime

a) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies

See Drug Consult reference: PREGNANCY RISK CATEGORIES

2) Crosses Placenta: Unknown

3) Clinical Management

a) There is insufficient clinical experience with the use of aripiprazole in pregnancy to confirm its safety in tha a successful outcome in a 27-year-old, schizoaffective woman who was treated with aripiprazole during differ According to the manufacturer, aripiprazole was teratogenic and fetotoxic in animal studies (Prod Info Abilify(caution should be exercised with aripiprazole use pregnant women.

4) Literature Reports

a) In the case of a 27-year-old, medically healthy, schizoaffective woman, exposure to aripiprazole during dif
associated with fetal toxicity. The patient was being effectively treated with aripiprazole 15 mg/day when she
aripiprazole was withdrawn following a risk-to-benefit analysis. However, at week 20 of gestation, the patient
a revised risk-to-benefit analysis, aripiprazole was re-initiated at a 10 mg/day dose which was continued throu
weight gain at full term was 10 kg. Ultrasound scans and laboratory tests for serum glucose, thyroid function,
were normal. Although spontaneous labor occurred at term, development of unexplained fetal distress in the
section which resulted in the birth of a male infant weighing 3.25 kg. Failure to establish lactation led to the in
follow-up, the infant had achieved normal milestones (Mendhekar et al, 2006).

B) Breastfeeding

1) Thomson Lactation Rating: Infant risk cannot be ruled out.

a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk wh
potential benefits of drug treatment against potential risks before prescribing this drug during breastfeeding.

2) Clinical Management

a) It is not known whether aripiprazole is excreted into human breast milk and the potential for adverse effec
drug are unknown. It is not known if aripiprazole affects the quantity or composition of breastmilk. According t
into the milk of lactating rats (Prod Info Abilify(TM), 2002a).

3) Literature Reports

a) No reports describing the use of aripiprazole during human lactation or measuring the amount, if any, of th

a) Active Metabolites

1) dehydro-aripiprazole (Prod Info ABILIFY(R) oral tablets, orally-disintegrating tablets, oral solution, IM

3.5 Drug Interactions

3.5.1 Drug-Drug Combinations

Carbamazepine

Fluoxetine

Itraconazole

Ketoconazole

Paroxetine

Quinidine

Ranolazine

3.5.1.A Carbamazepine

1) Interaction Effect: decreased aripiprazole concentrations

2) Summary: Coadministration of carbamazepine 200 milligrams (mg) twice daily with aripiprazole 30 mg on
concentration (Cmax) and the area under the concentration-time curve (AUC) values of both aripiprazole and
approximately 70%. Aripiprazole is partly metabolized by cytochrome P450 3A4 (CYP3A4) enzymes. Coadm
CYP3A4 inducer, could increase aripiprazole clearance causing decreased blood concentrations. The dose c
administered concurrently with carbamazepine. If therapy with carbamazepine is discontinued, the dose of ar
Info ABILIFY(R) oral tablets, oral solution, 2005).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Coadministration of aripiprazole and carbamazepine has resulted in decreased arip
aripiprazole should be doubled when it is administered concurrently with carbamazepine. If therapy with carb
aripiprazole should then be decreased.

7) Probable Mechanism: induction of CYP3A4-mediated aripiprazole metabolism

3.5.1.B Fluoxetine

1) Interaction Effect: increased aripiprazole levels

2) Summary: Aripiprazole is partly metabolized by cytochrome P450 2D6 (CYP2D6) enzymes. Coadministra
fluoxetine, may inhibit aripiprazole elimination causing increased blood concentrations. Consider a dosage re
coadministered. If therapy with fluoxetine is discontinued, the dose of aripiprazole should then be increased (
solution, 2005).

3) Severity: moderate

4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Increased aripiprazole plasma levels may result if used concomitantly with fluoxetin aripiprazole when these agents are coadministered. If therapy with fluoxetine is discontinued, the dose of arip
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of aripiprazole

3.5.1.C Itraconazole
1) Interaction Effect: increased aripiprazole concentrations
2) Summary: Coadministration of ketoconazole 200 milligrams (mg) per day for 14 days with a single 15 mg concentration-time curve (AUC) values of both aripiprazole and its active metabolite, dehydro-aripiprazole, by partly metabolized by cytochrome P450 3A4 (CYP3A4) enzymes. Ketoconazole, a potent CYP3A4 inhibitor, c in increased blood concentrations. Coadministration of aripiprazole with itraconazole, also a strong CYP3A4 i Consider reducing aripiprazole dose by one-half when these agents are coadministered. If therapy with itracc aripiprazole should then be increased (Prod Info ABILIFY(R) oral tablets, oral solution, 2005).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Increased aripiprazole plasma levels may result if used concomitantly with itraconaz approximately one-half when these agents are coadministered. If therapy with itraconazole is discontinued, th increased.
7) Probable Mechanism: inhibition of CYP3A4-mediated aripiprazole metabolism

3.5.1.D Ketoconazole
1) Interaction Effect: increased aripiprazole concentrations
2) Summary: Coadministration of ketoconazole 200 milligrams (mg) daily for 14 days with a single 15 mg arip under the concentration-time curve (AUC) values of both aripiprazole and its active metabolite, dehydro-aripip Aripiprazole is partly metabolized by cytochrome P450 3A4 (CYP3A4) enzymes. Coadministration with ketoc inhibit aripiprazole elimination resulting in increased blood concentrations. Reduce the aripiprazole dose to or are coadministered. If therapy with ketoconazole is discontinued, the dose of aripiprazole should then be incr solution, 2005).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Coadministration of aripiprazole and ketoconazole has resulted in increased aripipr dose to one-half of its normal dose when these agents are coadministered. If therapy with ketoconazole is dis then be increased.
7) Probable Mechanism: inhibition of CYP3A4-mediated aripiprazole metabolism

3.5.1.E Paroxetine
1) Interaction Effect: increased aripiprazole levels
2) Summary: Aripiprazole is partly metabolized by cytochrome P450 2D6 (CYP2D6) enzymes. Coadministra paroxetine, may inhibit aripiprazole elimination causing increased blood concentrations. Consider a dosage r are coadministered. If therapy with paroxetine is discontinued, the dose of aripiprazole should then be increas solution, 2005).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Increased aripiprazole plasma levels may result if used concomitantly with paroxeti aripiprazole when these agents are coadministered. If therapy with paroxetine is discontinued, the dose of ari
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of aripiprazole

3.5.1.F Quinidine
1) Interaction Effect: increased aripiprazole levels
2) Summary: Coadministration of quinidine 166 milligrams (mg) daily for 13 days with a single 10 mg dose of concentration-time curve (AUC) value of aripiprazole by 112% and decreased the AUC of its active metabolit is partly metabolized by cytochrome P450 2D6 (CYP2D6) enzymes. Coadministration with quinidine, a poten elimination resulting in increased blood concentrations. Reduce the aripiprazole dose to one-half of its norma If therapy with quinidine is discontinued, the dose of aripiprazole should then be increased (Prod Info ABILIF
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Coadministration of aripiprazole and quinidine has resulted in increased aripiprazol dose to one-half of its normal dose when these agents are coadministered. If therapy with quinidine is discon increased.
7) Probable Mechanism: inhibition of CYP2D6-mediated metabolism of aripiprazole

3.5.1.G Ranolazine
1) Interaction Effect: an increase in aripiprazole serum concentration

2) Summary: Ranolazine, and/or its metabolites, partially inhibit cytochrome P450-2D6-mediated aripiprazole aripiprazole exposure. Use caution when these agents are coadministered. Monitor patients for signs of incre aripiprazole doses as needed (Prod Info RANEXA(R) extended-release oral tablets, 2008).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concurrent administration of aripiprazole and ranolazine may increase aripiprazole these agents are coadministered. Monitor patients for signs of increased aripiprazole adverse effects and low RANEXA(R) extended-release oral tablets, 2008).
7) Probable Mechanism: ranolazine inhibition of cytochrome P450-2D6-mediated metabolism of aripiprazole

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters

A) Therapeutic
1) Physical Findings
a) Monitor patients for improvement of schizophrenic (positive and negative), bipolar, or depressive sympton

B) Toxic
1) Laboratory Parameters
a) Elevated creatine phosphokinase, myoglobinuria, and acute renal failure may be signs of neuroleptic mali experienced previous NMS, they should be closely monitored since NMS may reoccur (Prod Info ABILIFY(R) ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
b) Monitor patients with an established diagnosis of diabetes mellitus for worsening of glucose control during Patients with risk factors for diabetes mellitus (eg, obesity, family history of diabetes) who are beginning treat undergo fasting blood glucose testing at the beginning of treatment and periodically throughout treatment. Pa during atypical antipsychotic treatment should undergo fasting blood glucose testing (Prod Info ABILIFY(R) o DISCMELT(R) orally disintegrating tablets, 2008).
2) Physical Findings
a) Clinical worsening, suicidality, or unusual changes in behavior, should be monitored closely, particularly d times of dose changes and especially in children, adolescents, and young adults age 24 years and younger. emerging suicidality include anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, in hypomania, and mania. Instruct family members and caregivers to monitor daily for these symptoms and to re discontinuing treatment if symptoms are severe, abrupt in onset, were not part of the patient's presenting sym persistently worse, or where emergent suicidality or symptoms are precursors of worsening depression or sui solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
b) Elderly patients treated with aripiprazole for dementia-related psychosis (unapproved use) should be mon ischemic attack, and pneumonia; any cardiovascular, cerebrovascular, or infectious events.
c) Abnormal-movement detection (extrapyramidal symptoms) and early signs of tardive dyskinesia (eg, worm monitored, especially in the elderly and in elderly women. Longer duration of treatment and increased total cu tardive dyskinesia, but may also develop after brief treatment periods at low doses. Consider discontinuing tr dyskinesia appear following therapy (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DI 2008).
d) Blood pressure and heart rate determinations should be monitored, particularly in patients with preexisting conditions which predispose patients to hypotension (eg, dehydration, hypovolemia) or concomitant antihype
e) Body temperature regulation may be impaired especially in patients with conditions contributing to elevatio exercise, extreme heat exposure, dehydration) or concomitant drugs with anticholinergic effects.
f) ECG monitoring at baseline and periodically during therapy has been suggested (Pacher & Kecskemeti, 2
g) Esophageal dysmotility and aspiration should be monitored, especially elderly patients and in patient with use).
h) Excessive sedation and orthostatic hypotension should be monitoring in patients receiving concomitant pa (R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
i) Hyperpyrexia, muscle rigidity, altered mental status, irregular pulse or blood pressure, tachycardia, diapho

indicative of neuroleptic malignant syndrome (NMS). If patients have experienced previous NMS, they should
(Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tab
j) Polydipsia, polyuria, polyphagia, and weakness may be symptoms of hyperglycemia. Patients who exhibit
antipsychotic treatment should undergo fasting blood glucose testing. In some instances, hyperglycemia has
stopped; however, some patients required ongoing antidiabetic treatment despite discontinuation of the susp
tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).
k) Seizures should be monitored in patients with a history of seizures, or with conditions that lower the seizu
tablets, oral solution, IM injection, ABILIFY DISCMELT(R) orally disintegrating tablets, 2008).

4.2 Patient Instructions

A) Aripiprazole (By mouth)

Aripiprazole

Treats mental illnesses, including schizophrenia and some symptoms of bipolar disorder (manic episodes). Also u
depression.

When This Medicine Should Not Be Used:
You should not use this medicine if you or your child have had an allergic reaction to aripiprazole.

How to Use This Medicine:
Liquid, Tablet, Dissolving Tablet

Your doctor will tell you how much of this medicine to use and how often. Your dose may need to be changed
best for you. Do not use more medicine or use it more often than your doctor tells you to.
You may take this medicine with or without food.
Measure the oral liquid medicine with a marked measuring spoon, oral syringe, or medicine cup.
If you are using the oral disintegrating tablet, make sure your hands are dry before you handle the tablet. Do
tablet until you are ready to take it. Remove the tablet from the blister pack by peeling back the foil, then takir
through the foil. Place the tablet on your tongue. It should melt quickly. If possible, take the tablet without any
Do not split the tablet.
This medicine should come with a Medication Guide. Read and follow these instructions carefully. Ask your d
Ask your pharmacist for the Medication Guide if you do not have one. Your doctor might ask you to sign som
information.

If a Dose is Missed:

If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next d
skip the missed dose. Do not use extra medicine to make up for a missed dose.

How to Store and Dispose of This Medicine:

Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light. Ope
for up to 6 months after opening, but not beyond the expiration date on the bottle.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after
also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, a

Make sure your doctor knows if you are also using medicine to lower blood pressure, such as hydrochlorothia
Accupril®, Cozaar®, Diovan®, Lotrel®, Norvasc®, Toprol®, Zestril®.
Tell your doctor if you are also using carbamazepine (Tegretol®), fluoxetine (Prozac®), ketoconazole (Nizora
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and a
sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:

Make sure your doctor knows if you or your child are pregnant or breastfeeding, or if you have heart disease
have a history of heart attack, stroke, seizures, drug abuse, alcohol abuse, or if you have ever experienced s
(NMS) in the past.
For some children, teenagers, and young adults, this medicine can increase thoughts of suicide. Tell your do
your child start to feel more depressed and have thoughts about hurting yourselves. Report any unusual thou
child, especially if they are new or are getting worse quickly. Make sure the doctor knows if you or your child
big increase in energy, or start to act reckless. Also tell the doctor if you or your child have sudden or strong f
restless, violent, or scared. Let the doctor know if you, your child, or anyone in your family has bipolar disorde
tried to commit suicide.
This medicine may raise your blood sugar. Tell your doctor if you or your child have diabetes. It may be nece
more often. The oral liquid form of this medicine also contains sugar.
Tardive dyskinesia (a movement disorder) may occur and may not go away after you stop using the medicine
your child have any of the following symptoms while taking this medicine: lip smacking or puckering, puffing c
of the tongue, uncontrolled chewing movements, or uncontrolled movements of the arms and legs.

Older adults may be more sensitive to the side effects of this medicine, including stroke. Make sure the docto
medicine has Alzheimer's disease. This medicine is not used to treat behavioral problems in older adults with
The oral disintegrating tablet form of this medicine contains phenylalanine. Make sure your doctor knows if yo
This medicine may make you or your child dizzy or drowsy. Avoid driving, using machines, or doing anything
alert. You may also feel lightheaded when getting up suddenly from a lying or sitting position, so get up slowly
You or your child may get overheated more easily while you are using this medicine. It might reduce how mu
you do not sweat enough. Be careful if you exercise often or are in high heat or humidity. If your body gets to
confused. You might vomit or have an upset stomach. Call your doctor if you are too hot and can not cool dow

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, d
Anxiety, irritability, nervousness, restlessness, or trouble sleeping.
Change in how much or how often you urinate.
Chest pain, fast or slow heartbeat.
Confusion, unusual behavior, depressed mood, or thoughts of hurting yourself or others.
Excessive hunger or thirst, increased urination, and weakness.
Extreme sleepiness or weakness with nausea, vomiting, or diarrhea.
Fever, sweating, confusion, uneven heartbeat, or muscle stiffness.
Lightheadedness, dizziness, or fainting.
Problems with balance or walking.
Seizures or tremors.
Swelling in your hands, ankles, or feet.
Trouble swallowing.
Twitching or muscle movements you cannot control (often in your face, tongue, or jaw).
Unusual bleeding, bruising, or weakness.

If you notice these less serious side effects, talk with your doctor:
Blurred vision.
Change in appetite.
Dry mouth or drooling.
Headache or flu symptoms.
Muscle or joint pain.
Nausea, vomiting, constipation, or upset stomach.
Runny or stuffy nose.
Tiredness.
Unexpected weight gain or loss.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

B) Aripiprazole (Injection)
Aripiprazole

Treats agitation associated with schizophrenia or bipolar disorder (manic or mixed).

When This Medicine Should Not Be Used:
You should not receive this medicine if you have had an allergic reaction to aripiprazole.

How to Use This Medicine:
Injectable
Your doctor will prescribe your exact dose and tell you how often it should be given. This medicine is given as
A nurse or other trained health professional will give you this medicine.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, a
Make sure your doctor knows if you are also using medicine to lower blood pressure, such as hydrochlorothia
Accupril®, Cozaar®, Diovan®, Lotrel®, Norvasc®, Toprol®, Zestril®.
Tell your doctor if you are also using carbamazepine (Tegretol®), fluoxetine (Prozac®), ketoconazole (Nizora
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and a
sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:
Make sure your doctor knows if you are pregnant or breastfeeding, or if you have heart disease or low blood
of heart attack, stroke, seizures, drug abuse, alcohol abuse, or if you have ever experienced symptoms of ne
past.
For some children, teenagers, and young adults, this medicine can increase thoughts of suicide. Tell your do
your child start to feel more depressed and have thoughts about hurting yourselves. Report any unusual thou
child, especially if they are new or are getting worse quickly. Make sure the doctor knows if you or your child

big increase in energy, or start to act reckless. Also tell the doctor if you or your child have sudden or strong f
restless, violent, or scared. Let the doctor know if you, your child, or anyone in your family has bipolar disorde
tried to commit suicide.
Older adults may be more sensitive to the side effects of this medicine, including stroke. Make sure the docto
medicine has Alzheimer's disease. This medicine is not used to treat behavioral problems in older adults with
This medicine may raise your blood sugar. Tell your doctor if you have diabetes. It may be necessary to mea
Tardive dyskinesia (a movement disorder) may occur and may not go away after you stop using the medicine
your child have any of the following symptoms while taking this medicine: lip smacking or puckering, puffing c
of the tongue, uncontrolled chewing movements, or uncontrolled movements of the arms and legs.
This medicine may make you dizzy or drowsy. Avoid driving, using machines, or doing anything else that cou
also feel lightheaded when standing or sitting up straight, so stand up or sit up slowly.
You or your child may get overheated more easily while you are using this medicine. It might reduce how mu
you do not sweat enough. Be careful if you exercise often or are in high heat or humidity. If your body gets to
confused. You might vomit or have an upset stomach. Call your doctor if you are too hot and can not cool do

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, c
Anxiety, irritability, nervousness, restlessness, or trouble sleeping.
Change in how much or how often you urinate.
Chest pain, fast or slow heartbeat.
Confusion, unusual behavior, depressed mood, or thoughts of hurting self or others.
Dry mouth, increased thirst or hunger, or muscle cramps.
Fever, sweating, confusion, uneven heartbeat, or muscle stiffness.
Lightheadedness, dizziness, or fainting.
Seizures or tremors.
Severe drowsiness or sleepiness.
Trouble swallowing.
Twitching or muscle movements you cannot control (often in your face, tongue, or jaw).
Unusual bleeding or bruising.
Unusual tiredness or weakness.

If you notice these less serious side effects, talk with your doctor:
Headache or flu symptoms.
Nausea, vomiting, or upset stomach.
Redness, pain, swelling, itching, blistering, or rash where the shot was given.
Weight gain or loss.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Current users of atypical antipsychotic drugs (including aripiprazole) and typical antipsychotic drugs had a similar c
according to a retrospective cohort of 93,300 adult users of antipsychotic drugs and 186,600 matched controls. The st
(mean 45.7 +/- 11.8 years) with similar cardiovascular risk at baseline who had at least one filled prescription and had
years. Sudden cardiac death was defined as occurring in the community and excluded deaths of patients admitted to t
extrinsic causes, or causes not related to ventricular tachyarrhythmia. Current use was defined as the interval betwee
end of the day's supply. Low and high doses was defined as comparable to less than 100 milligrams (mg) of chlorpron
chlorpromazine 300 mg or greater, respectively. The adjusted rate of sudden cardiac death (incidence-rate ratio) in cu
79,589 person-years was 2.26 (95% CI, 1.88 to 2.72, p less than 0.001) which was similar to the risk in current users c
years which was 1.99 (95% CI, 1.68 to 2.34, p less than 0.001). The risk of sudden cardiac death significantly increase
atypical antipsychotic drug groups. In atypical antipsychotic use, the incidence rate ratio increased from 1.59 (95% CI,
2.25 to 3.65) in high-dose use. To limit the effects of confounding of the study results, there was a secondary analysis
propensity score, which resulted in a similar risk of sudden death as the primary cohort analysis (Ray et al, 2009). In a
Medicine, it has been suggested that antipsychotic drugs continue to be used in patients with clear evidence of benefit
risk profiles (eg, elderly patients), there should be an age-dependent justification required prior to administration. It has
tested) that ECGs be performed before and shortly after initiation of antipsychotic therapy to screen for existing or eme
& Avorn, 2009).

B) Agitation Associated with Schizophrenia or Bipolar Mania

1) Aripiprazole as an intramuscular injection is approved for the treatment of agitation associated with schizophre
Info ABILIFY(R) oral tablets, oral solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007).

2) Aripiprazole was more effective than placebo for the acute treatment of agitation in patients with schizophrenia
disorder in a dose-ranging, multicenter, randomized, double-blind clinical trial (Tran-Johnson et al, 2007).

3) A double-blind, placebo-controlled study demonstrated that intramuscular aripiprazole was noninferior to intrar
in voluntarily hospitalized agitated patients with schizophrenia or schizoaffective disorder (Andrezina et al, 2006).

4) In one short-term (24-hour), placebo-controlled trial (n=291), intramuscular aripiprazole was statistically superi
agitation in patients with Bipolar I Disorder (manic or mixed; using the Positive and Negative Syndrome Scale (PA
Clinical Global Impression of Improvement (CGI-I) scale scores) (Prod Info ABILIFY(R) oral tablets, oral solution,
disintegrating tablets, 2007).

C) Bipolar I Disorder, Mixed or Manic Episodes

1) Aripiprazole is indicated for the treatment of manic and mixed episodes associated with bipolar I disorder with and maintenance therapy) and pediatric patients age 10 to 17 years (acute therapy only) (Prod Info ABILIFY(R) o DISCMELT(TM) orally disintegrating tablets, 2007).

2) In a multicenter, randomized, double-blind, placebo-controlled study, aripiprazole was more effective than plac episodes in patients (n=262) with bipolar disorder (Keck et al, 2003).

3) In a randomized, double-blind, parallel-group trial (n=161), maintenance treatment with oral aripiprazole, at do to 26 weeks, resulted in a longer time to relapse compared to placebo in adults with a recent manic or mixed bipo aripiprazole (Keck et al, 2006).

D) Major Depressive Disorder, Adjunctive Treatment in Patients Receiving Antidepressants

1) Aripiprazole is indicated for use as an adjunctive treatment to antidepressants for major depressive disorder (F IM injection, DISCMELT(TM) orally disintegrating tablets, 2007).

2) In two 6-week, placebo-controlled trials (n=743), treatment with aripiprazole was superior to placebo in reducir depressive disorder (MDD) and an inadequate response to prior antidepressant therapies; additionally, one of the functioning with aripiprazole compared to placebo (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, D 2007).

E) Schizophrenia

1) Aripiprazole is indicated for the treatment of schizophrenia in adults and pediatric patients 13 to 17 years of ag solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007).

2) Aripiprazole therapy was effective compared to placebo in the prevention of relapse in patients with chronic, st randomized, double-blind, placebo-controlled study (n=310) (Anon, 2003).

3) In a placebo-controlled, phase III study involving relapsed schizophrenic or schizoaffective patients (n=414), a 10 mg daily (fixed doses) were each statistically superior to placebo with regard to changes in Positive and Negat Psychiatric Rating Scale (BPRS) total scores; based on responder analysis (a 30% reduction in PANSS-total scor aripiprazole was significantly more effective than placebo, whereas haloperidol was not (Kane et al, 2000).

4) In a 6-week, placebo-controlled trial in adolescents 13 to 17 years of age, oral aripiprazole at doses of 10 or 3(placebo in the treatment of schizophrenia (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, DISCMEL

See Drug Consult reference: FIRST- VS SECOND-GENERATION ANTIPSYCHOTIC AGENTS FOR SCHIZOPHREN

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) Aripiprazole is an atypical antipsychotic agent (quinolinone derivative). It exhibits relatively high affinity for dop HT1A and 5-HT2A receptors (Prod Info Abilify(TM), 2002b; Lawler et al, 1999; Inoue & Nakata, 2001). The efficac to partial agonist activity at D2 and 5-HT1A receptors (Lawler et al, 1999; Prod Info Abilify(TM), 2002b; Inoue & N antagonist activity at 5-HT2A receptors has also been speculated (Prod Info Abilify(TM), 2002b).

2) However, other actions may be involved. In vitro data have indicated D2- agonist activity of aripiprazole at pres at postsynaptic D2 receptors (regulating inhibition of cAMP synthesis) (Inoue et al, 2001; Inoue & Nakata, 2001; M Prioleau et al, 1998). These dual effects are seen at the same dose level (concentration) (Lawler et al, 1999), and drugs (typical and atypical). Preclinical and clinical data suggest that these actions minimize extrapyramidal and e (Inoue et al, 2001; Inoue & Nakata, 2001; Lawler et al, 1999).

3) Electrophysiological studies in animals suggest that aripiprazole acts as a dopamine-D2 agonist on dopaminer as a dopamine-D2 (and possibly D3) antagonist on striatal neurons and nucleus accumbens neurons (Matsubaya

4) In a small magnetoencephalographic study involving schizophrenic patients (n=5), treatment with aripiprazole decrease (normalizing effect) of abnormal delta and theta activity, loosely correlating with decreases in Positive a (Canive et al, 1998). The authors suggest evaluation of delta activity (near-normalization) as a predictor of respon accumulation in a larger number of patients is needed.

B) REVIEW ARTICLES

1) Pharmacologic basis for using partial agonists in schizophrenia (Inoue & Nakata, 2001).

4.5 Therapeutic Uses

Bipolar disorder - Psychomotor agitation

Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes

Bipolar I disorder, Monotherapy, manic or mixed episodes

Borderline personality disorder

Dementia

Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants

Psychomotor agitation - Schizophrenia

Schizophrenia

4.5.A Bipolar disorder - Psychomotor agitation

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes (injectable only); Pediatric, no
Efficacy: Adult, Effective
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole injection is approved for the treatment of agitation associated with schizophrenia and bipolar
(R) oral tablets, oral solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007a).
In one short-term (24-hour), placebo-controlled trial, intramuscular aripiprazole was statistically superior
in patients with Bipolar I Disorder (manic or mixed; using the Positive and Negative Syndrome Scale [PA
Clinical Global Impression of Improvement [CGI-I] scale scores) (Prod Info ABILIFY(R) oral tablets, oral s
disintegrating tablets, 2007a).

3) Adult:

a) In one short-term (24-hour), placebo-controlled trial (n=291), intramuscular aripiprazole (fixed doses of 9.7
statistically superior to placebo in improving symptoms of agitation in patients with Bipolar I Disorder (manic o
Syndrome Scale [PANSS] Excited Component scores and the Clinical Global Impression of Improvement [CG
active comparator treatment arm of lorazepam injection. Agitated patients predominantly meeting DSM-IV cri
received up to 3 injections during the 24-hour treatment period, with the second injection administered after th
efficacy measure was evaluated. All enrolled patients were judged by the clinical investigators as clinically ag
treatment with intramuscular medication. Additionally, all patients exhibited a level of agitation that met or exc
the five items comprising the PANSS Excited Component (eg; poor impulse control, tension, hostility, uncoop
least 2 individual item scores of 4 or greater using a 1 to 7 scoring system (1=absent, 4=moderate, 7=extrem
Component score ranged from 15 to 24 (out of a maximum score of 35) with the mean baseline score of 19; t
agitation with some patients experiencing mild or severe levels of agitation. The primary efficacy measure in t
Component from baseline to 2 hours post-injection. The CGI-I scale was a key secondary measure. After the
15 mg) were statistically superior to placebo in the PANSS Excited Component and on the CGI-I scale. There

tablets, 2007a).

4.5.B Bipolar I disorder, Adjunctive therapy with lithium or valproate for acute manic or mixed episodes

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, yes (age 10 years and older)
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole is indicated for use in adults and children age 10 years or older as adjunctive therapy with lit
episodes of bipolar I disorder, with or without psychotic features (Prod Info ABILIFY(R) oral tablets, solut
2008).
Aripiprazole, added to either valproate or lithium, significantly improved symptoms of mania as early as o
who were partially nonresponsive to monotherapy during a randomized, placebo-controlled trial (Vieta et

3) Adult:

a) Aripiprazole, added to either valproate or lithium, significantly improved symptoms of mania as early as or
disorder (manic or mixed episodes) who were partially nonresponsive to monotherapy during a randomized, p
a 3 to 42 day screening phase to stabilize lithium (serum levels of 0.6 to 1 millimole/liter) or valproate (serum
therapy. Once stabilized, patients entered the baseline phase where they continued on valproate or lithium th
were allowed during week 1 (4 milligrams (mg) or less/day) and week 2 (3 mg or less/day) of this phase. Prop
daily) was also permitted during this time. If after 2 weeks there was an inadequate clinical response (Young
or greater during the screening phase and 25% or less improvement on the Y-MRS total score), patients were
with either placebo (n=131) or aripiprazole (n=253) 15 mg orally once a day for the 6 week double-blind phas
aripiprazole could be increased to 30 mg orally once a day after 7 days (mean aripiprazole dose at week 6 wa
treatment with benzodiazepines (2 mg or less of lorazepam or equivalents) were allowed for a maximum of 1
primary efficacy measure was the mean change from baseline to week 6 in Y-MRS total score (last observati
4 and weekly thereafter. A key secondary efficacy measure was the mean change from baseline to week 6 in
(CGI-BP) severity of illness (mania) score. At week 6, significantly greater improvements in Y-MRS total scor
treatment group compared with the placebo group (-13.3 (standard deviation (SD) 7.9) and -10.7 (SD 7.6), re
all subsequent endpoints, therapy with aripiprazole plus mood stabilizer resulted in significantly greater impro
than lithium/valproate monotherapy (p less than 0.05). Aripiprazole did not worsen manic symptoms and dem
elevated mood, sexual interest, irritability, speech, disruptive/aggressive behavior, and insight. Additionally, a

significant reductions in CGI-BP severity of illness mania score (-1.9 (SD 1.3)) compared with placebo (-1.6 (
depression was also significantly lower in patients receiving aripiprazole (7.7%) compared with patients recei
suggests that improvement in mania was not associated with a destabilization into depression. Tolerability ar
was similar to that demonstrated in previous aripiprazole monotherapy studies. The most frequently reported
occurred at a significantly greater rate with aripiprazole than with placebo (18.6% and 5.4%, respectively; p=(
adverse events occurred in 9% and 5% of patients receiving aripiprazole and placebo, respectively (Vieta et a

1) Maintenance Therapy

a) It is unclear how long a patient should remain on aripiprazole therapy for the treatment of bipolar
symptomatically stable on aripiprazole monotherapy for at least 6 weeks demonstrated a benefit fro
continued on treatment beyond 6 weeks should be reassessed at regular intervals to determine the
ABILIFY(R) oral tablets, solution, orally disintegrating tablets, IM injection, 2008).

4) Pediatric:

a) The efficacy of adjunctive aripiprazole therapy in pediatric patients 10 years of age and older with bipolar
additional pharmacokinetic comparisons in adults and pediatric patients (Prod Info ABILIFY(R) oral tablets, s
injection, 2008).

4.5.C Bipolar I disorder, Monotherapy, manic or mixed episodes

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, yes (10 to 17 years old (acute therapy))
Efficacy: Adult, Effective; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole is indicated for the treatment of manic and mixed episodes associated with bipolar I disorde
(acute and maintenance therapy) and pediatric patients age 10 to 17 years (acute therapy only) (Prod In
disintegrating tablets, IV injection, 2008).
In a multicenter, randomized, double-blind, placebo-controlled study, aripiprazole was more effective tha
mixed episodes in patients (n=262) with bipolar disorder (Keck et al, 2003).
In a randomized, double-blind, parallel-group trial (n=161), maintenance treatment with oral aripiprazole,
for up to 26 weeks, resulted in a longer time to relapse compared to placebo in adults with a recent mani
stabilized on aripiprazole (Keck et al, 2006).
In a 4 week, double-blind, placebo-controlled study in pediatric patients with bipolar disorder (n=296), tre
symptomatology compared to placebo (Prod Info ABILIFY(R) oral tablets, solution, disintegrating tablets,

3) Adult:

a) Acute Therapy

1) Aripiprazole was more effective than placebo in the treatment of acute manic or mixed episodes in pa
randomized, double-blind, placebo-controlled study, patients (n=262) with bipolar disorder, mixed or mar
(Y-MRS) score of at least 20 received aripiprazole 30 milligrams (mg)/day (reduced to 15 mg/day if need
weeks. Patients were hospitalized for at least the first 2 weeks of treatment. Response was defined as a
50%. From baseline to endpoint, total Y-MRS scores of aripiprazole-treated patients were significantly m
received placebo (mean, -8.2 vs -3.4, respectively; p=0.002). This significant difference was present fron
also significantly higher in aripiprazole-treated patients as compared with placebo at all time points from
0.02) to endpoint (40% vs 19%, respectively; p less than or equal to 0.005). Adverse events were similar
constipation, somnolence, vomiting, akathisia, and accidental injury occurred more than twice as often in
placebo (Keck et al, 2003).

b) Maintenance Therapy

1) In a randomized, double-blind, parallel-group, placebo-controlled trial (n=161), oral aripiprazole, at do
more effective than placebo for preventing relapse in adults with a recent manic or mixed episode who w
double-blind phase, patients (n=567) with bipolar I disorder received open-label treatment with aripiprazo
stable. Stability was defined as a Young Mania Rating Scale (YMRS) total score of 10 or less and a Mon
(MADRS) total score of 13 or less during 4 consecutive visits over a minimum of 6 weeks. Mean YMRS s
and 2.6 +/- 0.3 for patients randomized to placebo and aripiprazole, respectively, at the start of double-bl
+/- 0.4 and 3.9 +/- 0.4, respectively. Following completion of the stabilization phase, 161 patients (mean
phase and were randomly assigned oral aripiprazole (n=78) or placebo (n=83) for up to 26 weeks. Aripip
during the open-label phase, with adjustments made to either 15 or 30 mg/day depending on clinical effe
medications were excluded, except for lorazepam (1 to 2 mg/day) and anticholinergic agents (up to benz
taken 12 hours before rating scale assessments). The primary efficacy measure, evaluated using Kaplar
mood episode, either manic, depressive, or mixed. Relapse was defined by study discontinuation due to
additional or increased doses of non-study medications for mood episode). Although 58% of study patier
n=55), mainly due to lack of efficacy (aripiprazole, n=19 ; placebo, n=36), patients receiving at least 1 do
primary outcome assessment were included in the analysis. The time to relapse was significantly longer
to the placebo-treated patients (p=0.02; hazard ratio (HR) 0.52, 95% confidence interval (CI), 0.3 to 0.91
lower in the aripiprazole group (25%; n=19/77) compared to the placebo group (43%; n=36/83; p=0.013)
the aripiprazole and placebo groups, respectively (p=0.009). Among key secondary efficacy endpoints, t
aripiprazole group vs placebo group (p=0.01; HR, 0.31; 95% CI, 0.12 to 0.77). The time to depressive rel
HR, 0.83; 95% CI, 0.35 to 2.01). However, the study was not powered to detect differences in secondary

episodes of manic (70%) or mixed (30%) symptoms at enrollment. Compared to placebo, the mean char
significantly in favor of aripiprazole during weeks 18 to 26 (p 0.01 to 0.05). There were no significant diffe
mean MADRS total scores. At week 26, the mean changes from baseline in the Clinical Global Impressic
score (aripiprazole, 0.7 vs placebo, 1.3; p=0.02) and mania score (aripiprazole, 0.4 vs placebo, 0.9; p=0.
events in the aripiprazole group included tremor (9.1%), akathisia (6.5%), vaginitis (6.4%) and pain in the
twice the incidence of placebo. Among aripiprazole-treated patients, 13% (n=7/56) experienced clinically
more) vs none of the placebo-treated patients (Keck et al, 2006).

4) Pediatric:

a) In a 4 week, double-blind, placebo-controlled study in pediatric patients with bipolar disorder (n=296), trea
symptomatology compared to placebo. Pediatric patients aged 10 to 17 years with manic and mixed episodes
without psychotic features and a Young Mania Rating Scale (Y-MRS) score of 20 or greater received a target
or 30 mg/day or placebo. Doses were initiated at 2 mg/day and increased to 5 mg after 2 days and then to a t
treatment arm) or 30 mg in 13 days (30 mg/day treatment arm). At week 4, both aripiprazole doses were supe
(Prod Info ABILIFY(R) oral tablets, solution, disintegrating tablets, IV injection, 2008).

4.5.D Borderline personality disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Addition of aripiprazole may be beneficial for patients with borderline personality disorder who are resista
(Bellino et al, 2008).
Aripiprazole was superior to placebo for the treatment of multiple markers of borderline personality disor
Aripriprazole continued to demonstrate superior efficacy in the treatment of multiple markers of borderlin
follow up period (n=52) (Nickel et al, 2007).

3) Adult:

a) In a double-blind, placebo-controlled study, aripiprazole was superior to placebo for the treatment of multi
(n=52). Adult and adolescent patients, who met Diagnostic and Statistical Manual of Mental Disorders-IV (DS
disorder were randomized in a 1:1 fashion to receive either aripiprazole 15 milligrams (mg) tablets orally daily
women/4 men) for 8 weeks. The primary outcome was the mean change in score from baseline to week 8 in
D), the Hamilton Anxiety Rating Scale (HAM-A), the State-Trait Anger Expression Inventory (STAXI) and the
consisted of 9 symptoms: somatization, obsessive-compulsiveness, insecurity in social contact, depression, a
paranoid thinking and psychoticism. The intent-to-treat analysis revealed that aripiprazole was significantly su
and 8 of the 9 symptoms of SCL-90-R, excluding somatization as seen in the following table. The most comm
headache, insomnia, nausea, numbness, constipation and anxiety. Self injury occurred before and during stu
aripiprazole versus placebo during treatment, respectively. Limitations to this study include a small sample pc
(Nickel et al, 2006).

1) Aripiprazole continued to demonstrate superior efficacy in the treatment of multiple markers of borde follow up, open-label, observational study (n=52). After final evaluation at 8 weeks in the previous study, discontinued (ex-placebo) and patients in the aripiprazole group continued 15 milligrams daily. The prima checklist (SCL-90-R), Hamilton Anxiety Rating Scale (HAM-A), Hamilton Depression Rating Scale (HAM at 18 months. Aripiprazole continued to demonstrate significantly superior efficacy compared with ex-pla HAM-A and HAM-D as indicated in the table. Self injury occurred in both groups during the 18 months of aripiprazole and ex-placebo, respectively. Two patients in the ex-placebo group attempted suicide. Both numbness, restlessness, constipation and anxiety (Nickel et al, 2007).

Changes in all scales of the symptom check list (SCL-90-R) HAM-D, HAM-A, and STAXI at 18 mont

Marker	ARI-G	
SCL-90-R, somatization	59 +/- 5.1	
SCL-90-R, obsessive/compulsiveness	53.1 +/- 6.9

2) An open-label study revealed addition of aripiprazole may be beneficial for patients with borderline pe sertraline treatment (n=21). Adult outpatients, (18 to 50 years of age) diagnosed with borderline persona respond to 12 weeks of sertraline 100 to 200 milligrams (mg) daily received aripiprazole 10 mg (initial do remained constant, for 12 weeks. Patients were considered responders if the Clinical Global Impression much improved or much improved) and a decrease of the Brief Psychiatric Rating Scale (BPRS) score w

to-treat analysis at week 12 revealed a statistically significant improvement in the responders (n=16) in n (p=0.018) and 34.63 +/- 3.89 (p=0.005), respectively. Statistically significant secondary outcomes that er Borderline Personality Disorder Severity Index (BPDSI) for impulsivity 5.66 +/- 1.18 (p=0.011), BPDSI fo 1.28 (p=0.036) and Barratt Impulsiveness Scale (BIS-11) 64.88 +/- 7.53 (p=0.017). However, no significa Rating Scale (HAM-D), the Hamilton Anxiety Rating Scale (HAM-A), Social Occupational Functioning As BPDSI. The most common adverse effects were headache (37.5%), insomnia and anxiety (25%). Limitat population size and short duration of treatment (Bellino et al, 2008).

4.5.E Dementia

See Drug Consult reference: BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA

4.5.F Major depressive disorder, Adjunctive treatment in patients also receiving antidepressants

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole is indicated for use as an adjunctive treatment to antidepressants for major depressive disor solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007).
In two 6-week, placebo-controlled trials (n=743), treatment with aripiprazole was superior to placebo in re major depressive disorder (MDD) and an inadequate response to prior antidepressant therapies; addition patient functioning with aripiprazole compared to placebo (Prod Info ABILIFY(R) oral tablets, oral solutio disintegrating tablets, 2007).

3) Adult:

a) In two 6-week, placebo-controlled trials (n=381, n=362), treatment with aripiprazole was superior to placel patients with major depressive disorder (MDD) and an inadequate response to prior antidepressant therapy; improved patient functioning with aripiprazole compared to placebo. Patients with DSM-IV criteria for MDD, a 50% patient-perceived improvement after 6 weeks or greater of antidepressant therapy at or above the minim antidepressant therapies in the current depressive episode, and an inadequate response (defined as less tha the Hamilton Depression Rating Scale (HAMD17), a minimal HAMD17 score of 14, and a Clinical Global Imp minimal improvement) to 8 weeks of prospective antidepressant therapy were eligible. Prior therapies include extended-release, fluoxetine, escitalopram, or sertraline. Patients initially received oral aripiprazole 5 milligrar therapy. The aripiprazole dose was adjusted by 5 mg/day in 1-week intervals based on patient tolerability and (patients on potent CYP2D6 inhibitors (eg, fluoxetine, paroxetine)) or 2 to 20 mg/day (patients not on potent C aripiprazole doses were 10.7 and 11.4 mg/day in the two studies. Response to therapy was determined using Asberg Depression Rating Scale (MADRS), which assessed depressive symptoms and the 3-item, patient-ra assessed the impact of depression on work/school, social life, and family life functioning (0=not at all to 10=e aripiprazole was found to be superior in reducing mean MADRS total scores in both studies and in reducing r smaller mean reduction in total MADRS scores was observed in males compared to females; otherwise, resp prospective antidepressant choice, or race (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, DISC 2007).

4.5.G Psychomotor agitation - Schizophrenia

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes (injectable only); Pediatric, no
Efficacy: Adult, Effective
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole injection is approved for the treatment of agitation associated with schizophrenia and bipolar (R) oral tablets, oral solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007a).
A double-blind, placebo-controlled study demonstrated that intramuscular aripiprazole was noninferior to placebo in voluntarily hospitalized agitated patients with schizophrenia or schizoaffective disorder (Andre In placebo-controlled trials, intramuscular aripiprazole was statistically superior to placebo in improving s schizophrenia (Tran-Johnson et al, 2007; Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, DI 2007a).

3) Adult:

a) Aripiprazole was more effective than placebo for the acute treatment of agitation in patients with schizoph schizophreniform disorder in a dose-ranging, multicenter, randomized, double-blind clinical trial. Patients who Positive and Negative Syndrome Scale (PANSS)-Excited Component (PEC) scores of 15 to 32, and a score 5 PEC items (excitement, hostility, tension, uncooperativeness, and poor impulse control; scores range from receive one of 4 aripiprazole doses (1 milligram (mg) (n=57), 5.25 mg (n=63), 9.75 mg (n=57), or 15 mg (n=5 (n=62). All doses were administered intramuscularly within 1 hour of baseline assessment and repeated up to

but no more than 20 hours could elapse between the first and third doses. In the placebo arm, aripiprazole 15
required. A rescue benzodiazepine, such as lorazepam, was permitted only at least 60 minutes after the seco
antipsychotic medications were discontinued prior to the study. The primary endpoint was the mean change f
one dose of aripiprazole compared to placebo, with a p-value of 0.0167 indicating a statistically significant dif
score at 2 hours was noted between each dose of aripiprazole, except the 1-mg group, and haloperidol comp
versus placebo). Significant differences were observed as early as 45 minutes in the aripiprazole 9.75-mg gro
The PEC response (defined as at least a 40% reduction in the mean PEC score from baseline to 2 hours) for
the haloperidol group ($p < 0.05$). The secondary endpoint of the Agitation-Calmness Evaluation Scale (ACES
compared to placebo for the 9.75-mg aripiprazole group ($p < 0.01$) and the haloperidol group ($p < 0.01$). Addi
Agitated Behavior Scale (CABS) score, the Clinical Global Impressions-Severity of Illness (CGI-S) score, the
(CGI-I) score, and the Brief Psychiatric Rating Scale (BPRS) total score were significantly improved at 2 hour
aripiprazole groups and the haloperidol group. Only the CGI-I score was significantly improved in the 1-mg ar
were observed for the mean change in BPRS-positive scores after 2 hours in any group compared to placebo
the placebo group compared to the aripiprazole 5.25-mg to 15-mg groups and the haloperidol group ($p < 0.05$
adverse events in the aripiprazole groups were headache (13%), dizziness (10%), somnolence (7%), and na
of patients in the aripiprazole groups, 10.5% of patients in the haloperidol group, and no patients in the placel
1.8% of the aripiprazole groups, 7% of the haloperidol group, and 0% of the placebo group (Tran-Johnson et

b) A double-blind, placebo-controlled study demonstrated that intramuscular aripiprazole was noninferior to i
placebo in voluntarily hospitalized, agitated patients with schizophrenia or schizoaffective disorder as measur
excited components from the Positive and Negative Syndrome Scale (PANSS)) to 2 hours after the first injec
cooperation, excitement, poor impulse control, and tension on a scale of 1 (absent) to 7 (extreme). Patients w
9.75 mg intramuscularly (IM) (n=175), haloperidol 6.5 mg IM (n=185), or placebo (n=88). The noninferiority m
score was 2.5. Patients could receive up to three IM injections spaced at least 2 hours apart. Analysis of the
improvement in PEC score at 2 hours from baseline of -7.27 aripiprazole group, -7.75 haloperidol group, and
after the first injection the percentage of patients achieving a clinical response (defined as a reduction in PEC
achieved by 55% aripiprazole group, 58% haloperidol group, and 36% in the placebo group (p less than 0.00
occurred in 41% aripiprazole patients (n=70), 34% haloperidol patients (n=62), and 57% in placebo (n=50), w
second dose of -5.92, -6.73 and -2.16 (p less than 0.001 vs placebo), respectively. The most frequently repor
(n=175) was headache (7.4%), dizziness (6.3%), nausea (5.7%) and insomnia (5.7%), and in the haloperidol
headache (8.2%), and extrapyramidal disorder (5.5%) (Andrezina et al, 2006).

c) In two short-term (24-hour), placebo-controlled trials, intramuscular aripiprazole was statistically superior t
in patients with schizophrenia (using the Positive and Negative Syndrome Scale [PANSS] Excited Componer
Improvement [CGI-I] scale scores). Both trials included a single active comparator treatment arm of haloperic
meeting DSM-IV criteria for schizophrenia received up to 3 injections during the 24-hour treatment period, wit
initial 2-hour period, when the primary efficacy measure was evaluated. All enrolled patients were judged by t
and clinically appropriate candidates for treatment with intramuscular medication. Additionally, all patients exl
exceeded a threshold score of 14 or greater on the five items comprising the PANSS Excited Component (eg
uncooperativeness and excitement items) with at least 2 individual item scores of 4 or greater using a 1 to 7 s
7=extreme). In both studies, the baseline PANSS Excited Component score ranged from 15 to 24 (out of a m
score of 19; this suggested mainly moderate levels of agitation with some patients experiencing mild or sever
measure in both trials was the change in the PANSS Excited Component from baseline to 2 hours post-inject
measure. In the first study (n=350), four fixed aripiprazole injection doses of 1 milligram (mg), 5.25 mg, 9.75 r
2-hour period, the 5.25 mg, 9.75 mg, and 15 mg doses were statistically superior to placebo in the PANSS Ex
the second study (n=445), one fixed aripiprazole injection dose of 9.75 mg was evaluated. After the initial 2-h
statistically superior to placebo in the PANSS Excited Component and on the CGI-I scale (Prod Info ABILIFY
DISCMELT(TM) orally disintegrating tablets, 2007a)

4.5.H Schizophrenia

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, yes (13 to 17 years old)
Efficacy: Adult, Effective; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Aripiprazole is indicated for the treatment of schizophrenia in adults and pediatric patients 13 to 17 years
solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 2007a).
Aripiprazole has been more effective than placebo in treating adult patients with acutely relapsed schizo
improve cognitive function in some patients (Petrie et al, 1998a; Saha et al, 1999b).
Longer time to relapse was seen in adult patients with schizophrenia treated with aripiprazole therapy (A
Treatment with oral aripiprazole, at doses of 10 or 30 milligrams per day for 6 weeks, was superior to pla
adolescents 13 to 17 years of age (Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, DISCME

3) Adult:

a) General Information

1) Relatively large double-blind, placebo-controlled studies (unpublished) have indicated the efficacy of
in patients with acute relapse of schizophrenia or schizoaffective disorder (Petrie et al, 1998a; Kane et al
optimal dose appears to be 10 or 15 mg once daily; additional clinical benefit has not usually been obser

oral tablets, disintegrating tablets, solution, 2006). These studies indicated significant improvement relati
Syndrome Scale (PANSS)-total, PANSS-positive, PANSS-negative, Clinical Global Improvement (CGI)-s
(BPRS) scores. The drug demonstrated a low propensity for extrapyramidal symptoms. All studies have
extended open treatment phase was instituted in one study (Petrie et al, 1998a), although results were n

b) Clinical Trials

1) Aripiprazole therapy was effective in the prevention of relapse in patients with chronic, stable schizop
blind, placebo-controlled study, patients (n=310) with at least a 2-year history of schizophrenia and stabl
received oral aripiprazole (15 milligrams daily) or placebo for 26 weeks. Time to relapse after randomizat
treated patients as compared with patients who received placebo (p less than 0.001). Additionally, a high
relapsed as compared with those in the aripiprazole group (57% vs 33.8%, respectively). The relative ris
versus placebo was 0.59 (95% confidence interval, 0.45 to 0.75; p less than 0.001). Mean changes from
greater with aripiprazole therapy as compared with placebo for the Positive and Negative Syndrome Sca
subscale score, PANSS-derived Brief Psychiatric Rating Scale (BPRS) core score, Clinical Global Impre
or equal to 0.01, all values), and CGI-Severity score (p less than or equal to 0.05). Insomnia, tremor, aka
frequently reported adverse events with aripiprazole therapy (Pigott et al, 2003)(Anon, 2003).

2) In a placebo-controlled, phase III study involving relapsed schizophrenic or schizoaffective patients (r
haloperidol 10 mg daily (fixed doses) were each statistically superior to placebo with regard to changes i
on responder analysis (a 30% reduction in PANSS-total scores from baseline at last visit), each dose of a
than placebo, whereas haloperidol was not. There was evidence of better tolerability with aripiprazole co
requirements for extrapyramidal effects, prolactin increases, weight increase). Extrapyramidal symptoms
placebo, and fewer patients receiving aripiprazole discontinued treatment due to adverse events compar
2000). However, this study did not report statistical comparisons of aripiprazole and haloperidol for any p
effects); responder-analysis data revealed only a small difference between the two drugs. Overall, this st
aripiprazole is significantly more efficacious than haloperidol.

3) Some improvement in neurocognitive function (eg, verbal learning, executive functioning, vigilance) w
mg daily) in a randomized study (n=256); the drug tended to be superior to olanzapine (Kern et al, 2001a

4) Pediatric:

a) In a 6-week, placebo-controlled trial in adolescents 13 to 17 years of age, oral aripiprazole at doses of 10
placebo in the treatment of schizophrenia. Study patients (n=302) were outpatients who met the Diagnostic a
edition) criteria for schizophrenia and had a baseline Positive and Negative Syndrome Scale (PANSS) score
fixed daily doses of aripiprazole 10 mg, aripiprazole 30 mg, or placebo. Aripiprazole was initiated at 2 mg/day
and 11 days for the 10-mg and 30-mg groups, respectively. The mean improvement in PANSS total score fro
superior in both aripiprazole groups compared to placebo. The 30 mg/day dose was not found to be more effi
most common treatment-related adverse events with a possible dose-response relationship were extrapyram
21.6%; placebo, 5%); somnolence (incidence: 10 mg, 11%; 30 mg, 21.6%; placebo, 6%); and tremor (incider
(Prod Info ABILIFY(R) oral tablets, oral solution, IM injection, DISCMELT(TM) orally disintegrating tablets, 20

4.6 Comparative Efficacy / Evaluation With Other Therapies

Chlorpromazine

Haloperidol

Olanzapine

Perphenazine

4.6.A Chlorpromazine

4.6.A.1 Schizophrenia

a) Based upon comparisons of minimum effective dosages identified in placebo- controlled, fixed-dose and f
minimum effective dose of aripiprazole was 15 milligrams/day (equivalent to chlorpromazine 200 milligrams/d

4.6.B Haloperidol

4.6.B.1 Schizophrenia

a) SUMMARY: Aripiprazole (up to 30 mg daily) and haloperidol (up to 20 mg daily) appear similarly effective
schizophrenia or schizoaffective disorder; adverse effects may be less with aripiprazole.

b) Haloperidol 5 to 20 mg daily, but not aripiprazole (5 to 30 mg daily), was superior to placebo with respect
study involving acutely relapsed inpatients with DSM-III/IV schizophrenia (n=103). Both haloperidol and aripip
responder analysis based on CGI-severity scores (Prod Info Abilify(TM), 2002).

c) In a placebo-controlled, phase III study involving relapsed schizophrenic or schizoaffective patients (n=41
haloperidol 10 mg daily (fixed doses) were each statistically superior to placebo with regard to changes in PA
responder analysis (a 30% reduction in PANSS-total scores from baseline at last visit), each dose of aripipraz

placebo, whereas haloperidol was not. There was evidence of better tolerability with aripiprazole compared to extrapyramidal effects, prolactin increases, weight increase). Extrapyramidal symptoms were reportedly simil patients receiving aripiprazole discontinued treatment due to adverse events compared to haloperidol and pla did not report statistical comparisons of aripiprazole and haloperidol for any parameter (efficacy versus basel data revealed only a small difference between the two drugs. Overall, this study does not provide evidence th than haloperidol.

d) Results of phase II studies also suggested fewer adverse effects with aripiprazole compared to haloperido studies, lower changes from baseline in Simpson-Angus Scale scores (parkinsonian symptoms) and less req all doses of aripiprazole (2, 10, or 30 mg daily) than with haloperidol 10 mg daily; prolactin levels were not inc significant increases with haloperidol, and significantly less weight gain was evident in the aripiprazole groups not presented.

4.6.C Olanzapine

4.6.C.1 Schizophrenia

a) A trend toward greater improvement in some areas of neurocognitive function (eg, verbal learning, workin mg daily compared to olanzapine 15 mg daily in a randomized study (n=256) (Kern et al, 2001). However, a p study are unavailable (unpublished).

4.6.D Perphenazine

4.6.D.1 Schizophrenia, Treatment resistant

a) Both aripiprazole and perphenazine improved symptoms associated with treatment-resistant schizophreni study. Patients (n=416) with treatment-resistant schizophrenia (ie, failure of at least 2 trials of antipsychotic th last 2 years) with a Positive and Negative Syndrome Scale (PANSS) total score of at least a 75, a score grea of conceptual disorganization, suspiciousness, hallucinatory behavior, or delusions, and a Clinical Global Imp or greater. After a 2-day washout period, patients entered a 4 to 6 week open-label treatment phase receiving or risperidone 2 to 8 mg/day to confirm treatment resistance. At the end of this open-label screening period, 3 washout period then were randomized to 6 weeks of treatment with aripiprazole 15 to 30 mg/day or perphena was mean change in PANSS score during the 6-week double-blind treatment period. In the aripiprazole group 9.8 points (95% confidence interval (CI), -13.2 to -6.3) from a mean total baseline score of 97.5 (95% CI, 95 t decrease in PANSS total score was 10.5 points (95% CI, -14 to -7) from a mean total baseline score of 99.5 (groups was not statistically significant (p-value not reported). At the end of 6 weeks, 27% (40/150) of patients of patients responded to perphenazine treatment, with response defined as at least a 30% decrease in PANS Extrapyramidal symptoms were reported in 13.7% (n=21) of patients in the aripiprazole group and 19.4% (n= Serious adverse events were reported in 21% (n=32) and 17% (n=24) of patients treated with aripiprazole an common being psychosis (9.8% and 6.3%, respectively) (Kane et al, 2007).

DRUGDEX® Evaluations

AMPHETAMINE/DEXTROAMPHETAMINE

0.0 Overview

1) Class
- **a)** This drug is a member of the following class(es):
  Central Nervous System Agent
  CNS Stimulant

2) Dosing Information
- **a)** Adult
  - **1)** Attention deficit hyperactivity disorder
    - **a)** extended-release, 20 mg ORALLY daily (Prod Info ADDERALL XR(R) extended-release oral capsules, 20
  - **2)** Narcolepsy
    - **a)** immediate-release, 5 to 60 mg/day ORALLY in divided doses (Prod Info ADDERALL(R) oral tablets, 2006
- **b)** Pediatric
  - **1)** (immediate-release) not FDA approved in children under 3 years of age with attention deficit hyperactivity diso 2006)
  - **2)** (extended-release) not FDA approved in children under 6 years of age with attention deficit hyperactivity disor release oral capsules, 2006)
    - **a)** Attention deficit hyperactivity disorder
      - **1)** immediate release (age 3 to 5 yr), initial 2.5 mg ORALLY every morning; may increase daily dose in 2 optimal response (Prod Info ADDERALL(R) oral tablets, 2006)
      - **2)** immediate release (age 6 yr and older), initial 5 mg ORALLY once or twice daily; may increase daily d optimal response; give first dose in the morning and subsequent doses at 4 to 6 hour intervals; MAX 40 r 2006)
      - **3)** extended release (6 to 12 yr), initial 10 mg ORALLY every morning (alternatively, 5 mg/day if appropr increments at weekly intervals until optimal response; MAX 30 mg/day (Prod Info ADDERALL XR(R) ext
      - **4)** extended release (13 to 17 yr), initial 10 mg ORALLY every morning; may increase to 20 mg/day afte extended-release oral capsules, 2006)
    - **b)** Narcolepsy
      - **1)** immediate release (age 6 to 12 yr) initial, 5 mg ORALLY once daily; may increase daily dose in 5 mg response (Prod Info ADDERALL(R) oral tablets, 2006)
      - **2)** immediate release (age 12 yr and older) initial, 10 mg ORALLY once daily; may increase daily dose i optimal response (Prod Info ADDERALL(R) oral tablets, 2006)

3) Contraindications
- **a)** advanced arteriosclerosis (Prod Info ADDERALL(R) oral tablets, 2006)
- **b)** agitated states; may aggravate symptoms (Prod Info ADDERALL(R) oral tablets, 2006)
- **c)** cardiovascular disease, symptomatic (Prod Info ADDERALL(R) oral tablets, 2006)
- **d)** concomitant use of monoamine oxidase inhibitors (MAOI), or within 14 days of MAOI use; hypertensive crisis may 2006)
- **e)** drug dependence, history of; potential for abuse (Prod Info ADDERALL(R) oral tablets, 2006)
- **f)** glaucoma (Prod Info ADDERALL(R) oral tablets, 2006)
- **g)** hypersensitivity/idiosyncrasy to sympathomimetic amines (Prod Info ADDERALL(R) oral tablets, 2006)
- **h)** hypertension, moderate to severe (Prod Info ADDERALL(R) oral tablets, 2006)
- **i)** hyperthyroidism (Prod Info ADDERALL(R) oral tablets, 2006)

4) Serious Adverse Effects
- **a)** Cardiomyopathy
- **b)** Cerebrovascular accident
- **c)** Dead - sudden death
- **d)** Mania
- **e)** Myocardial infarction
- **f)** Psychotic disorder
- **g)** Seizure

5) Clinical Applications
- **a)** FDA Approved Indications
  - **1)** Attention deficit hyperactivity disorder
  - **2)** Narcolepsy

1.0 Dosing Information

Drug Properties

Storage and Stability

Adult Dosage

Pediatric Dosage

1.1 Drug Properties
A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product In

1.2 Storage and Stability
A) Preparation
1) Oral
a) Give first dose (immediate-release) on awakening, and additional doses at 4 to 6-hour intervals. Avoid late
Info ADDERALL(R) oral tablets, 2006; Prod Info ADDERALL(R) XR extended release oral capsule, 2005).
b) Extended-release capsules may be swallowed whole with or without food. The entire capsule contents ma
immediately; the applesauce with sprinkled beads should be consumed in its entirety without chewing. Do no
ADDERALL(R) XR extended release oral capsule, 2005).

1.3 Adult Dosage

1.3.1 Normal Dosage

1.3.1.A Oral route

Attention deficit hyperactivity disorder

Narcolepsy

1.3.1.A.1 Attention deficit hyperactivity disorder
a) Extended-Release
1) The recommended initial dose for patients with attention deficit hyperactivity disorder is 20 milligr
extended-release oral capsules, 2006).

1.3.1.A.2 Narcolepsy
a) The recommended dose of immediate-release tablets is 5 to 60 milligrams/day ORALLY in divided do
2006).

1.4 Pediatric Dosage

1.4.1 Normal Dosage

1.4.1.A Oral route

Attention deficit hyperactivity disorder

Narcolepsy

1.4.1.A.1 Attention deficit hyperactivity disorder
a) Immediate-Release
1) For children aged 3 to 5 years, the recommended initial dose of immediate-release tablets is 2.5
be increased in 2.5-mg increments at weekly intervals until optimal response (Prod Info ADDERALL
2) For children aged 6 years and older, the recommended initial dose of immediate-release is 5 mill
increase in 5-mg increments at weekly intervals until optimal response, up to 40 mg/day. Give first d
to 6 hour intervals (Prod Info ADDERALL(R) oral tablets, 2006).
b) Extended-Release
1) For children 6 years of age and older, the starting dose of extended-release amphetamine/dextro
in the morning. Doses may be increased by 10 mg at weekly intervals to a MAXIMUM dose of 30 mg
XR(R) extended-release oral capsules, 2006).
2) For patients using immediate-release tablets, they should be switched to the same total daily dos
taken once daily in the morning (Prod Info Adderall XR(TM), 2001).

1.4.1.A.2 Narcolepsy
a) Immediate-Release

1) For children aged 6 to 12 years, the recommended initial dose of immediate-release tablets is 5 r
be increased in 5-mg increments at weekly intervals until optimal response (Prod Info ADDERALL(F
2) For children aged 12 years and older, the recommended initial dose of immediate-release tablet
dose increase in 10-mg increments at weekly intervals until optimal response. Take first dose on aw
intervals (Prod Info ADDERALL(R) oral tablets, 2006).

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING

1) Oral (Tablet; Capsule, Extended Release)

a) Amphetamines have a high potential for abuse. Administration of amphetamines for prolonged periods of time
avoided. Particular attention should be paid to the possibility of subjects obtaining amphetamines for non-therape
should be prescribed or dispensed sparingly.

b) Misuse of amphetamine may cause sudden death and serious cardiovascular adverse events (Prod Info ADDI

3.1 Contraindications

A) advanced arteriosclerosis (Prod Info ADDERALL(R) oral tablets, 2006)
B) agitated states; may aggravate symptoms (Prod Info ADDERALL(R) oral tablets, 2006)
C) cardiovascular disease, symptomatic (Prod Info ADDERALL(R) oral tablets, 2006)
D) concomitant use of monoamine oxidase inhibitors (MAOI), or within 14 days of MAOI use; hypertensive crisis may
2006)
E) drug dependence, history of; potential for abuse (Prod Info ADDERALL(R) oral tablets, 2006)
F) glaucoma (Prod Info ADDERALL(R) oral tablets, 2006)
G) hypersensitivity/idiosyncrasy to sympathomimetic amines (Prod Info ADDERALL(R) oral tablets, 2006)
H) hypertension, moderate to severe (Prod Info ADDERALL(R) oral tablets, 2006)
I) hyperthyroidism (Prod Info ADDERALL(R) oral tablets, 2006)

3.2 Precautions

A) amphetamine misuse; may cause sudden death and serious cardiovascular events (Prod Info ADDERALL(R) oral
B) drug dependence, history of; potential for abuse (Prod Info ADDERALL(R) oral tablets, 2006)
C) bipolar disorder, comorbid; may precipitate a mixed/manic episode (Prod Info ADDERALL(R) oral tablets, 2006)
D) cardiovascular conditions which may be compromised by increases in blood pressure or heart rate (e.g., pre-existi
infarction, or ventricular arrhythmia) (Prod Info ADDERALL(R) oral tablets, 2006)
E) EEG abnormalities, especially with history of; may lower convulsive threshold (Prod Info ADDERALL(R) oral tablet
F) psychosis, pre-existing; may exacerbate symptoms of behavior disturbance and thought disorder (Prod Info ADDE
G) seizures, especially with a history of; may lower convulsive threshold (Prod Info ADDERALL(R) oral tablets, 2006)
H) structural cardiac abnormalities/conditions, serious, especially in children and adolescents; sudden death has beer
Info ADDERALL(R) oral tablets, 2006)
I) tics, motor and phonic, history of; risk of exacerbation (Prod Info ADDERALL(R) oral tablets, 2006)
J) Tourette's syndrome, history of; risk of exacerbation (Prod Info ADDERALL(R) oral tablets, 2006)

3.3 Adverse Reactions

Cardiovascular Effects

Endocrine/Metabolic Effects

Gastrointestinal Effects

Neurologic Effects

Psychiatric Effects

3.3.1 Cardiovascular Effects

Cardiomyopathy

Chest pain

Dead - sudden death

Hypertension

Myocardial infarction

Palpitations

Tachycardia

3.3.1.A Cardiomyopathy

1) Cardiomyopathy has been associated with chronic amphetamine use (Prod Info ADDERALL(R) oral capsı extended-release oral capsules, 2007).

3.3.1.B Chest pain

1) In a placebo controlled, 4-week, study of adults with ADHD, 0.5% of 191 patients discontinued Adderall XI symptoms such as exertional chest pain, unexplained syncope, or other symptoms suggestive of cardiac dise a prompt cardiac evaluation (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.1.C Dead - sudden death

1) Incidence: rare

2) Children and Adolescents - With Preexisting Cardiac Risk

a) Sudden death has been reported in children and adolescents with structural cardiac abnormalities or medications at usual doses. Patients, including adults with serious structural or other cardiac abnormaliti abnormalities) should generally not be treated with stimulant medications. A cardiac evaluation (eg, elect performed in any patient experiencing exertional chest pain, unexplained syncope, or other symptoms in ADDERALL(R) oral capsules, 2007; Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

3) Children and Adolescents - Healthy

a) A retrospective, case-controlled study examines the association between stimulant medication, incluc combination drugs, and unexplained sudden death in healthy children and adolescents. In a collection of across the United States, 564 cases of sudden death in children and adolescents between the ages of 7 564 youngsters who died as passengers in motor vehicle accidents. The study determined that 1.8% (n= unexplained deaths were taking stimulant medication compared with only 0.4% (n=2) of youths in the mc 95% CI, 1.4 to 74.9; p=0.02). Limitations to this study included the time lag between the youths stimulant collected, family recall of information regarding clinical diagnoses, inconsistent postmortem inquiry, and t conditions. The authors stated that this finding should be considered when evaluating the overall risk and and adolescents (Gould et al, 2009). Given the limitations of this study, the U.S. Food and Drug Adminis benefits associated with stimulant medications (US Food and Drug Administration, 2009).

3.3.1.D Hypertension

1) Incidence: 7% to 22%, pediatric (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) An average elevation of blood pressure of 2 to 4 mmHg has been reported following administration of Adc have larger increases. Larger increases in blood pressure should be monitored. Because stimulant medicatic with caution in patients with cardiac conditions which may be exacerbated by further blood pressure increase recent myocardial infarction, ventricular arrhythmia) (Prod Info ADDERALL(R) oral capsules, 2007; Prod Info capsules, 2007).

3) A 4-week controlled study was conducted in adolescents with ADHD. Isolated systolic blood pressure elev of patients in the Adderall XR treatment group compared to 11% of placebo-treated patients. Isolated diastoli were observed in 22% of patients in the Adderall XR treatment group compared to 25% of placebo-treated pa release oral capsules, 2007).

4) A single-dose study of 23 adolescents showed isolated increases in systolic blood pressure in patients tre patients treated with Adderall XR 20 mg (35%). All increases were transitory, appeared maximal at 2 to 4 hou (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.1.E Myocardial infarction

1) Myocardial infarction has been reported in adults receiving amphetamine therapy at normal doses. Patien

other cardiac abnormalities (eg, cardiomyopathy, heart rhythm abnormalities) should generally not be treated (eg, electrocardiogram, echocardiogram) should be performed in any patient experiencing exertional chest pa indicative of cardiac disease (Prod Info ADDERALL(R) oral capsules, 2007; Prod Info ADDERALL XR(R) ext

3.3.1.F Palpitations

1) Palpitation has been associated with amphetamine use (Prod Info ADDERALL(R) oral capsules, 2007; Pr capsules, 2007).

3.3.1.G Tachycardia

1) Incidence: 6% (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Average heart rate increases of 3 to 6 bpm have been reported with stimulant medications. Patients shoul Because stimulant medications can cause increases in blood pressure, use with caution in patients with card further blood pressure increases (eg, preexisting hypertension, heart failure, recent myocardial infarction, ver (R) extended-release oral capsules, 2007).

3) Tachycardia has been reported in 6% of patients in the Adderall XR treatment group (n=191) compared to randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod Info capsules, 2007). Tachycardia has been reported with Adderall also (Prod Info ADDERALL(R) oral capsules,

3.3.3 Endocrine/Metabolic Effects

3.3.3.A Weight loss

1) Incidence: 4% to 9%, pediatric; 11%, adults (Prod Info ADDERALL XR(R) extended-release oral capsules

2) Weight loss has occurred in 4% of pediatric patients in the Adderall XR treatment group (n=374) compare in a randomized, double-blind, placebo-controlled, parallel-group study conducted in children ages 6 to 12 wi extended-release oral capsules, 2007).

3) Weight loss has occurred in 9% of patients in the Adderall XR treatment group (n=233) compared to 0% c randomized, double-blind, placebo-controlled, multicenter, parallel-group study conducted in adolescents age XR(R) extended-release oral capsules, 2007).

4) Weight loss has occurred in 11% of patients in the Adderall XR treatment group (n=191) compared to 0% randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod Info capsules, 2007).

3.3.4 Gastrointestinal Effects

Abdominal pain

Loss of appetite

Xerostomia

3.3.4.A Abdominal pain

1) Incidence: 11% to 14%, pediatrics (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Abdominal pain has occurred in 14% of pediatric patients in the Adderall XR treatment group (n=374) com (n=210) in a randomized, double-blind, placebo-controlled, parallel-group study conducted in children ages 6 extended-release oral capsules, 2007).

3) Abdominal pain has been reported in 11% of patients in the Adderall XR treatment group (n=233) compar in a randomized, double-blind, placebo-controlled, multicenter, parallel-group study conducted in adolescents ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.4.B Loss of appetite

1) Incidence: 22% to 36% (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Loss of appetite has been reported in 22% (n=374) of pediatric patients in the Adderall XR treatment grou placebo group (n=210) in a randomized, double-blind, placebo-controlled, parallel-group study conducted in ADDERALL XR(R) extended-release oral capsules, 2007).

3) Loss of appetite has been reported in 36% of patients in the Adderall XR treatment group (n=233) compa in a randomized, double-blind, placebo-controlled, multicenter, parallel-group study conducted in adolescents ADDERALL XR(R) extended-release oral capsules, 2007).

4) Loss of appetite has been reported in 33% of patients in the Adderall XR treatment group (n=191) compa in a randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod capsules, 2007).

3.3.4.C Xerostomia

1) Incidence: 35% (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Aptyalism has been reported in 35% of patients in the Adderall XR treatment group (n=191) compared to randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod Info

capsules, 2007).

3.3.9 Neurologic Effects

Central nervous system stimulation, Overstimulation

Cerebrovascular accident

Gilles de la Tourette's syndrome

Headache

Insomnia

Seizure

Tic

Tremor

3.3.9.A Central nervous system stimulation, Overstimulation

1) Overstimulation has been associated with amphetamine use (Prod Info ADDERALL(R) oral capsules, 200 release oral capsules, 2007).

3.3.9.B Cerebrovascular accident

1) Cerebrovascular accident has been associated with amphetamine use (Prod Info ADDERALL(R) oral cap extended-release oral capsules, 2007).

3.3.9.C Gilles de la Tourette's syndrome

1) Summary

a) Exacerbation of Tourette's syndrome has been reported following administration of amphetamines (P Prod Info ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.9.D Headache

1) Incidence: 26% (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Headache has been reported in 26% of patients in the Adderall XR treatment group (n=191) compared to randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod Info capsules, 2007).

3.3.9.E Insomnia

1) Incidence: 12% to 17%, pediatric; 27%, adults (Prod Info ADDERALL XR(R) extended-release oral capsu

2) Insomnia occurred in 17% of pediatric patients in the Adderall XR treatment group (n=374) compared to 2 randomized, double-blind, placebo-controlled, parallel-group study conducted in children ages 6 to 12 with AI release oral capsules, 2007).

3) Insomnia occurred in 12% of patients in the Adderall XR treatment group (n=233) compared to 4% of pati randomized, double-blind, placebo-controlled, multicenter, parallel-group study conducted in adolescents age XR(R) extended-release oral capsules, 2007).

4) Insomnia was reported in 27% of patients in the Adderall XR treatment group (n=191) compared to 13% c randomized, double-blind, placebo-controlled, parallel-group study conducted in adults with ADHD (Prod Info capsules, 2007).

3.3.9.F Seizure

1) Some clinical evidence suggests patients with a history of seizures or EEG abnormalities may have a low XR should be discontinued if seizures are present (Prod Info ADDERALL(R) oral capsules, 2007; Prod Info A capsules, 2007).

3.3.9.G Tic

1) Exacerbation of motor and phonic tics has been reported following administration of amphetamines (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.9.H Tremor

1) Tremors have been reported following administration of amphetamines (Prod Info ADDERALL(R) oral cap extended-release oral capsules, 2007).

3.3.12 Psychiatric Effects

Dysphoric mood

Euphoria

Feeling nervous

Mania

Psychotic disorder

Restlessness

3.3.12.A Dysphoric mood

1) Dysphoria has been associated with amphetamine use (Prod Info ADDERALL(R) oral capsules, 2007; Pro capsules, 2007).

3.3.12.B Euphoria

1) Euphoria has been associated with amphetamine use (Prod Info ADDERALL(R) oral capsules, 2007; Proc capsules, 2007).

3.3.12.C Feeling nervous

1) Incidence: 6% (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007)

2) Nervousness has been reported in 6% of pediatric patients in the Adderall XR treatment group (n=374) co (n=210) in a randomized, double-blind, placebo-controlled, parallel-group study conducted in children ages 6 extended-release oral capsules, 2007).

3) Nervousness has been reported in 6% of patients in the Adderall XR treatment group (n=233) compared t a randomized, double-blind, placebo-controlled, multicenter, parallel-group study conducted in adolescents a XR(R) extended-release oral capsules, 2007).

3.3.12.D Mania

1) In a review of 49 randomized, controlled pediatric ADHD clinical trials involving pscyhostimulant medicatic hydrochloride, modafinil and dextromethylphenidate hydrochloride), the rate of psychosis/mania events in pe (95% CI, 0.74 to 2.65) per 100 person-years, with no comparable adverse events recorded in the placebo gro Administration to manufacturers of marketed ADHD drugs for submission of postmarketing case reports of ps 2005, yielded a total of 865 reports (pediatrics and adults) in which signs and/or symptoms of psychoses or n involved pediatric subjects, with almost half of the reports in children 10 years-old or younger, and approxima similar psychiatric conditions. Visual and/or tactile sensations of insects, snakes, or worms were commonly re each of the psychostimulant medications (methylphenidate hydrochloride, atomoxetine hydrochloride, and mi product) included in the analysis; and in many cases a strong temporal association was identified. The onset weeks, but in some cases it was months or years from the start of ADHD treatment and symptom onset (Mos

3.3.12.E Psychotic disorder

1) In a review of 49 randomized, controlled pediatric ADHD clinical trials involving pscyhostimulant medicatic hydrochloride, modafinil and dextromethylphenidate hydrochloride), the rate of psychosis/mania events in pe (95% CI, 0.74 to 2.65) per 100 person-years, with no comparable adverse events recorded in the placebo gro Administration to manufacturers of marketed ADHD drugs for submission of postmarketing case reports of ps 2005, yielded a total of 865 reports (pediatrics and adults) in which signs and/or symptoms of psychoses or n involved pediatric subjects, with almost half of the reports in children 10 years-old or younger, and approxima similar psychiatric conditions. Visual and/or tactile sensations of insects, snakes, or worms were commonly re each of the psychostimulant medications (methylphenidate hydrochloride, atomoxetine hydrochloride, and mi product) included in the analysis; and in many cases a strong temporal association was identified. The onset weeks, but in some cases it was months or years from the start of ADHD treatment and symptom onset (Mos

2) Psychotic or manic symptoms may occur among patients without prior history of psychosis, or may worse Chronic intoxication may result in severe psychosis, often similar to schizophrenia. Symptoms of psychosis o (4/3482) exposed to methylphenidate or amphetamine for several weeks at usual doses, in a pooled analysis studies (Prod Info ADDERALL XR(R) extended-release oral capsules, 2007).

3.3.12.F Restlessness

1) Restlessness has been associated with amphetamine use (Prod Info ADDERALL(R) oral capsules, 2007; oral capsules, 2007).

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) Amphetamine

a) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info ADDERALL XR(R) oral

1) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or ot women or studies in women and animals are not available. Drugs should be given only if the potential be

See Drug Consult reference: PREGNANCY RISK CATEGORIES

b) Crosses Placenta: Yes

c) Clinical Management

1) Because there is evidence of developmental and behavioral adverse effects in humans and animals f ADDERALL XR(R) oral capsules, 2007; Eriksson & Zetterstrom, 1994a; Levin, 1971a), amphetamines sl potential benefit to the mother outweighs the potential risk to the fetus (Prod Info ADDERALL XR(R) oral

d) Literature Reports

1) There are no adequate and well-controlled studies in pregnant women. There has been one report of esophageal fistula, and anal atresia (vater association) in a baby born following maternal exposure to de trimester of pregnancy. The risk of premature delivery and low birth weight is increased in infants born to infants may also experience symptoms of withdrawal as demonstrated by dysphoria, including agitation, XR(R) oral capsules, 2007). A statistically significant correlation between aggressive behavior and amph reported (Eriksson & Zetterstrom, 1994a).

2) Eleven infants were born with biliary atresia to mothers who had taken amphetamines in various dose development of a biliary tree). In a controlled group of 50 normal infants, it was noted that 3 of 50 mother

3) A large prospective, observational study of pregnancy and child development was undertaken relatec phenmetrazine) prescribed to gravid women during different stages of pregnancy and evaluated for their rate (SCA) per 100 live-born children at age 5 years did not differ from the SCA rate of the group of child There was, however, an excess of oral clefts in the infants of mothers who had amphetamines prescribe period. A rough test of efficacy of anorectic drugs was made by comparing mean weight gain in 4-week p showed only short-term and limited reduction of weight gain (Milkovich & Van Den Berg, 1977a).

4) In animal studies, there was no evidence of adverse effects on embryofetal morphological developme amphetamine/dextroamphetamine product (amphetamine d- to l-enantiomer ratio of 3:1) was orally admi up to 6 mg/kg/day (1.5 times the maximum recommended human dose (MRHD) of 30 mg/day on a body the MRHD), respectively, throughout the period of organogenesis. Fetal malformations and death and se mice following parenteral administration of d-amphetamine doses of 50 mg/kg/day (approximately 6 time term neurochemical and behavioral alterations (ie, learning and memory deficits, altered locomotor activi prenatal or early postnatal exposure to amphetamine (d- or d,l-), at doses similar to those used clinically 2007).

e) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info ADDERALL XR(R) oral

1) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or ot women or studies in women and animals are not available. Drugs should be given only if the potential be

See Drug Consult reference: PREGNANCY RISK CATEGORIES

f) Crosses Placenta: Yes

g) Clinical Management

1) Because there is evidence of developmental and behavioral adverse effects in humans and animals f ADDERALL XR(R) oral capsules, 2007; Eriksson & Zetterstrom, 1994a; Levin, 1971a), amphetamines sl potential benefit to the mother outweighs the potential risk to the fetus (Prod Info ADDERALL XR(R) oral

h) Literature Reports

1) There are no adequate and well-controlled studies in pregnant women. There has been one report of esophageal fistula, and anal atresia (vater association) in a baby born following maternal exposure to de trimester of pregnancy. The risk of premature delivery and low birth weight is increased in infants born to infants may also experience symptoms of withdrawal as demonstrated by dysphoria, including agitation, XR(R) oral capsules, 2007). B) Breastfeeding
1) Amphetamine
a) American Academy of Pediatrics Rating: Drugs of abuse for which adverse effects on the infant during bre
b) Thomson Lactation Rating: Infant risk has been demonstrated.
1) Evidence and/or expert consensus has demonstrated harmful infant effects when used during breastf
prescribed or patients should be advised to discontinue breastfeeding.
c) Clinical Management
1) Amphetamines have been shown to be excreted in human breast milk (Prod Info ADDERALL XR(R)
al, 1984). Adverse effects reported in exposed infants include irritability and poor sleeping patterns (Proc
Therefore, nursing mothers who are using amphetamines should be advised to avoid nursing (Prod Info
d) Literature Reports
1) Two case reports described methylamphetamine and amphetamine exposure in 4- and 2-month-old r
methylamphetamine by the 2 mothers ages 29 and 26 years, respectively, who were recruited from the i
HIT trial. The women self-injected a single methylamphetamine dose of unknown purity and quantity. Fo
collected. A 5- to 10-mL breast milk sample was collected just prior to drug use and then in 2 to 6 hour ir
methylamphetamine use. Methylamphetamine and amphetamine were estimated using high-performanc

detected in the urine and breast milk of both subjects was methylamphetamine with a small quantity of a methylamphetamine and amphetamine half-lives were 13.6 and 43 hours, respectively, in subject 1, and average concentration (Cavg) of methylamphetamine in the breast milk was 111 and 281 mcg/L for subje absolute infant dose of 16.7 and 42.2 mcg/kg/day. The Cavg of amphetamine in the breast milk was 4 ar resulting in an absolute infant dose of 0.8 and 2.5 mcg/kg/day (Bartu et al, 2009).

2) Concentrations of amphetamine were 3 and 7 times higher in breast milk than maternal plasma on th respectively, following administration of amphetamine 20 mg daily to a nursing mother with narcolepsy. A in the urine of the infant. Although only a small fraction of maternal dose is expected to be transferred to that patients abstain from long-term nursing during amphetamine treatment (Steiner et al, 1984).

e) American Academy of Pediatrics Rating: Drugs of abuse for which adverse effects on the infant during bre

f) Thomson Lactation Rating: Infant risk has been demonstrated.

1) Evidence and/or expert consensus has demonstrated harmful infant effects when used during breastf prescribed or patients should be advised to discontinue breastfeeding.

g) Clinical Management

1) Amphetamines have been shown to be excreted in human breast milk (Prod Info ADDERALL XR(R) al, 1984). Adverse effects reported in exposed infants include irritability and poor sleeping patterns (Proc Therefore, nursing mothers who are using amphetamines should be advised to avoid nursing (Prod Info

h) Literature Reports

1) Two case reports described methylamphetamine and amphetamine exposure in 4- and 2-month-old r methylamphetamine by the 2 mothers ages 29 and 26 years, respectively, who were recruited from the i HIT trial. The women self-injected a single methylamphetamine dose of unknown purity and quantity. Fo collected. 3.5.1.A Acetazolamide

1) Interaction Effect: amphetamine toxicity (hypertension, hyperpyrexia, seizures)
2) Summary: Concomitant acetazolamide and amphetamine therapy resulted in enhanced amphetamine effe
and the renal excretion of amphetamine is decreased due to increased reabsorption (Rowland, 1969; Anggar
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Lower doses of dextroamphetamine may be required with urinary alkalizers. Monito
7) Probable Mechanism: decreased renal clearance

3.5.1.B Acetazolamide

1) Interaction Effect: amphetamine toxicity (hypertension, hyperpyrexia, seizures)
2) Summary: Acetazolamide tends to alkalinize the urine, increasing the unionized amphetamine urine conce
tubular reabsorption. Enhanced effects of amphetamines may occur due to increased amphetamine concentr
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor for amphetamine toxicity and adjust the dose or discontinue the acetazolan
7) Probable Mechanism: decreased clearance

3.5.1.C Amitriptyline

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been rep & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.D Amoxapine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been rep & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although

ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt
appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.E Calamus

1) Interaction Effect: reduced effect of amphetamines
2) Summary: Calamus antagonized spontaneous motor activity and amphetamine-induced hyperactivity in m
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Use caution with concomitant use of calamus and amphetamines.
7) Probable Mechanism: not specified
8) Literature Reports
a) Calamus antagonized spontaneous motor activity and amphetamine-induced hyperactivity in mice. C
(0.2 milliliters of 10, 25, 50 milligrams/kilogram (mg/kg)). One group of mice received 4 mg/kg chlorproma
spontaneous motor activity was compared to untreated mice. In another test, mice were injected IP with
calamus followed by amphetamine. Calamus significantly reduced spontaneous motor activity in a mann
and 25 mg/kg and significantly reduced amphetamine-induced hyperactivity at 25 mg/kg (Panchal et al,

3.5.1.F Chlorpromazine

1) Interaction Effect: decreased amphetamine and chlorpromazine effectiveness
2) Summary: Amphetamine may inhibit the antipsychotic effects of chlorpromazine (Casey, 1961) and chlorp
amphetamine (Modell & Hussar, 1965; Espelin & Done, 1968).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Avoid combining amphetamines and chlorpromazine where possible.
7) Probable Mechanism: antagonism

3.5.1.G Citalopram

1) Interaction Effect: an increased risk of serotonin syndrome
2) Summary: Concurrent use of citalopram and dextroamphetamine resulted in symptoms of serotonin syndr
citalopram and dextroamphetamine are used concomitantly, monitor closely for symptoms of serotonin syndr
threatening. If serotonin syndrome develops, discontinue the offending agents and provide supportive care ar
Shannon, 2005).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: A case of serotonin syndrome was reported with coadministration of citalopram and
citalopram and dextroamphetamine are used concomitantly, monitor closely for symptoms of serotonin syndr
(including hyper-reflexia, tremor, muscle rigidity, clonus, peripheral hypertonicity, and shivering), autonomic h
diaphoresis, the presence of bowel sounds, and diarrhea), and mental status changes (including agitation an
threatening. If serotonin syndrome develops, discontinue the offending agents and provide supportive care ar
Shannon, 2005).
7) Probable Mechanism: additive pharmacologic effects
8) Literature Reports
a) A 32-year-old male on dextroamphetamine experienced serotonin syndrome approximately 1 week a
dextroamphetamine 5 mg three times daily for attention deficit hyperactivity disorder. He started 75 mg a
was increased to 150 mg daily. Approximately 2 weeks after starting venlafaxine he experienced markec
admission he was alert and oriented. He experienced diaphoresis, shivering, and fine motor tremor. His
pressure was 142/93 mmHg, and temperature was 37.3 degrees Celsius. No nystagmus or ocular clonus
reactive. He had generalized hypertonia, hyperreflexia, inducible ankle clonus, frequent myoclonic jerkin
oris muscle. No abnormality was shown on ECG, except sinus tachycardia with a baseline tremor. Dextr
discontinued and cyproheptadine (up to a total of 32 mg over 3 hours) was administered. Symptoms res
morning. Dextroamphetamine was restarted 3 days later. Four days later citalopram was started. Approx
symptoms as he did with dextroamphetamine and venlafaxine. Agitation, nausea, diarrhea, and teeth cle
was discontinued. Two doses of cyproheptadine were given and within 2 days he was asymptomatic (Pri

3.5.1.H Clomipramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte
from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit
Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m
most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh
moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo
& Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs
monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed

5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism c imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.I Clorgyline
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo (Prod Info Dexedrine(R), 1995c). Amphetamines stimulate the release of norepinephrine, and the use of mon more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrad of norepinephrine, which increases sympathetic activity (Gilman et al, 1990d). Coadministration of indirect-ac in severe hypertension and hyperpyrexia (Krisko et al, 1969d; Lloyd & Walker, 1965d; Mason, 1962d; Dally, 1 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a m
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature as being associated include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964b).
b) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991h).

3.5.1.J Clorgyline
1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995j). An norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: established
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature as being associated include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964o).

3.5.1.K Desipramine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte

from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur with
Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m
most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sho
moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo
& Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs
monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho
increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf
capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if
closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen
amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet
VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab
2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism o
imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in
effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb
methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th
pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g
fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical
doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc
1969). However, a systemic review of stimulants in the treatment of depression concluded that although
ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt
appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.L Dothiepin

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported
from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur with
Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m
most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sho
moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo
& Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs
monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho
increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf
capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if
closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen
amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet
VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab
2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism o
imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

3.5.1.M Doxepin

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been rep & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.N Furazolidone

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: Furazolidone has significant MAOI activity (Pettinger et al, 1968; Pettinger et al, 1966). Use of days following the administration of a monoamine oxidase inhibitor is contraindicated (Prod Info Dexedrine(R activity such as dextroamphetamine cause the release of norepinephrine, and the use of MAOIs results in m nerve receptor sites through inhibition of catecholamine degradation; concurrent use leads to greater amount sympathetic activity (Gilman et al, 1990e). Coadministration of indirect-acting sympathomimetics and MAOIs & Bermudez, 1982; Cuthbert et al, 1969; Terry et al, 1975; Horler & Wynne, 1965).

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a

7) Probable Mechanism: increased norepinephrine availability

3.5.1.O Furazolidone

1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: Furazolidone has significant MAOI activity (Pettinger et al, 1968a; Pettinger et al, 1966a) and s sympathomimetics. Sympathomimetics with indirect/mixed activity such as amphetamine cause the release results in more norepinephrine being made available at nerve receptor sites through inhibition of catecholami amounts of norepinephrine which increases sympathetic activity (Gilman et al, 1990p). Coadministration of in Inhibitors has resulted in serious hypertension (Smookler & Bermudez, 1982a; Cuthbert et al, 1969a; Terry e

3) Severity: major

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: Concurrent use of amphetamines and an MAO inhibitor, or medications with MAO I

7) Probable Mechanism: increased norepinephrine availability

3.5.1.P Guanethidine

1) Interaction Effect: decreased guanethidine effectiveness

2) Summary: Amphetamines displace guanethidine from the neuron and interfere with neuron uptake. If pos (Ober & Wang, 1973).

3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor patient for signs of decreased guanethidine effectiveness. Adjust the dosag
7) Probable Mechanism: antagonism
8) Literature Reports
a) Concomitant guanethidine and amphetamine administration has been reported to result in antagonisr appears that amphetamine displaces guanethidine from its site of action thereby reversing its hypotensiv 1971).
b) Available data indicate that amphetamine does not alter the orthostatic hypotension seen with guanet systolic blood pressure (Ober & Wang, 1970; Ober & Wang, 1971).

3.5.1.Q Imipramine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs n most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism c imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.R Iproniazid
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo (Prod Info Dexedrine(R), 1995h). Amphetamines stimulate the release of norepinephrine, and the use of mor more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrad of norepinephrine, which increases sympathetic activity (Gilman et al, 1990i). Coadministration of indirect-act in severe hypertension and hyperpyrexia (Krisko et al, 1969h; Lloyd & Walker, 1965h; Mason, 1962h; Dally, 1 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a n
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a c (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s

patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991n).

3.5.1.S Iproniazid

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995h). A norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964m).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.T Isocarboxazid

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a m (Prod Info Dexedrine(R), 1995a; Prod Info Marplan(R), 1998). Amphetamines cause the release of norepinep norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degradation. norepinephrine, which increases sympathetic activity (Gilman et al, 1990b). Coadministration of indirect-actin severe hypertension and hyperpyrexia (Krisko et al, 1969b; Lloyd & Walker, 1965b; Mason, 1962b; Dally, 196 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a r
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature with this combinatio arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964a).
b) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991d).

3.5.1.U Isocarboxazid

1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic days should elapse following the discontinuation of MAOIs before amphetamine therapy is instituted (Prod In cause the release of norepinephrine, and the use of MAO inhibitors results in more norepinephrine being ma inhibition of catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which in Goldberg, 1964l).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: established
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature with this combinatio arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964k).
b) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991r).

3.5.1.V Lofepramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte

from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur with
Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m
most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh
moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo
& Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs
monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho
increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf
capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if
closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen
amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet
VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab
2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism o
imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i
effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb
methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th
pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g
fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical
doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc
1969). However, a systemic review of stimulants in the treatment of depression concluded that although
ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt
appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.W Moclobemide
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo
(Prod Info Dexedrine(R), 1995). Amphetamines stimulate the release of norepinephrine, and the use of monc
more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrac
of norepinephrine, which increases sympathetic activity (Gilman et al, 1990). Coadministration of indirect-acti
in severe hypertension and hyperpyrexia (Krisko et al, 1969; Lloyd & Walker, 1965; Mason, 1962; Dally, 1962
dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a m
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a c
(pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the
tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp
months during coadministration, and 31% of the patients continued treatment after the study. Four of the
discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha
dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s
patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor
(Fawcett et al, 1991).

3.5.1.X Moclobemide
1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic
the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995). Am
norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve
catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym
potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964e).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.Y Nialamide

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo (Prod Info Dexedrine(R), 1995j). Amphetamines stimulate the release of norepinephrine, and the use of mono more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrad of norepinephrine, which increases sympathetic activity (Gilman et al, 1990k). Coadministration of indirect-ac in severe hypertension and hyperpyrexia (Krisko et al, 1969j; Lloyd & Walker, 1965j; Mason, 1962j; Dally, 19 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a n

7) Probable Mechanism: increased norepinephrine availability

8) Literature Reports

a) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a c (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991p).

3.5.1.Z Nialamide

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995b). A norepinephrine, and the use of MAOIs results in more norepinephrine being made available at nerve recepto degradation; concurrent use leads to greater amounts of norepinephrine which increases sympathetic activity indirect-acting sympathomimetics and MAOIs has resulted in severe hypertension and hyperpyrexia (Krisko e 1962k; Dally, 1962k).

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m

7) Probable Mechanism: increased norepinephrine availability

3.5.1.AA Nortriptyline

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism c imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical

doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc
1969). However, a systemic review of stimulants in the treatment of depression concluded that although
ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt
appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.AB Opipramol

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte
from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit
Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m
most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh
moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo

1969). However, a systemic review of stimulants in the treatment of depression concluded that although
ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt
appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.AC Pargyline

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo
(Prod Info Dexedrine(R), 1995i). Amphetamines cause the release of norepinephrine, and the use of MAOIs
available at nerve receptor sites through inhibition of catecholamine degradation; concurrent use leads to gre
sympathetic activity (Gilman et al, 1990j). Coadministration of indirect-acting sympathomimetics and MAOIs h
hyperpyrexia (Krisko et al, 1969i; Lloyd & Walker, 1965i; Mason, 1962i; Dally, 1962i).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a n
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AD Pargyline

1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindica
the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995e). A
norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve
catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym
potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964i).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AE Phenelzine

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: Amphetamines cause the release of norepinephrine, and the use of monoamine oxidase inhibit being made available at nerve receptor sites through inhibition of catecholamine degradation. Concurrent use which increases sympathetic activity (Gilman et al, 1990a). Coadministration of indirect-acting sympathomime hypertension and hyperpyrexia (Krisko et al, 1969a; Lloyd & Walker, 1965a; Mason, 1962a; Dally, 1962a). So dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen However, the concurrent use of dextroamphetamine and phenelzine is contraindicated (Prod Info Nardil(R), 1

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a n

7) Probable Mechanism: increased norepinephrine availability

8) Literature Reports

a) Severe headaches and hypertensive crises are well-documented in the literature with this combinatio arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964).

b) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991b).

3.5.1.AF Phenelzine

1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995c). An norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964g).

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: established

6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m

7) Probable Mechanism: increased norepinephrine availability

3.5.1.AG Procarbazine

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo (Prod Info Dexedrine(R), 1995f). Amphetamines stimulate the release of norepinephrine, and the use of mon more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrad of norepinephrine, which increases sympathetic activity (Gilman et al, 1990g). Coadministration of indirect-ac in severe hypertension and hyperpyrexia (Krisko et al, 1969f; Lloyd & Walker, 1965f; Mason, 1962f; Dally, 19 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a n

7) Probable Mechanism: increased norepinephrine availability

8) Literature Reports

a) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991l).

3.5.1.AH Procarbazine

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)

2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995d). An norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964h).

3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AI Protriptyline

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs m most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism o imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.AJ Rasagiline

1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension) and serotonin syndrome (hy status changes)
2) Summary: Amphetamines cause the release of norepinephrine, and the use of MAO inhibitors results in m nerve receptor sites through inhibition of catecholamine degradation; concurrent use leads to greater amount sympathetic activity (Gilman et al, 1990o). Severe hypertensive reactions have been reported following the a and sympathomimetics. A minimum of 14 days should elapse after discontinuing rasagiline before initiating th oral tablets, 2006).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent use of amphetamine and rasagiline is contraindicated. Allow 14 day rasagiline and the initiation of therapy with amphetamine.
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AK Selegiline

1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a m (Prod Info Dexedrine(R), 1995g). Amphetamines cause the release of norepinephrine, and the use of MAOIs available at nerve receptor sites through inhibition of catecholamine degradation; concurrent use leads to gre sympathetic activity (Gilman et al, 1990h). Coadministration of indirect-acting sympathomimetics and MAOIs hyperpyrexia (Krisko et al, 1969g; Lloyd & Walker, 1965g; Mason, 1962g; Dally, 1962g).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a r

7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature as being associated include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964d).

3.5.1.AL Selegiline
1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension) and serotonin syndrome (hy status changes)
2) Summary: The concurrent use of amphetamine and selegiline is contraindicated. At least 14 days should before amphetamine therapy is instituted and a minimum of 7 days should elapse after discontinuing propoxy (Prod Info EMSAM(R) transdermal patch, 2006; Prod Info Biphetamine(R), 1995f). Amphetamines cause the inhibitors results in more norepinephrine being made available at nerve receptor sites through inhibition of ca to greater amounts of norepinephrine which increases sympathetic activity (Gilman et al, 1990o).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: established
6) Clinical Management: The concurrent use of amphetamine and selegiline is contraindicated. Allow 14 day selegiline and the initiation of therapy with amphetamine or allow a minimum of 7 days to elapse between the initiation of therapy with selegiline.
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature as being associated include cardiac arrhythmias, chest pain, circulatory failure, hyperpyrexia, and death (Goldberg, 1964j).

3.5.1.AM Sibutramine
1) Interaction Effect: an increased risk of hypertension and tachycardia
2) Summary: Sibutramine has been associated with substantial increases in blood pressure and heart rate ir administration of sibutramine and other centrally acting appetite suppressants has not been systematically ev and tachycardia may result. Therefore, the concurrent administration of sibutramine with another centrally act (Prod Info Meridia(R), 1997).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concomitant administration of sibutramine with other centrally active appetite s
7) Probable Mechanism: additive pharmacologic effects

3.5.1.AN Sodium Bicarbonate
1) Interaction Effect: amphetamine toxicity (hypertension, hyperpyrexia, seizures)
2) Summary: Sodium bicarbonate (ie, greater than 2 grams daily) may alkalinize the urine, increasing the un allowing for increased renal tubular reabsorption. Enhanced effects of amphetamine may occur due to increa al, 1973a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Lower doses of dextroamphetamine may be required with urinary alkalinizers. Moni
7) Probable Mechanism: decreased dextroamphetamine clearance

3.5.1.AO Sodium Bicarbonate
1) Interaction Effect: amphetamine toxicity (hypertension, hyperpyrexia, seizures)
2) Summary: Sodium bicarbonate (ie, greater than 2 grams daily) may alkalinize the urine, increasing the un allowing for increased renal tubular reabsorption. Enhanced effects of amphetamine may occur due to increa (Anggard et al, 1973b).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor for possible amphetamine toxicity (eg, hypertension, hyperpyrexia, or seizu
7) Probable Mechanism: decreased renal clearance

3.5.1.AP Toloxatone
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a m (Prod Info Dexedrine(R), 1995b). Amphetamines stimulate the release of norepinephrine, and the use of mor more norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degrad of norepinephrine, which increases sympathetic activity (Gilman et al, 1990c). Coadministration of indirect-ac in severe hypertension and hyperpyrexia (Krisko et al, 1969c; Lloyd & Walker, 1965c; Mason, 1962c; Dally, 1 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid

5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a r
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991f).

3.5.1.AQ Toloxatone
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995a). A norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964f). As a inhibitor, toloxatone may not potentiate the effects of amphetamine to the same frequency, extent, and durati further studies confirm the safety and efficacy of this combined therapy, concomitant use is contraindicated.
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AR Tranylcypromine
1) Interaction Effect: a hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: Use of dextroamphetamine concomitantly or within 14 days following the administration of a mo (Prod Info Dexedrine(R), 1995e). Amphetamines cause the release of norepinephrine, and the use of monoa norepinephrine being made available at nerve receptor sites through inhibition of catecholamine degradation. norepinephrine, which increases sympathetic activity (Gilman et al, 1990f). Coadministration of indirect-acting severe hypertension and hyperpyrexia (Krisko et al, 1969e; Lloyd & Walker, 1965e; Mason, 1962e; Dally, 196 dextroamphetamine or pemoline in addition to a MAOI was observed during a study of patients with treatmen
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Dextroamphetamine use during or within 14 days following the administration of a r
7) Probable Mechanism: increased norepinephrine availability
8) Literature Reports
a) Severe headaches and hypertensive crises are well-documented in the literature with this combinatio arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964c).
b) In a study of 32 patients with treatment-refractory depression, efficacy of combination therapy with a (pemoline or dextroamphetamine) with a monoamine oxidase inhibitor (MAOI) was studied. Some of the tricyclic antidepressants and lithium, in addition to the study medications. Most of the patients (78%) exp months during coadministration, and 31% of the patients continued treatment after the study. Four of the discontinued the medications due to impotence, orthostatic hypotension, elevated blood pressure, or sha dextroamphetamine and a MAOI discontinued the medications due to memory problems, parkinsonian s patients experienced mood cycling, five to hypomania and one to mania. No patients developed symptor (Fawcett et al, 1991j).

3.5.1.AS Tranylcypromine
1) Interaction Effect: hypertensive crisis (headache, hyperpyrexia, hypertension)
2) Summary: The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindic the discontinuation of MAOIs before amphetamine therapy is instituted (Prod Info Biphetamine(R), 1995i). An norepinephrine, and the use of MAO inhibitors results in more norepinephrine being made available at nerve catecholamine degradation; concurrent use leads to greater amounts of norepinephrine which increases sym potential reactions include cardiac arrhythmias, chest pain, hyperpyrexia, and death (Goldberg, 1964n).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: established
6) Clinical Management: Amphetamine use is contraindicated during or within 14 days of administration of m
7) Probable Mechanism: increased norepinephrine availability

3.5.1.AT Trimipramine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reporte from the release of norepinephrine (Beaumont, 1973; Raisfeld, 1972). A similar reaction might also occur wit Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs n most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it sh moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been repo & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCA monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympatho increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Inf capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agen amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphet VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tab 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism o imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases i effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of comb methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of th pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine g fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may oc 1969). However, a systemic review of stimulants in the treatment of depression concluded that although ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated litt appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 19

3.5.1.AU Venlafaxine

1) Interaction Effect: an increased risk of serotonin syndrome
2) Summary: Two weeks of concurrent use of dextroamphetamine and venlafaxine resulted in symptoms of s et al, 2002). If dextroamphetamine and venlafaxine are used concomitantly, monitor closely for symptoms of life-threatening. If serotonin syndrome develops, discontinue the offending agents and provide supportive car Shannon, 2005).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: A case of serotonin syndrome was reported with coadministration of dextroamphet dextroamphetamine and venlafaxine are used concomitantly, monitor closely for symptoms of serotonin synd (including hyper-reflexia, tremor, muscle rigidity, clonus, peripheral hypertonicity, and shivering), autonomic h diaphoresis, the presence of bowel sounds, and diarrhea), and mental status changes (including agitation an threatening. If serotonin syndrome develops, discontinue the offending agents and provide supportive care a Shannon, 2005).
7) Probable Mechanism: additive pharmacologic effects
8) Literature Reports
a) A 32-year-old male on dextroamphetamine experienced serotonin syndrome approximately 2 weeks dextroamphetamine 5 mg three times daily for attention deficit hyperactivity disorder. He started 75 mg a was increased to 150 mg daily. Approximately 2 weeks after starting venlafaxine he experienced marked admission he was alert and oriented. He experienced diaphoresis, shivering, and fine motor tremor. His pressure was 142/93 mmHg, and temperature was 37.3 degrees Celsius. No nystagmus or ocular clonus reactive. He had generalized hypertonia, hyperreflexia, inducible ankle clonus, frequent myoclonic jerking oris muscle. No abnormality was shown on ECG, except sinus tachycardia with a baseline tremor. Dextr discontinued and cyproheptadine (up to a total of 32 mg over 3 hours) was administered. Symptoms res morning. Dextroamphetamine was restarted 3 days later. Four days later citalopram was started. Approx symptoms as he did with dextroamphetamine and venlafaxine. Agitation, nausea, diarrhea, and teeth cle was discontinued. Two doses of cyproheptadine were given and within 2 days he was asymptomatic (Pri

3.5.2 Drug-Food Combinations

3.5.2.A Acidic Food

1) Interaction Effect: altered serum concentrations
2) Summary: Maximal absorption of amphetamines occurs in the alkaline environment of the small intestine

taken with amphetamines may impair gastrointestinal absorption. Foods that increase urinary pH may decrea reabsorption of the amphetamine and increased serum levels. Foods that acidify urine increase renal clearan levels (Prod Info Dexedrine(R), 1998; Beckett & Rowland, 1965).
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Dextroamphetamine should not be administered with acidic foods, such as citric fru
7) Probable Mechanism: pH-dependent absorption and clearance

4.0 Clinical Applications

Monitoring Parameters

Therapeutic Uses

4.1 Monitoring Parameters

A) Therapeutic
1) Physical Findings
a) Attention Deficit Hyperactivity Disorder (ADHD)
1) Improvement in mental and behavioral symptoms, including inappropriate inattention, impulsivity, hyp
b) Narcolepsy
1) Decreased frequency of narcoleptic attacks.
B) Toxic
1) Physical Findings
a) It is not conclusive whether chronic use of stimulants in children may be associated with suppression of gr during treatment (Prod Info Adderall (R) XR, 2005).
1) Attention Deficit Hyperactivity Disorder (ADHD)
a) The American Academy of Pediatrics (AAP) does not recommend the routine use of electrocardi cardiology evaluations (which were previously recommended by the American Heart Association (AH conditions that might place the child at risk for sudden cardiac death) before initiating stimulant thera ADHD in most children. The APA cited specific reasons for changing the recommendation including between stimulant drugs used to treat ADHD and sudden cardiac death (SCD), the frequency of suc stimulant drugs is not higher than that in the general population of children, and lack of cost-effective evaluation by pediatric cardiologist (Perrin et al, 2008).
b) Based on the American Academy of Pediatrics (AAP) and the American Heart Association (AHA monitoring recommendations have been established to assist clinicians in the evaluation of children amphetamine/dextroamphetamine combinations, for ADHD (Perrin et al, 2008; Vetter et al, 2008):
- Conduct a thorough examination prior to initiating amphetamine/dextroamphetamine combinat attention should be given to symptoms indicative of a cardiac condition, including palpitations, r
- Obtain a complete family and patient history for conditions associated with SCD, and determir the-counter medications.
- Conduct a complete physical evaluation of the patient for hypertension, cardiac murmurs, phys and signs of irregular cardiac rhythms.
- Perform further evaluation if family history, patient history or physical exam is suggestive of ca visits, and if indicated, consult pediatric cardiologist .
- Continue to assess the patient for cardiac symptoms and any changes in family history at follo
- Blood pressure and heart rate should be evaluated at baseline, during routine follow-up within 12 months. Increases in blood pressure and heart rate have been reported with stimulant use.

4.5 Therapeutic Uses

Attention deficit hyperactivity disorder

Narcolepsy

4.5.A Attention deficit hyperactivity disorder

FDA Labeled Indication
1) Overview
FDA Approval: Adult, yes; Pediatric, yes (immediate-release, age 3 years and older; extended-release, a
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Amphetamine aspartate/amphetamine sulfate/dextroamphetamine saccharate/dextroamphetamine sulfa
treatment of attention deficit hyperactivity disorder (ADHD) (Prod Info ADDERALL XR(R) extended-relea

3) Adult:

a) Adderall(R), a mixture of L- and D-amphetamine, was effective in some cases of adult attention deficit hyp study (n=24). Dosing of Adderall was initiated at 5 milligrams (mg) twice daily orally and titrated according to a positive response was shown by 54% of patients (13 of 24) using the Clinical Global Impression scale to de much improved and 3 (12%) were much improved. Two patients (8%) were minimally improved. Among thes 10.33 mg or 0.14 mg/kg/day, and side effects were decreased appetite, insomnia, and sedation. Overall, 9 pa of 7 with comorbid anxiety experienced immediate acute anxiety (diaphoresis, tremor, shortness of breath, ar after day 1. Excluding those 4, mean score on the Copeland Symptom Checklist for adult ADD decreased fro ADD scales dropped from 76.75 to 50.85 (p less than 0.001 and 0.0001, respectively) (Horrigan and Barnhill,

4) Pediatric:

a) Extended-Release

1) In a double-blind, randomized, placebo-controlled, parallel-group study, extended release Adderall (A treatment of attention deficit hyperactivity disorder (ADHD) in children ages 6 to 12 years old. Patients (n Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria for hyperactive-impulsive or combined subt placebo (n=210), or 10 milligrams per day (mg/day; n=129), 20 mg/day (n=121), or 30 mg/day (n=124) A for a 1-week washout period. Once active treatment began, a dose escalation regimen was used for the 10 mg once daily was administered to all Adderall XR(TM) groups and increased each week by 10 mg p Efficacy was evaluated using the Conners Global Index Scale (teacher's version, CGIS-T or parent's ver Adderall XR (TM) groups showed significant improvement in CGIS scores compared to baseline and pla scores were 10.6, 11.5, 12.1, and 11.2 for the placebo, 10 mg/d, 20 mg/d, and 30 mg/day groups, respe study endpoint was -0.9, -5.3, -6.0, and -6.4, respectively. Adverse events that occurred more frequently group were anorexia (21.9% in Adderall XR(TM) groups versus 1.9% in placebo), insomnia (16.6% versu emotional lability (8.6% versus 1.9%), vomiting (7.2% versus 3.8%), and nervousness (5.6% versus 1.9% withdrawn from the study due to adverse events (Biederman et al, 2002).

b) Immediate-Release

1) Seven-day courses of oral Adderall(R) (a mixture of AMPHETAMINE AND DEXTROAMPHETAMINE (mg/kg) and 0.3 mg/kg, both twice daily, were found to be an efficacious treatment for attention-deficit/hy adolescents 5 to 18 years of age, based on a randomized, double-blind, crossover study. A 54% respons criteria requiring positive assessments seen by both parent and teacher, 81% were seen to respond as r to teachers. Overall, 137 of 154 subjects (89%) responded based on either parent or teacher positive ev by parent and teacher), 60% of children 5 to 7 years of age responded; 71% of those 8 to 9 years respor older. Side effects of Adderall(R) included decreased appetite, stomachache, insomnia, and headache; d prominent with the 0.3 mg/kg dose. According to the study design, subjects were randomized to start on 7-day treatment periods (Adderall(R), placebo, Adderall(R), placebo; or vice versa starting with placebo). hours, a washout period between the 7-day treatment periods was not thought to be necessary. The low dose, with a maximum Adderall(R) dose of 40 mg/day (Ahmann et al, 2001).

4.5.B Narcolepsy

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes (immediate release formulation only); Pediatric, yes ((6 years and older) imme
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Amphetamine aspartate/amphetamine sulfate/dextroamphetamine saccharate/dextroamphetamine sulfa
treatment of narcolepsy (Prod Info ADDERALL XR(R) extended-release oral capsules, 2006)

DRUGDEX® Evaluations

CLOMIPRAMINE

0.0 Overview

1) Class
- **a)** This drug is a member of the following class(es):
  Antidepressant
  Antidepressant, Tricyclic
  Central Nervous System Agent

2) Dosing Information
- **a)** Clomipramine Hydrochloride
  - **1)** Adult
    - **a)** Delusional disorder
      - **1)** initial, 25 mg/day ORALLY, may increase dosage to 100 mg/day during the first 2 weeks (MAX dose 250 mg/day, mean dose 140 mg/day)
    - **b)** Depression
      - **1)** initial, 75 mg/day ORALLY (3 divided doses); may increase dosage slowly as needed and tolerated to a range of 100-250 mg/day (3 divided doses)
    - **c)** Obsessive-compulsive disorder
      - **1)** initial, 25 mg/day ORALLY, may increase dosage to 100 mg per day during the first 2 weeks (MAX dose 250 mg/day outpatients, 300 mg/day inpatients)
    - **d)** Panic disorder
      - **1)** 25-75 mg/day ORALLY
  - **2)** Pediatric
    - **a)** safety and effectiveness in children up to 10 years of age have not been established
      - **1)** Depression
        - **a)** 20-30 mg/day ORALLY; may increase dosage by 10 mg/day at 4-5 day intervals as needed and tolerated
      - **2)** Obsessive-compulsive disorder
        - **a)** 10 yrs and older, initial, 25 mg/day ORALLY, may increase the dosage as needed and tolerated up to 100 mg/day; MAX dose 200 mg/day OR 3 mg/kg of body weight (whichever is less)

3) Contraindications
- **a)** Clomipramine Hydrochloride
  1) coadministration with an MAOI or use within 14 days of discontinuing an MAOI; may cause serious reactions (eg, hyperpyretic crisis, seizures, coma, death) (Prod Info ANAFRANIL(R) oral capsules, 2007)
  2) hypersensitivity to clomipramine hydrochloride or other tricyclic antidepressant (Prod Info ANAFRANIL(R) oral capsules, 2007)
  3) myocardial infarction, during the acute recovery period (Prod Info ANAFRANIL(R) oral capsules, 2007)

4) Serious Adverse Effects
- **a)** Clomipramine Hydrochloride
  1) Agranulocytosis
  2) Body temperature above normal
  3) Depression, worsening
  4) Hepatotoxicity
  5) Hyperglycemia
  6) Leukopenia
  7) Myocardial infarction
  8) Orthostatic hypotension
  9) Pancytopenia
  10) Seizure
  11) Suicidal thoughts
  12) Suicide
  13) Thrombocytopenia

5) Clinical Applications
- **a)** Clomipramine Hydrochloride
  - **1)** FDA Approved Indications
    - **a)** Obsessive-compulsive disorder
  - **2)** Non-FDA Approved Indications
    - **a)** Delusional disorder
    - **b)** Depression
    - **c)** Panic disorder

1.0 Dosing Information

Drug Properties

Adult Dosage

Pediatric Dosage

1.1 Drug Properties

A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product Index)

B) Synonyms

Chlorimipramine
Chlorimipramine Hydrochloride
Clomipramine
Clomipramine HCl
Clomipramine Hydrochloride

C) Physicochemical Properties

1) Molecular Weight

a) Clomipramine hydrochloride: 351.3 (Prod Info Anafranil(R), 2001)

2) pH

a) Clomipramine hydrochloride: pH of a 10% solution in water is 3.5 to 5 (Sweetman, 2004)

3) Solubility

a) Clomipramine hydrochloride: Freely soluble in water, in methanol, and in methylene chloride; insoluble in ethyl ether and in hexane (Prod Info Anafranil(R), 2001)

1.3 Adult Dosage

1.3.1 Normal Dosage

Clomipramine

Clomipramine Hydrochloride

1.3.1.A Clomipramine

1.3.1.A.1 Cataplexy - Narcolepsy

See Drug Consult reference: NARCOLEPSY AND CATAPLEXY - DRUG THERAPY

1.3.1.B Clomipramine Hydrochloride

Intravenous route

Oral route

1.3.1.B.1 Intravenous route

a) In a study evaluating the effects of intravenous pulse loading of clomipramine in obsessive-compulsive disorder, 7 patients were given clomipramine 150 milligrams (mg) intravenously, over 90 minutes. The next day, clomipramine 200 mg intravenously, was given. The doses were preceded by trimethobenzamide hydrochloride 250 mg to reduce nausea. Oral clomipramine 150 mg was started 4.5 days after the second dose. This was increased by 25 mg every fourth day to 250 mg/day. Six out of 7 patients had responded before the oral dosing was started (Koran et al, 1997).

b) One worker has commented on his experience in treating over 60 patients with severe OCD with intravenous clomipramine (CMI) (Warneke, 1992). These patients had not responded to oral CMI and approximately 2/3 showed marked reduction in Y-BOCS scores. As much as 350 milligrams was used in a single infusion and induration and inflammation were the only reason (2 cases) that infusions had to be stopped. Duration of treatment was 14 days (one infusion each day). Patients were then changed to oral treatment.

c) A 62-year-old patient with a long history of obsessive compulsive disorder, whose symptoms were not adequately controlled with oral clomipramine (CMI) was treated with intravenous (IV) CMI. A daily dose of 25 milligrams in 500 milliliters of a dextrose-saline mixture (infused over 2 hours) was given followed by increases to 250 milligrams. Intravenous CMI was stopped after 10 days and replaced with oral CMI 250 milligrams. The patient took oral treatment for 18 months at which time the dose was

gradually decreased and the drug was eventually stopped.

1.3.1.B.2 Oral route

a) Treatment for obsessive-compulsive disorder with clomipramine should be initiated at a dosage of 25 milligrams daily and gradually increased, as tolerated, to approximately 100 milligrams during the first 2 weeks. During initial titration, clomipramine should be given in divided doses with meals to reduce gastrointestinal side effects. Thereafter, the dosage may be increased gradually over the next several weeks, up to a maximum of 250 milligrams daily. After titration, the total daily dose may be given once daily at bedtime to minimize daytime sedation (Prod Info Anafranil(R), 2001b).

b) When clomipramine is administered concomitantly with another drug that inhibits cytochrome P450 2D6, the dose of clomipramine or of the other drug may need to be lower than that usually prescribed. And, when either drug is withdrawn, the dose of the other may need to be increased (Prod Info Anafranil (R), 2001b).

c) During clinical trials for the treatment of OBSESSIVE-COMPULSIVE DISORDER, the usual therapeutic oral dose of clomipramine ranged from 75 to 300 milligrams/day in divided doses (Yaryura-Tobias et al, 1976; Marks et al, 1980a; Ananth et al, 1981a). Therapy usually starts at 25 milligrams at night with gradual increases over 4 weeks as tolerated.

d) The usual therapeutic oral dose of clomipramine for DEPRESSION ranges from 100 to 250 milligrams/day in 3 divided doses although daily doses as low as 50 or 75 milligrams have also been used (De Wilde et al, 1983a; Dimitriou et al, 1984a; Dunbar et al, 1985a; Larsen et al, 1984).

e) Clomipramine in low doses (25 to 75 milligrams orally per day) was reported effective in the treatment of panic ANXIETY and AGORAPHOBIA in outpatients in an uncontrolled clinical trial (Gloger et al, 1989). There was a trend towards the need for higher doses in agoraphobia (mean, 56 milligrams) as opposed to panic disorder (mean, 40 milligrams). Low-dose clomipramine 60 mg/day was as effective as high-dose clomipramine 150 mg/day in the treatment of phobias, anxiety, and panic attacks in a multi-center study (Caillard et al, 1999).

1.4 Pediatric Dosage

1.4.1 Normal Dosage

Clomipramine

Clomipramine Hydrochloride

1.4.1.A Clomipramine

1.4.1.A.1 Anorexia nervosa

See Drug Consult reference: ANOREXIA NERVOSA - DRUG THERAPY

1.4.1.B Clomipramine Hydrochloride

Intravenous route

Oral route

1.4.1.B.1 Intravenous route

a) A single pulse dose of clomipramine 200 milligrams intravenously has been administered to depressed adolescents (14-to 18-years-old), demonstrating dramatic and rapid reduction in depressive symptoms at day 6 post-clomipramine infusion as compared to placebo. The clomipramine effect may persist for up to 8 weeks in some patients (Sallee et al, 1997).

b) The use of intravenous clomipramine (CMI) in a 15-year-old female patient with obsessive compulsive disorder was reported (Warneke, 1985). After oral treatment with 200 milligrams of CMI plus 4 grams of L-tryptophan at bedtime for 3 weeks and no response, the patient was started on intravenous CMI. Doses ranged from 200 to 300 milligrams in 8 of 14 infusions. Dramatic response was seen, with marked reduction of obsessional thoughts and some reduction of compulsive rituals.

1.4.1.B.2 Oral route

a) As with adults, the starting dose for treating OBSESSIVE-COMPULSIVE DISORDER with clomipramine is 25 milligrams daily and should be gradually increased during the first 2 weeks, as tolerated, up to a daily maximum of 3 milligrams/kilogram or 100 milligrams, whichever is smaller. These initial doses should be divided and taken with meals to reduce gastrointestinal side effects. Thereafter, the dosage may be increased gradually over the next several weeks up to a daily maximum

of 3 milligrams/kilogram or 200 milligrams, whichever is smaller. After titration, the total daily dose may be given once daily at bedtime to minimize daytime sedation (Prod Info Anafranil(R), 2001b).
b) Oral clomipramine in the range of 100 to 200 milligrams/day in divided doses was successful in treating obsessive compulsive disorder in children aged 10 to 18 years (Flament et al, 1985a). The dose was started at 50 milligrams/day and was gradually increased to a maximum of 200 milligrams/day if tolerated.

2.0 Pharmacokinetics

Onset and Duration

Drug Concentration Levels

ADME

2.1 Onset and Duration

A) Onset
- **1)** Initial Response
  - **a)** Obsessive-compulsive disorder, oral: 4 to 10 weeks (Marks et al, 1980b).
  - **b)** Obsessive-compulsive disorder, intravenous: 5.5 days (Koran et al, 1997a).
  - **c)** Depression, oral: 2 weeks (Wolfersdorf et al, 1987a).

2.2 Drug Concentration Levels

A) Therapeutic Drug Concentration
- **1)** Obsessive-compulsive disorder, 100 to 250 ng/mL (clomipramine) plus 230 to 550 ng/mL (desmethylclomipramine) (Insel et al, 1983a; Stern et al, 1980a).
- **2)** Depression, greater than 160 to 200 ng/mL clomipramine plus desmethylclomipramine (Faravelli et al, 1984).
  - **a)** In a dose-effect study, there was a pronounced inter-patient variability in response. The authors attributed this to a variability in clomipramine steady state kinetics, clomipramine dose-dependent kinetics, and genetic polymorphism related to CYP2D6 (Anon, 1999).

B) Time to Peak Concentration
- **1)** Oral: 2 to 6 hours (mean, 4.7 hours) (Prod Info Anafranil(R), 2001a; Della Corte et al, 1993).

C) Area Under the Curve
- **1)** 600 ng/ml (0.7 mg/kg) (Della Corte et al, 1993).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

2.3.1 Absorption

A) Bioavailability
- **1)** Oral: 20% to 78% (Kuss & Jungkunz, 1986; de Cuyper et al, 1981).

B) Effects of Food
- **1)** None (Prod Info Anafranil(R), 2001a).

2.3.2 Distribution

A) Distribution Sites
- **1)** Protein Binding
  - **a)** 97% (Prod Info Anafranil(R), 2001a; Reynolds, 1988).
    - **1)** Principally bound to albumin (Prod Info Anafranil(R), 2001a).
- **2)** OTHER DISTRIBUTION SITES
  - **a)** Cerebrospinal fluid (CSF), CSF:plasma ratio is 2.6 (Prod Info Anafranil(R), 2001a).

B) Distribution Kinetics

1) Volume of Distribution
a) 12 L/kg (range, 7 to 20 L/kg) (Nagy & Johansson, 1977).

2.3.3 Metabolism
A) Metabolism Sites and Kinetics
1) Liver (Nagy & Johansson, 1977).
a) Extensive first-pass effect (Nagy & Johansson, 1977).
b) The metabolism of CLOMIPRAMINE and desmethylclomipramine may be capacity limited (Prod Info Anafranil(R), 2001a).
B) Metabolites
1) Desmethylclomipramine, active (Nagy & Johansson, 1977).
a) Responders have a trend towards lower plasma CLOMIPRAMINE to desmethylclomipramine ratios (Mavissakalian et al, 1990).
2) 8-OH clomipramine and 8-OH desmethylclomipramine (Insel et al, 1983a).

2.3.4 Excretion
A) Kidney
1) Renal Excretion (%)
a) 51% to 60% recovered in the urine (Prod Info Anafranil(R), 2001a).
B) Total Body Clearance
1) 12.7 TO 56.5 L/hr (Shimoda et al, 1999).
a) In an interethnic study comparing the clearance of clomipramine between Japanese and Swedish patients, Japanese patients had a much lower clearance (12.7 L/hr) than the Swedish patients (62.7 L/hr) (Shimoda et al, 1999).
C) Other
1) OTHER EXCRETION
a) Feces, 24% to 32% recovered in the feces (Prod Info Anafranil(R), 2001a).

2.3.5 Elimination Half-life
A) Parent Compound
1) ELIMINATION HALF-LIFE
a) 19 hours to 37 hours (mean, 32 hours) (Prod Info Anafranil(R), 2001a; Dawling et al, 1980).
1) The half-life of CLOMIPRAMINE may be lengthened at higher doses (200 to 250 mg/day) (Prod Info Anafranil(R), 2001a).
B) Metabolites
1) Desmethylclomipramine, 54 to 77 hours (mean, 69 hours) (Prod Info Anafranil(R), 2001a).

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING
1) Clomipramine Hydrochloride
a) Oral (Capsule)
Suicidality and Antidepressant Drugs
Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorders. Anyone considering the use of clomipramine hydrochloride or any other antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antidepressants compared to placebo in adults beyond age 24; there was a reduction in risk with antidepressants compared to placebo in adults aged 65 and older. Depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide. Patients of all ages who are started on antidepressant therapy should be monitored appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber. Clomipramine hydrochloride is not approved for use in pediatric patients except for patients with obsessive compulsive disorder (OCD) (Prod Info ANAFRANIL(R) oral capsules, 2007).

3.1 Contraindications

A) Clomipramine Hydrochloride

1) coadministration with an MAOI or use within 14 days of discontinuing an MAOI; may cause serious reactions (eg, hyperpyretic crisis, seizures, coma, death) (Prod Info ANAFRANIL(R) oral capsules, 2007)

2) hypersensitivity to clomipramine hydrochloride or other tricyclic antidepressant (Prod Info ANAFRANIL(R) oral capsules, 2007)

3) myocardial infarction, during the acute recovery period (Prod Info ANAFRANIL(R) oral capsules, 2007)

3.2 Precautions

A) Clomipramine Hydrochloride

1) suicidal ideation and behavior or worsening depression; increased risk, particularly in children, adolescents, and young adults during the first few months of therapy or following changes in dosage (Prod Info ANAFRANIL (R) oral capsules, 2007)

2) abrupt withdrawal; serious discontinuation symptoms have been reported (Prod Info ANAFRANIL(R) oral capsules, 2007)

3) adrenal medulla tumor (eg, pheochromocytoma, neuroblastoma); may cause hypertensive crisis (Prod Info ANAFRANIL(R) oral capsules, 2007)

4) bipolar disorder; increased risk of precipitation of a mixed/manic episode with only antidepressant treatment (Prod Info ANAFRANIL(R) oral capsules, 2007)

5) cardiovascular disease; may increase risk of ECG changes (Prod Info ANAFRANIL(R) oral capsules, 2007)

6) concurrent use with electroshock therapy; may increase hazards of electroshock therapy (Prod Info ANAFRANIL(R) oral capsules, 2007)

7) condition that may lower the seizure threshold (ie, alcoholism, brain damage, concomitant use of other drugs that lower seizure threshold); increased risk of seizure (Prod Info ANAFRANIL(R) oral capsules, 2007)

8) glaucoma, history of narrow-angle; exacerbation of condition due to cholinergic antagonism (Prod Info ANAFRANIL(R) oral capsules, 2007)

9) hyperthyroidism or concurrent use of thyroid medications; may cause cardiac toxicity (Prod Info ANAFRANIL (R) oral capsules, 2007)

10) intraocular pressure, increased; exacerbation of condition due to cholinergic antagonism (Prod Info ANAFRANIL(R) oral capsules, 2007)

11) liver disease; risk of hepatotoxicity (Prod Info ANAFRANIL(R) oral capsules, 2007)

12) mania/hypomania; risk of disease activation (Prod Info ANAFRANIL(R) oral capsules, 2007)

13) neuroleptic malignant syndrome; has been reported with clomipramine therapy (Prod Info ANAFRANIL(R) oral capsules, 2007)

14) renal function, significantly impaired (Prod Info ANAFRANIL(R) oral capsules, 2007)

15) schizophrenia, unrecognized; may precipitate psychosis (Prod Info ANAFRANIL(R) oral capsules, 2007)

16) seizures, history; may lower the convulsive threshold (Prod Info ANAFRANIL(R) oral capsules, 2007)

17) surgery, elective with general anesthetics (Prod Info ANAFRANIL(R) oral capsules, 2007)

18) urinary retention, history of; exacerbation of condition due to cholinergic antagonism (Prod Info ANAFRANIL (R) oral capsules, 2007)

3.3 Adverse Reactions

Cardiovascular Effects

Dermatologic Effects

Endocrine/Metabolic Effects

Gastrointestinal Effects

Hematologic Effects

Hepatic Effects

Musculoskeletal Effects

Neurologic Effects

Psychiatric Effects

Renal Effects

Reproductive Effects

Other

3.3.1 Cardiovascular Effects

3.3.1.A Clomipramine Hydrochloride

Cardiac arrest

Hypotension

3.3.1.A.1 Cardiac arrest

a) According to one study, the use of higher-dose tricyclic antidepressants (TCAs) was associated with an increased risk of SUDDEN CARDIAC DEATH, while lower doses did not increase this risk. In a cohort study including 481,744 persons and 1487 cases of sudden cardiac death occurring in a community setting, researchers found that compared to non-use, the current use of TCAs was associated with a dose-related increase in the risk of sudden cardiac death. For doses lower than 100 milligrams (mg) (amitriptyline or its equivalent), the rate ratio was 0.97 (95% CI, 0.72 to 1.29), however this increased to 2.53 (95% CI, 1.04 to 6.12) for doses of 300 mg or more (p=0.03, test for dose-response). In the entire cohort, users of TCAs in doses of 100 mg or higher (amitriptyline or its equivalent) had a 41% increased rate of sudden cardiac death (rate ratio, 1.41; 95% CI, 1.02 to 1.95). However, TCAs taken in doses of less than 100 mg (amitriptyline or its equivalent) were not associated with an increased risk of sudden cardiac death in the entire cohort or in any subgroups, including persons with treated cardiovascular disease. Use of selective serotonin reuptake inhibitors was not associated with an increased risk of sudden cardiac death (rate ratio, 0.95; 95% CI, 0.42 to 2.15) (Ray et al, 2004).

b) In a case report, a 31-year-old severely depressed woman developed severe epileptic convulsions followed by cardiac ARREST during a 300 mg infusion of parenteral clomipramine (Singh, 1972a). The patient had been started on parenteral clomipramine 25 mg/day which was slowly increased to 250 mg/day over 14 days. The cardiac arrest occurred on day 15 of treatment. She was resuscitated by external cardiac massage; EKG showed slight T wave flattening. One week later the patient restarted on oral clomipramine and was discharged 6 weeks later with no further cardiac problems.

3.3.1.A.2 Hypotension

a) Orthostatic hypotension worsened in both younger (less than 55 years of age, n=74) and older (55 to 70 years of age, n=28) people after taking clomipramine 150 milligrams per day for 2 weeks, but the fall in blood pressure was more severe in the older population (Stage et al, 2002).

b) A 57-year-old man who had been taking clomipramine 150 milligrams at bedtime for 2 years developed hypotension when he received general anesthesia in preparation for mitral valve repair. Anesthesia was induced with sodium thiopental and fentanyl and maintained with isoflurane. Forty-five minutes after induction of anesthesia, blood pressure and vascular resistance declined. Blood pressure was unresponsive to ephedrine, phenylephrine, and dopamine. After skin incision and sternotomy, systolic blood pressure decreased precipitously, to 55 millimeters of mercury. Despite multiple boluses of ephedrine and an infusion of norepinephrine, the patient developed third-degree atrioventricular block. Cardiopulmonary bypass was begun, and the surgery proceeded. The dosage of norepinephrine was increased before weaning from cardiopulmonary bypass. Prior to surgery, the patient had experienced postural hypotension, which was attributed to clomipramine. Therefore, a presumptive diagnosis of clomipramine-induced hypotension precipitated by anesthesia was made, and clomipramine was withheld. The patient was gradually weaned from norepinephrine (Malan et al, 2001).

c) Hypotension, TACHYCARDIA, and DIZZINESS have been reported at therapeutic doses of oral clomipramine (75 to 300 mg/day) (Dunbar et al, 1985a; De Wilde et al, 1983a; Pinder et al, 1980a). Most cases were mild and did not require any treatment.

3.3.2 Dermatologic Effects

3.3.2.A Clomipramine Hydrochloride

Diaphoresis

Discoloration of skin

3.3.2.A.1 Diaphoresis

a) Increased SWEATING was experienced by significantly more patients on clomipramine 50 to 300 mg/day than those on placebo during clinical trials of agoraphobic and obsessive compulsive patients (Johnston et al, 1988; Stern et al, 1980).

3.3.2.A.2 Discoloration of skin

a) A case of pseudocyanotic PIGMENTATION has occurred with clomipramine (Tunca et al, 1989).

3.3.3 Endocrine/Metabolic Effects

3.3.3.A Clomipramine Hydrochloride

Body temperature above normal

Galactorrhea

Hyperglycemia

Syndrome of inappropriate antidiuretic hormone secretion

Weight change finding

3.3.3.A.1 Body temperature above normal

a) More than 30 cases of hyperthemia have been associated with clomipramine. Most instances occurred when clomipramine was used in combination with other drugs. NEUROLEPTIC MALIGNANT SYNDROME has developed when clomipramine was administered concomitantly with a neuroleptic agent (Prod Info Anafranil(R), 2001b).

b) Sixteen of 38 inpatients with DSM-IIIR major depression treated with clomipramine alone developed at least one sympton of the serotonin syndrome in a prospective study (Lejoyeux et al, 1993). This syndrome includes confusion, agitation, myoclonus, diaphoresis, tremor, and diarrhea. In 14 cases, tremor and myoclonus occurred simultaneously and 10 patients presented tremor, myoclonus, diaphoresis, and shivering. With the exception of 2 patients, symptoms were transient, lasted less than 1 week, and resolved with treatment.

c) Two cases of clomipramine-moclobemide overdose resulted in fatal serotonin syndrome (Neuvonen et al, 1993j). A 23-year-old male and 19-year-old female ingested 1000-1500 mg moclobemide, an MAO-A selective inhibitor and 225 to 500 mg clomipramine in order to "get high". Two to 3 hours later they were euphoric, but developed extreme tremor within the next 2 hours followed by convulsions and loss of consciousness. Both patients died 9 to 10 hours after ingestion, one in status epilepticus and the other while in hyperthermia following generalized epileptiform convulsions. Blood levels of both drugs at autopsy were lower than expected, based on the estimated amount of drug ingested. This may reflect prolonged absorption or postmortem redistribution. There were no levels of desmethyl or hydroxy metabolites of clomipramine reported.

3.3.3.A.2 Galactorrhea

a) Summary

1) Clomipramine therapy has been associated with the development of galactorrhea, hyperprolactinemia, and amenorrhea.

b) Several cases of HYPERPROLACTINEMIA and galactorrhea have been reported with clomipramine therapy. A severely depressed woman in her late twenties was admitted to a psychiatric unit and started on oral clomipramine 75 mg twice daily and L-tryptophan 1 g 3 times daily. Two days later the patient developed profuse galactorrhea which was associated with AMENORRHEA. L-tryptophan was reduced and eventually stopped over a 3-week period with no change in breast secretion. Clomipramine was reduced to 25 mg twice daily and bromocriptine 2.5 mg twice daily was initiated. Galactorrhea gradually resolved after 6 weeks of this therapy and menstruation also returned at this time (Anand, 1985).

c) A woman who had been on oral clomipramine 10 mg twice daily for several years for anxiety developed galactorrhea, loss of libido, and uncomfortable breast engorgement 6 months after an increase of clomipramine to 50 mg at night (Fowlie & Burton, 1987). Her plasma prolactin levels were also above normal. Clomipramine was discontinued and within 2 weeks galactorrhea was reduced; within 3 months her breasts became normal and galactorrhea had resolved.

3.3.3.A.3 Hyperglycemia

a) Hyperglycemia, glucosuria and diabetes mellitus has been reported with the use of clomipramine (Prod Info ANAFRANIL(R) oral capsules, 2007a).

b) An 84-year-old woman developed severe hyperglycemia within 5 months following the initiation of clomipramine 25 mg/day. The patient had a medical history of well-controlled hypertension, atrial fibrillation and concomitant medications included aspirin and irbesartan. Her BMI was 23 kg/m(2) and she had a negative family history of diabetes or glucose intolerance. Upon physical examination the patient was dehydrated and neurological examination noted obtunded consciousness without other abnormalities. Laboratory analysis revealed severe hyperglycemia (serum glucose, 459 mg/dL (25.5 mmol/L)), ketonemia, metabolic acidosis, elevated HbA1C level (12%), serum sodium (158 mmol/L), SCr (1.8 mg/dL), glycosuria and ketonuria. Additional laboratory test results were within normal ranges (eg, CBC, serum lipase and serum amylase) and chest radiography and CT of the head and abdomen were unremarkable. Upon hospitalization, the clomipramine was discontinued and the patient was treated with IV insulin (30 units/day) and IV fluids. The patient's blood glucose level normalized with treatment and after 10 days, the insulin therapy was discontinued and the patient was discharged from the hospital. Three months after hospital discharge, laboratory analysis reported HbA1C level at 5% and the patient agreed to restart the clomipramine under medical surveillance. One week after restarting the clomipramine, the patient developed hyperglycemia (serum glucose, 250 mg/dL (13.88 mmol/L)), glycosuria, and ketonuria. Again, the clomipramine was discontinued and the blood glucose normalized after 2 days. A temporal relationship appears to exist between the administration of clomipramine and the development of hyperglycemia and with the resolution of the hyperglycemia upon withdrawal of clomipramine(Mumoli & Cei, 2008).

3.3.3.A.4 Syndrome of inappropriate antidiuretic hormone secretion

a) HYPONATREMIA secondary to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been attributed to clomipramine (Pledger & Mathew, 1989). Hyponatremia developed in a 64-year-old woman 2 days following initiation of clomipramine 25 g three times daily. The patient was not receiving other medications. Clomipramine was discontinued and electrolyte levels a week later were normal.

3.3.3.A.5 Weight change finding

a) Weight gain was reported in 18% of patients in controlled studies receiving clomipramine compared to 1% of patients administered placebo. Twenty-eight percent of these patients had weight gain of at least 7% of their initial body weight and several patients had weight gains in excess of 25% of their initial body weight. Conversely, 5% of patients receiving clomipramine and 1% receiving placebo had weight losses of at least 7% of their body weight (Prod Info Anafranil(R), 2001b).

3.3.4 Gastrointestinal Effects

3.3.4.A Clomipramine Hydrochloride

3.3.4.A.1 Gastrointestinal tract finding

a) Mild to moderate CONSTIPATION has been reported as an adverse effect by patients on clomipramine therapy (75 to 300 mg/day) (Dick & Ferrero, 1983)(Stern et al, 1980; Langohr et al, 1985a).

b) DRY MOUTH has been reported to occur in over 50% of patients on clomipramine therapy (75 to 300 mg/day) (Dunbar et al, 1985a); (Dick & Ferrero, 1983)(Flament et al, 1985; Johnston et al, 1988; Stern et al, 1980).

3.3.5 Hematologic Effects

3.3.5.A Clomipramine Hydrochloride

Agranulocytosis

Hematology finding

Pancytopenia

3.3.5.A.1 Agranulocytosis

a) Incidence: rare

b) Agranulocytosis has been reported with tricyclic antidepressants (Miller, 1963; Bird, 1960; Crammer & Elkes, 1967) and clomipramine has been associated with this syndrome. A 37-year-old depressed woman received a total of 2.65 grams of both oral and parenteral clomipramine over a 26-day period (Souhami et al, 1976). She developed a sore throat and fever 3 weeks after stopping treatment. A white cell count revealed a complete absence of neutrophils. The patient developed a candida infection and was admitted to the hospital for antibiotic therapy. After 12 days of NEUTROPENIA, there was an increase in the lymphocyte count followed by a sudden reappearance of neutrophils. Clinical

improvement was noted with the reappearance of neutrophils and the patient was discharged 40 days after admission. In a second report, a 49-year-old postmenopausal caucasian female was treated with clomipramine 150 mg at bedtime for 38 days. Four days after stopping the drug, a routine hemogram revealed leukopenia: 1200/mm(3) from 4500/mm(3) one month earlier. One week later, the white blood cell count was 4200 and the agranulocytosis had resolved (Gravenor et al, 1986).
c) A 67-year-old man developed concurrent severe agranulocytosis with elevation of hepatic transaminases after treatment with clomipramine (CMI) for 1 month at 175 mg/day. The white count returned to normal 14 days after discontinuation of CMI (Alderman et al, 1993).

3.3.5.A.2 Hematology finding

a) Clomipramine has caused LEUKOPENIA, agranulocytosis, THROMBOCYTOPENIA, ANEMIA, and pancytopenia. Leukocyte and differential blood counts should be obtained in patients who develop fever and sore throat during treatment with clomipramine (Prod Info Anafranil(R), 2001b).

3.3.5.A.3 Pancytopenia

a) Incidence: rare
b) A 54-year-old man developed pancytopenia after being treated with oral clomipramine 50 mg/day for approximately 40 days and parenteral clomipramine 50 mg/day for several days before the onset of symptoms (Magni et al, 1987). Several days after admission the patient experienced increased fatigue, drowsiness, pallor and ecchymoses on the arms. A complete blood count revealed a progressive reduction of all cell lines, with platelets and white blood cells leading the way. On day 20 after admission clomipramine was discontinued and his blood count began to rise. The patient was discharged on day 49 with his blood count still below baseline, but continuing to rise.

3.3.6 Hepatic Effects

3.3.6.A Clomipramine Hydrochloride

Allergic hepatitis

Hepatotoxicity

3.3.6.A.1 Allergic hepatitis

a) A 41-year-old woman developed allergic hepatitis with extreme eosinophilia during the second month of treatment with clomipramine for suicidal depression. After 4 weeks of clomipramine treatment (dose incremented to 150 milligrams/day), she developed right-sided upper abdominal pain and had fever, which normalized after 2 days. Abdominal pain persisted. Liver enzymes were elevated, but there was no eosinophilia. By 6 weeks, eosinophils had increased to 65% of the differential white blood cell count. Allergic hepatitis was diagnosed and clomipramine was discontinued. Hematopoietic side-effects disappeared within 2 weeks. Liver function took longer to normalize. Her depression was then successfully treated with a chemically unrelated substance (moclobemide) (Wiersma et al, 2000).

3.3.6.A.2 Hepatotoxicity

a) Incidence: 1-3%
b) Clomipramine has induced elevated aspartate aminotransferase (AST or SGOT) and alanine aminotransferase (ALT or SGPT) in approximately 1% and 3% of patients, respectively, to levels 3 times the upper limit of normal (Prod Info Anafranil(R), 2001b). Caution is indicated in treating patients with known liver disease, and periodic monitoring of hepatic enzymes is recommended in such patients.
c) A 67-year-old man developed concurrent severe agranulocytosis with elevation of hepatic transaminases after treatment with clomipramine (CMI) for 1 month at 175 mg/day. The white count returned to normal 14 days after discontinuation of CMI (Alderman et al, 1993).

3.3.8 Musculoskeletal Effects

3.3.8.A Clomipramine Hydrochloride

Fracture of bone

Fracture of bone, Nonvertebral

3.3.8.A.1 Fracture of bone

a) In a case-control study including fracture cases (n=124,655) during the year 2000 and age- and gender-matched controls (n=373,962), there was an increased risk of any fracture in participants who

were using an average standard daily dose of clomipramine (adjusted odds ratio (OR), 1.49; 95% CI, 1.19 to 1.88) compared to those who were not exposed to clomipramine. Clomipramine use was associated with an increased risk of hip fracture (adjusted OR, 2.04; 95% CI, 1.11 to 3.75), but not forearm (adjusted OR, 1.61; 95% CI, 0.89 to 2.89) or spine fracture (adjusted OR, 2.79; CI, 0.88 to 8.8) (Vestergaard et al, 2008)

3.3.8.A.2 Fracture of bone, Nonvertebral

a) In a prospective, population-based, cohort study (n=7983) with a mean follow-up of 8.4 years, there was an increased risk of nonvertebral fracture in adult participants older than 55 years of age (mean age of 77.5 years) who were currently using an tricyclic antidepressant (TCA), including amitriptyline, clomipramine, dosulepine, doxepine, imipramine, maprotiline, nortriptyline, and opipramol, compared to those who were not exposed to antidepressants. Current TCA use was associated with an increased risk of nonvertebral fracture (hazard ratio (HR), 1.6; 95% confidence interval (CI), 1.08 to 2.38) compared with no antidepressant use. Current TCA use was also associated with an increased risk of nonvertebral fracture (HR, 1.6; 95% CI, 1.02 to 2.5) compared with past antidepressant use (n=1217). Duration of TCA use of greater than 6 months was not associated with an increased risk of fractures when compared with no antidepressant use and with past antidepressant use. Fractures of the hip (most frequent), wrist, humerus, and pelvis were reported (Ziere et al, 2008).

3.3.9 Neurologic Effects

Clomipramine

Clomipramine Hydrochloride

3.3.9.A Clomipramine

3.3.9.A.1 Seizure

See Drug Consult reference: COMPARATIVE INCIDENCE OF SEIZURES FROM ANTIDEPRESSANTS

3.3.9.B Clomipramine Hydrochloride

Central nervous system finding

Gilles de la Tourette's syndrome

Seizure

Serotonin syndrome

3.3.9.B.1 Central nervous system finding

a) Summary

1) Increased aggression, tremor and decreased cognitive function have been associated with clomipramine administration in obsessive-compulsive disorder (OCD) and depressed patients and in normal volunteers. It has also precipitated panic attacks in patients with panic disorder.

b) TREMOR is a commonly reported adverse effect with clomipramine 75 to 300 mg/day in both depressive and obsessive compulsive disorder patients (Flament et al, 1985; Stern et al, 1980; Larsen et al, 1984; Levin, 1982a). In one study, the tremor was rapid with low amplitude and was successfully treated within a few days with oral biperiden 6 mg/day (Klok et al, 1981a).

c) The effects of a 10-day regimen of clomipramine (CMI) 25 to 50 mg tid on psychomotor and cognitive function were assessed in 12 normal volunteer subjects. CMI had little effect on EEG but reaction speed was markedly slowed. Tolerance did not develop to acute MEMORY IMPAIRMENT on a verbal recall test and subjective ratings for mood and bodily symptoms were adversely affected by CMI (Allen et al, 1991).

d) Performance on tasks tapping automatic and voluntary aspects of memory, attention, and motor speed was examined in 14 patients with major depressive disorder, before and after 3 weeks of treatment with clomipramine 150 mg/day. Performance on tasks requiring frontal functions improved or did not change, whereas verbal learning and retention, where hippocampal functioning is critical, were impaired. The latter tasks were negatively related to cerebrospinal fluid (CSF) 5-HIAA levels and plasma concentration of clomipramine (Bartfai et al, 1991).

3.3.9.B.2 Gilles de la Tourette's syndrome

a) Vocal and motor tics (Tourettism) developed after administration of clomipramine to a young patient with obsessive compulsive disorder and schizoid personality disorder (Moshe et al, 1994).

3.3.9.B.3 Seizure

a) Summary

1) Seizures associated with clomipramine have been reported during therapy, upon withdrawal of therapy by patient or neonate, and with overdoses. The Medical Letter reports that 0.7% of approximately 3,000 patients in United States clinical trials with clomipramine have experienced seizures (Anon, 1988a).

b) Incidence: 0.7%

c) Several incidences of major motor SEIZURES and STATUS EPILEPTICUS have been reported during clinical trials. The patients had no history of epilepsy or seizures prior to clomipramine therapy. One patient who experienced 2 seizures while on oral clomipramine 150 mg/day had a slightly abnormal EEG before treatment began (Marshall, 1971). The other patient experiencing a seizure while on oral clomipramine 150 mg/day was withdrawn from the study (Anon, 1986). The patient who experienced status epilepticus was on oral clomipramine 50 mg 3 times a day. The seizures were controlled with anticonvulsants and he was withdrawn from the study (Klok et al, 1981a).

d) A 40-year-old man with no history of epileptic seizures or head trauma was admitted to an emergency room comatose with generalized tonic-clonic movements (Flechter et al, 1983). According to his wife, he had taken approximately 2.5 g (100 tablets each 25 mg) of clomipramine. Within 8 hours of admission he developed generalized myoclonic jerking. He was treated with diazepam, diuretics, and large volumes of intravenous fluids. Within 4 days the myoclonic attacks resolved and he became fully conscious.

e) Within 36 hours of stopping clomipramine 50 mg three times daily, a 67-year-old woman became unconscious and developed clonic contractions of her limbs (Robinson, 1978). Following her convulsion she was restarted on clomipramine and fully recovered in 6 weeks, at which time the drug was gradually reduced with no further problems. The patient had no history of epileptic seizures or head trauma.

f) Two cases of neonatal convulsions due to maternal withdrawal of clomipramine were reported (Cowe et al, 1982a). In the first case a 22-year-old mother had been receiving clomipramine at an unspecified dose for the last 7 weeks of pregnancy for depression. She delivered a normal term male infant which developed convulsions at 8 hours of age. Parenteral treatment with phenobarbital and paraldehyde did not control the convulsions, which occurred intermittently for 53 hours. In the second case a 38-year-old mother had been receiving clomipramine and flurazepam at unspecified doses throughout pregnancy. Convulsions in the infant began 7 hours after birth. Parenteral phenobarbital was started but the infant continued to have myoclonic jerks. After 24 hours parenteral clomipramine was started at 0.4 mg over 2 hours, which suppressed the convulsions for 11 hours. Twitching in all limbs returned at this time and the infant was started on a continuous infusion of clomipramine which was gradually decreased over 12 days. Oral clomipramine was started and also slowly decreased. The infant remained jittery but the convulsions were under control. The clomipramine was discontinued at day 17 with no ill effects.

g) During a 4-week comparative trial, 36 female patients received either oral clomipramine or oral fluvoxamine 50 mg 3 times daily. During the third treatment week, 1 patient on clomipramine developed status epilepticus that was controlled with anticonvulsants. The patient had no history of epilepsy and was withdrawn from the study (Klock et al, 1981).

h) Acute and chronic effects of clomipramine on the human EEG in patients treated for depression could not be differentiated (Ulrich et al, 1994).

3.3.9.B.4 Serotonin syndrome

a) A 60-year-old woman with depression and anxiety suffered a fatal case of serotonin syndrome secondary to her clomipramine treatment (Rosebush et al, 1999). The woman had been receiving clomipramine for 8 months and her dose had been increased to 250 mg daily. Other medication included lisinopril, glyburide, and clonazepam. She became ill over a period of hours and developed encephalopathy, myoclonus, hyperreflexia, tremulousness, diarrhea, and incoordination. Her creatine phosphokinase increased to 39,900 units/L. Liver function tests were elevated, platelet count was elevated, and her coagulation studies were consistent with disseminated intravascular coagulation. Her blood level of clomipramine plus the major metabolite was 2,230 nmol/L (normal range less than 1,900). She was treated with cooling blankets, intravenous fluids, lidocaine for ventricular tachycardia, and phenytoin for seizures. Rhabdomyolysis occurred resulting in acute renal failure and the need for dialysis. After 4 weeks, she developed opportunistic infections and died.

b) Sixteen of 38 inpatients with DSM-IIIR major depression treated with clomipramine alone developed at least one sympton of the serotonin syndrome in a prospective study (Lejoyeux et al, 1993). This syndrome includes confusion, agitation, myoclonus, diaphoresis, tremor, and diarrhea. In 14 cases, tremor and myoclonus occurred simultaneously and 10 patients presented tremor, myoclonus, diaphoresis, and shivering. With the exception of 2 patients, symptoms were transient, lasted less than 1 week, and resolved with treatment.

3.3.12 Psychiatric Effects

3.3.12.A Clomipramine Hydrochloride

Aggressive behavior

Delirium

Hallucinations

Mania

Panic attack

Suicidal thoughts

3.3.12.A.1 Aggressive behavior

a) Paranoid ideation and aggressive behavior developed in two adolescents with obsessive compulsive disorder during treatment with therapeutic doses of clomipramine. Possible pathogenetic factors involving serotonin and serotonin receptor abnormalities are discussed (Alarcon et al, 1991).

3.3.12.A.2 Delirium

a) Two women, 61 and 67 years old, whose DSM-IV major depression failed to respond to oral treatment with clomipramine 150 mg/day, developed delirium and HALLUCINATIONS when intravenous clomipramine 12.5 milligrams was added to the regimen. Delirium was diagnosed within 4 to 6 days after beginning intravenous administration. In both cases, discontinuation of intravenous administration resulted in gradual improvement, over days, of the delirious state. In both women, plasma levels of clomipramine and its metabolite, desmethylclomipramine, doubled with the introduction of intravenous dosing (Ueda et al, 2000).

3.3.12.A.3 Hallucinations

a) The onset of "music hallucinations" has been associated with the use of clomipramine 75 mg per day three weeks after it was initiated for the treatment of major depression in a 67-year-old widowed female patient (Valleda & Gentil, 1991).

3.3.12.A.4 Mania

a) MANIA developed in 6 of 25 patients being treated with clomipramine for unipolar depression (van Sheyen & van Kammen, 1979). The patients had been on oral clomipramine 150 to 225 mg/day in 3 divided doses for 6 to 13 weeks before the development of mania. Mania lasted from 15 to 49 days after clomipramine was stopped and perphenazine or haloperidol therapy was initiated. The duration of the mania strongly correlated with the duration of clomipramine therapy.

3.3.12.A.5 Panic attack

a) Low-dose (12.5 mg) intravenous clomipramine precipitated severe dysphoria/panic attacks in patients with diagnosed panic disorder (George et al, 1995).

3.3.12.A.6 Suicidal thoughts

a) Adult and pediatric patients being treated with antidepressants for major depressive disorder who experience symptoms of anxiety, agitation, panic attacks, insomnia, irritability, hostility (aggressiveness), impulsivity, akathisia (psychomotor restlessness), hypomania, or mania may be at risk of suicidal ideation and behavior (SUICIDALITY). This same concern applies to treating patients with other psychiatric and nonpsychiatric disorders. If these symptoms are observed, therapy should be reevaluated and it may be necessary to discontinue medications when symptoms are severe, sudden in onset, or were not part of the patient's initial symptoms. Patients and their caregivers should be provided with the Medication Guide that is available for this drug (Anon, 2004).

b) A causal role for antidepressants in inducing suicidality has been established in pediatric patients. Anyone considering the use of antidepressants in a child or adolescent must balance this risk with the clinical need. In pooled analyses of 24 short-term, placebo-controlled trials of nine antidepressants (citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, bupropion, mirtazapine, nefazodone, and venlafaxine extended-release) including over 4400 pediatric patients with major depressive disorder, obsessive compulsive disorder, or other psychiatric disorders, a greater risk of suicidal behavior or ideation during the first few months of therapy was demonstrated in patients receiving antidepressants as compared with placebo (4% vs 2%, respectively). The risk of suicidality was most consistently observed in the trials that included patients with major depressive disorder, but there were signs of risk emerging from trials in other psychiatric indications, such as obsessive compulsive disorder and social anxiety disorder. No suicides occurred in these trials. The risk of suicidality during longer-term use (ie,

beyond several months) in pediatric patients is not known. It is also unknown whether this risk extends to adult patients (Anon, 2004).

3.3.13 Renal Effects

3.3.13.A Clomipramine Hydrochloride

3.3.13.A.1 Urinary retention

a) A 15-year-old male experienced 2 episodes of urinary retention while on oral clomipramine therapy for obsessive-compulsive disorder (Hermesh et al, 1987). The patient was on clomipramine 50 mg 3 times a day and first experienced urinary adverse effects 3 weeks from the initiation of therapy. Subcutaneous bethanechol 5 mg and oral phenoxybenzamine 40 mg/day for 3 days failed to improve his symptoms. Improvement in his obsessive-compulsive behavior was noted throughout clomipramine therapy and was maximal when the dose was increased to 200 mg/day. However during week 20 of therapy the patient experienced urinary retention for 16 hours and required catheterization to remove 1200 mL of urine. Within 8 days of clomipramine discontinuation all urinary symptoms had resolved.

3.3.14 Reproductive Effects

Clomipramine

Clomipramine Hydrochloride

3.3.14.A Clomipramine

3.3.14.A.1 Sexual dysfunction

See Drug Consult reference: DRUG-INDUCED SEXUAL DYSFUNCTION

3.3.14.B Clomipramine Hydrochloride

Sexual dysfunction

Sperm finding

3.3.14.B.1 Sexual dysfunction

a) DELAYED EJACULATION has been reported during several studies of patients with obsessive compulsive disorder at clomipramine doses of 50 to 300 mg/day (Yaryura-Tobias et al, 1976; Insel et al, 1983; Volavka et al, 1985a).

b) Partial or total ANORGASMIA was experienced by 92% (n=24; 17 men and 7 women) of patients with obsessive compulsive disorder during a double-blind, placebo-controlled study to assess changes in sexual function (Monteiro et al, 1987). None of the 9 placebo patients experienced any sexual dysfunction. Patients received clomipramine 25 to 200 mg/day. Most patients still had interest in sex but noticed difficulty in achieving orgasm within the first few days of clomipramine therapy. Normal sexual function returned within 3 days of stopping clomipramine in all but 1 man who improved without treatment in 3 months.

c) Orgasmic inhibition was reported in 1 male and 2 female patients who were depressed with obsessive-compulsive features (Quirk & Einarson, 1982). Orgasmic dysfunction occurred shortly after beginning clomipramine, despite a return of libido as the depression improved. Two patients were switched to desipramine; this resulted in resolution of sexual dysfunction while maintaining depression control. The third patient manipulated the dosing interval and reduced the intensity of the anorgasmia. Strong anticholinergic/antiadrenergic activity is felt to be the cause of anorgasmia from clomipramine.

d) There have been several interesting cases of patients experiencing ORGASM when yawning while receiving clomipramine therapy. Upon discontinuation of clomipramine these symptoms resolved. These side effects were discovered during routine questioning, and no placebo-replacement or rechallenge with clomipramine have been tried (McLean et al, 1983).

e) Three cases of painful ejaculation associated with clomipramine during the first 3 weeks of treatment were reported. Dosage was 100 mg/d in one case and 150 mg/d in 2 cases. The adverse effect resolved within several days of dosage reduction or discontinuation of the medication (Aizenberg et al, 1991).

3.3.14.B.2 Sperm finding

a) All spermiograms of 9 patients treated with clomipramine 75 mg/day for 3 months were pathological in terms of volume, motility, and morphology compared with 37% of control patients (same as healthy

population). Hormone levels associated with the hypothalamic hypophyseal-gonadal axis were not affected in either group (Maier & Koinig, 1994).

3.3.16 Other

3.3.16.A Clomipramine Hydrochloride

Summary

Withdrawal sign or symptom

3.3.16.A.1 Summary

a) GENERAL

1) Other than orthostatic hypotension, side effects from clomipramine treatment (dry mouth, tremor, sweating, constipation, accommodation disturbances, sedation) were no more frequent or severe in an older population (55 to 70 years of age, n=28) than in a younger one (less than 55 years of age, n=74) (Stage et al, 2002).

3.3.16.A.2 Withdrawal sign or symptom

a) A variety of withdrawal symptoms have been reported in association with abrupt discontinuation of clomipramine, including dizziness, nausea, vomiting, headache, malaise, sleep disturbance, hyperthermia, and irritability. In addition, such patients may experience a worsening of psychiatric status. The dosage of clomipramine should be gradually tapered and the patient monitored carefully during discontinuation (Prod Info Anafranil(R), 2001b; Diamond et al, 1989).

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info Anafranil(R), 2001c) (All Trimesters)

a) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

2) Australian Drug Evaluation Committee's (ADEC) Category: C (Batagol, 1996)

a) Drugs which, owing to their pharmacological effects, have caused or may be suspected of causing harmful effects on the human fetus or neonate without causing malformations. These effects may be reversible. Accompanying texts should be consulted for further details.

See Drug Consult reference: PREGNANCY RISK CATEGORIES

3) Crosses Placenta: Yes

4) Clinical Management

a) Due to reported teratogenic effects with other tricyclic antidepressants, use of clomipramine during pregnancy should be avoided if possible, especially during the first trimester. The dangers of failure to treat major depression, however, are obvious, and in each case these dangers must be weighed against the potential for teratogenic effects.

5) Literature Reports

a) Clomipramine has not been associated with teratogenic effects in human case reports, however, other tricyclic antidepressants (imipramine, amitriptyline) have been associated with teratogenic effects. Neonatal withdrawal symptoms secondary to maternal use of clomipramine have been reported.

b) Two cases of neonatal convulsions due to maternal withdrawal of clomipramine have been reported (Cowe et al, 1982). In the first case a 22-year-old mother had been receiving clomipramine at an unspecified dose for the last 7 weeks of pregnancy for depression. She delivered a normal term male infant who developed convulsions at 8 hours of age. Parenteral treatment with phenobarbital and paraldehyde did not control the convulsions, which occurred intermittently for 53 hours. In the second case, a 38-year-old mother had been receiving clomipramine and flurazepam of unspecified doses throughout pregnancy. Convulsions in the infant began 7 hours after birth. Parenteral phenobarbital was started but the infant continued to have myoclonic jerks. After 24 hours parenteral clomipramine was started at 0.4 mg over 2 hours, which suppressed the convulsions for 11 hours. Twitching in all limbs returned at this time and the infant was started on a continuous infusion of clomipramine which was started and also slowly decreased. The infant remained jittery but the convulsions were under control. The clomipramine was discontinued at day 17 with no ill effects.

c) In a case report, a pregnant woman with endogenous depression had been taking oral clomipramine 200 mg daily throughout her pregnancy (Ostergaard & Pedersen, 1982). She delivered an infant who became cyanotic, lethargic, and tachypneic with moderate respiratory acidosis. Treatment with oxygen and incubation reversed these conditions. The infant developed twitches and tremors with an abnormal motor pattern within 24 hours of birth. Following treatment with phenobarbital, the symptoms gradually decreased and completely resolved in one week.

d) A mother treated with clomipramine during pregnancy delivered a normal infant at term (Schimmell et al, 1991). The newborn did show hypotonia and jitteriness at birth and both effects resolved spontaneously by 6 days of age. The infant was breast-fed while the mother took oral clomipramine in therapeutic dosage (150 mg/day), producing a clomipramine level in the infant of 0.4% of the material level. Four of five women who took clomipramine throughout their pregnancies delivered healthy babies with no evidence of congenital malformations. The fifth woman elected to terminate her pregnancy at 9 weeks. Thus, the authors concluded that clomipramine can be safely used in pregnant women and mothers who breast-feed their newborns without fear of clomipramine intoxication.

e) Based on data collected through the Motherisk Program, there appear to be no differences in cognitive function, temperament and general behavior in children exposed to clomipramine throughout gestation as compared to controls (Nulman et al, 2002). However, among infants who were exposed to either fluoxetine or tricyclic antidepressants thoughout gestation, those born to mothers with uncontrolled depressive symptoms showed lower cognitive and language achievements than those born to mothers who were well-controlled (Nulman et al, 2002).

B) Breastfeeding

1) American Academy of Pediatrics Rating: Drugs for which the effect on nursing infants is unknown but may be of concern. (Anon, 2001)

2) World Health Organization Rating: Compatible with breastfeeding. (Anon, 2002)

3) Thomson Lactation Rating: Infant risk cannot be ruled out.

a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk when used during breastfeeding. Weigh the potential benefits of drug treatment against potential risks before prescribing this drug during breastfeeding.

4) Clinical Management

a) According to the American Academy of Pediatrics, clomipramine is among those agents that may be of concern when used while breastfeeding (Anon, 2001). Although clomipramine appears in breast milk, the concentration is low and may not be pharmacologically significant.

5) Literature Reports

a) Clomipramine is excreted in breast milk. A mother treated with clomipramine during pregnancy delivered a normal infant at term (Schimmell et al, 1991a). The newborn did show hypotonia and jitteriness at birth and both effects resolved spontaneously by 6 days of age. The milk:plasma ratios on the 4th and 6th days were 1.62 and 1.04, respectively. The infant was started on breastfeeding at the 7th day of age while the mother took oral clomipramine in therapeutic dosage (150 mg/day), producing a clomipramine level in the infant of 0.4% of the maternal level. The milk:plasma ratios on the 10th, 14th, and 35th days were 0.76, 0.84, and 1.22, respectively.The infant remained asymptomatic.

b) A report describing four women maintained on clomipramine 75 mg to 125 mg per day who breastfed their infants demonstrated that infant serum concentrations of clomipramine metabolites (N-desmethylclomipramine, 8-hydroxyclomipramine and 8-hydroxydesmethylclomipramine) were below the assay sensitivity of 10 ng/mL. The measurements were taken after approximately 3 weeks of consistent maternal dosing, and all infants were noted to be developing normally (Wisner et al, 1995).

6) Drug Levels in Breastmilk

a) Parent Drug

1) Milk to Maternal Plasma Ratio

a) 0.76-1.62 (Schimmell et al, 1991a)

b) Active Metabolites

1) DESMETHYLCLOMIPRAMINE (Nagy & Johansson, 1977a)

3.5.1.A Acenocoumarol

1) Interaction Effect: increased risk of bleeding

2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970k; Williams et al, 1976k). Considerable interindividual differences may be

found (Pond et al, 1975k).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased acenocoumarol metabolism; increased acenocoumarol absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975j). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970j). The proposed mechanism of action was reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976j). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.B Amobarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.C Amphetamine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such

therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.D Amprenavir
1) Interaction Effect: increased tricyclic serum concentrations and potential toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias)
2) Summary: Coadministered amprenavir may increase serum concentrations of tricyclic antidepressants, causing a potential risk of arrhythmias or other serious adverse effects. Currently no interaction study has been conducted. Amprenavir is metabolized by cytochrome P450 3A4 enzymes in addition to being a CYP3A4 inhibitor, and tricyclics may partially depend on this pathway for metabolism. Plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly in patients also receiving amprenavir (Prod Info Agenerase(R), 2000).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: If concomitant therapy with amprenavir and a tricyclic antidepressant is unavoidable, plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly. Also monitor patients for signs and symptoms of tricyclic toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias).
7) Probable Mechanism: inhibition of cytochrome P450-mediated tricyclic metabolism

3.5.1.E Anisindione
1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970e; Williams et al, 1976e). Considerable interindividual differences may be found (Pond et al, 1975e).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased anisindione metabolism; increased anisindione absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975d). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970d). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent

TCAs (Williams et al, 1976d). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.F Aprobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.G Arbutamine

1) Interaction Effect: unreliable arbutamine test results
2) Summary: Because tricyclic antidepressants may affect heart rate, arbutamine should not be administered to a patient receiving a tricyclic antidepressant, since arbutamine test results may be unreliable (Prod Info GenESA(R), 1997).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Arbutamine should not be administered to a patient receiving tricyclic antidepressant therapy.
7) Probable Mechanism: alteration of heart rate by the tricyclic antidepressant

3.5.1.H Arformoterol

1) Interaction Effect: an increased risk of cardiovascular excitation
2) Summary: Concurrent administration of arformoterol with a tricyclic antidepressant (TCA) may lead to potentiation of arformoterol's adrenergic effects on the cardiovascular system. Therefore, extreme caution is advised if arformoterol is administered to patients who are being treated with a TCA (Prod Info BROVANA (TM) inhalation solution, 2006). Monitor patients closely for adverse cardiovascular effects.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Extreme caution and close observation for adverse cardiovascular effects are warranted when arformoterol is administered concurrently with a tricyclic antidepressant (TCA) as the cardiovascular effects of arformoterol can be potentiated by TCAs (Prod Info BROVANA(TM) inhalation solution, 2006).
7) Probable Mechanism: potentiation of cardiovascular effects

3.5.1.I Armodafinil

1) Interaction Effect: increased clomipramine exposure
2) Summary: Administration of armodafinil (R-enantiomer of modafinil) may cause moderate inhibition of CYP2C19 isozyme activity. Although not studied with clomipramine, a CYP2C19 substrate, concurrent administration of a single 400-mg dose of armodafinil with a 40-mg dose of omeprazole, also a CYP2C19 substrate, led to an approximately 40% increase in systemic exposure of omeprazole. Additionally, increased levels of clomipramine and its active metabolite, desmethylclomipramine, were reported in a narcoleptic patient receiving concomitant therapy with modafinil. Therefore, use caution when armodafinil and clomipramine are used concurrently. Dose reductions of clomipramine may be necessary (Prod Info NUVIGIL(TM) oral tablets, 2007). Also, monitor patients for increased clomipramine adverse events (dry mouth, sedation, urinary retention).

3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution with the coadministration of armodafinil and clomipramine as this may result in increased clomipramine exposure. Dose reductions of clomipramine may be necessary (Prod Info NUVIGIL(TM) oral tablets, 2007). Monitor patients for increased clomipramine adverse events (dry mouth, sedation, urinary retention).
7) Probable Mechanism: inhibition of CYP2C19-mediated clomipramine metabolism

3.5.1.J Atazanavir
1) Interaction Effect: increased plasma concentrations of tricyclic antidepressants (drowsiness, hypotension, akathisia)
2) Summary: Coadministration of atazanavir and tricyclic antidepressants has not been studied. However, the coadministration of atazanavir and tricyclic antidepressants has the potential to produce serious and/or life-threatening adverse events (Prod Info Reyataz(TM), 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: If atazanavir and tricyclic antidepressants are used concomitantly, monitor patient for clinical signs and symptoms of tricyclic antidepressant toxicity (hypotenstion, akathisia, anticholinergic effects, sedation, confusion, cardiac arrhythmias).
7) Probable Mechanism: unknown

3.5.1.K Atomoxetine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as clomipramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with clomipramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with clomipramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by clomipramine

3.5.1.L Belladonna
1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)
2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with tricyclic antidepressants. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the clinical severity of the interaction with tricyclic antidepressants is unknown. Caution is advised.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.
7) Probable Mechanism: additive anticholinergic effect

3.5.1.M Belladonna Alkaloids
1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)
2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with tricyclic antidepressants. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the clinical severity of the interaction with tricyclic antidepressants is unknown. Caution is

advised.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.
7) Probable Mechanism: additive anticholinergic effect

3.5.1.N Bepridil
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: In US clinical trials, the QT and QTc intervals were commonly prolonged by bepridil in a dose-related fashion (Prod Info Vascor(R), 2000). Tricyclic antidepressants (TCAs) have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982a).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Concurrent use of bepridil and other drugs which may prolong the QTc interval, including tricyclic antidepressants, is contraindicated.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.O Bethanidine
1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Antidepressants inhibit the uptake of bethanidine at its site of action in the adrenergic neuron. The antagonism may last for several days after discontinuation of the antidepressant (Skinner et al, 1969a; Avery, 1973a; Feagin et al, 1969).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The combination of bethanidine and clomipramine, as well as other tricyclic antidepressant agents, should be avoided. An alternative antihypertensive agent should be considered.
7) Probable Mechanism: decreased uptake of bethanidine into adrenergic neurons
8) Literature Reports
a) Adequate control of hypertension was reported in only 2 of 8 adult hypertensive patients who received bethanidine or debrisoquine concurrently with a tricyclic antidepressant. In 24 control patients given the same drugs without antidepressants, blood pressure control was achieved in 18. Withdrawal of antidepressant therapy in several patients resulted in postural hypotension that necessitated a reduction in dosage of bethanidine or debrisoquine (Skinner et al, 1969).

3.5.1.P Butabarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.Q Butalbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.R Cannabis

1) Interaction Effect: tachycardia and delirium

2) Summary: Concomitant tetrahydrocannabinol and tricyclic antidepressant therapy has increased the heart rate and cause delirium beyond that expected with either drug alone (Wilens et al, 1997a; Hillard & Vieweg, 1983a).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Caution is advised if patients use cannabis with a tricyclic antidepressant. Monitor heart rate changes closely.

7) Probable Mechanism: possibly due to beta-adrenergic effect of cannabis coupled with the anticholinergic effect of tricyclic antidepressants

8) Literature Reports

a) A 21-year-old female receiving oral nortriptyline 30 milligrams at bedtime for 9 months developed marked sinus tachycardia (160 beats/minute) within 30 minutes of smoking a cannabis cigarette. The patient's heart rate was about 90 beats/minute before smoking the cannabis. She had used cannabis many times before starting the nortriptyline without ill effects (Hillard & Vieweg, 1983).

b) Four cases of tachycardia, cognitive changes, and delirium have been reported in adolescent males treated with tricyclic antidepressants who smoked marijuana. One of the four cases was evaluated by a physician, the others were later accounts of the event. The toxic effects were considered by the reporters to have resulted from a drug interaction because they occurred with lower doses of marijuana than are common in other reports of marijuana toxicity (usually greater than 20 mg). In case 1, a 16-year-old male taking nortriptyline 75 mg/day presented with tachycardia (130 beats/minute), delirium, confusion, and short-term memory loss 30 minutes after smoking one marijuana cigarette. Symptoms resolved spontaneously after 24 hours. In case 2, and 18-year-old male taking desipramine 200 mg/day presented 12 hours after smoking marijuana with symptoms of edginess, severe dry mouth, lightheadedness, confusion, short-term memory impairment, and tachycardia (110 beats/minute). Symptoms resolved within 48 hours. Case 3, a 15-year-old male taking desipramine 150 mg/day and sertraline 50 mg/day, reported mood lability, irritability, and a racing heart after smoking 2 marijuana cigarettes which resolved after 16 hours. Case 4, a 16-year-old male taking desipramine and clonidine reported hallucinations, confusion, mild shortness of breath, and elevated heart rate after smoking marijuana. This was different than the effect he experienced prior to taking desipramine (Wilens et al, 1997).

3.5.1.S Carbamazepine

1) Interaction Effect: decreased clomipramine effectiveness

2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease antidepressant levels (Leinonen et al, 1991; Brown et al, 1990). Although not reported for clomipramine, a similar interaction could occur.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical
6) Clinical Management: Monitor for clinical efficacy of the clomipramine therapy and for any signs of toxicity of carbamazepine. Serum levels of both agents should be considered when either agent is added or discontinued, with appropriate dosage adjustments made accordingly.
7) Probable Mechanism: increased clomipramine metabolism
8) Literature Reports
a) Concomitant administration of imipramine and carbamazepine to children with attention deficit disorder (ADD) has been reported to result in a 50% decrease in the total plasma concentration of imipramine plus desipramine (Brown et al, 1988). Carbamazepine enhances the hepatic microsomal metabolism of imipramine and other tricyclic antidepressants by inducing hepatic enzymes (Moody et al, 1977). Although not reported specifically for clomipramine, be aware that the potential for a similar interaction exists. Patients on chronic carbamazepine therapy may require increased doses of tricyclic antidepressants.

3.5.1.T Chlorotrianisene
1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973g), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972g). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972g) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984g).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) The qualitative effects of concomitant administration of estrogen and TCAs was evaluated. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972f).
b) A case reported demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams (Khurana, 1972f). The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973f).
c) A study in which women received clomipramine and oral contraceptives or clomipramine alone was reviewed. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973c).
d) The effects of oral contraceptives on clomipramine in 42 women between the ages of 18 and 40 was studied. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980c).

e) Akathisia in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently was reported. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984f).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984c).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980c). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983c).

3.5.1.U Cimetidine

1) Interaction Effect: clomipramine toxicity (dry mouth, blurred vision, urinary retention)
2) Summary: Cimetidine impairs the metabolism of tricyclic antidepressants (Miller et al, 1983; Sutherland et al, 1987; Steiner & Spina, 1987). Although not reported for clomipramine, it is likely that a similar interaction would occur because of the mechanism involved.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Consider monitoring serum tricyclic antidepressant levels within the first few days of starting or discontinuing cimetidine. An H2 blocker that does not impair the metabolism of the tricyclic agents, such as ranitidine or famotidine, may be an alternative.
7) Probable Mechanism: decreased clomipramine metabolism

3.5.1.V Cisapride

1) Interaction Effect: cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cisapride therapy has resulted in serious cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, torsades de pointes, and QT prolongation. Because tricyclic antidepressant agents also may prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of cisapride with a drug from this class is contraindicated (Prod Info Propulsid(R), 2000).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent use of cisapride and tricyclic antidepressants is contraindicated.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.W Clonidine

1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Concomitant clonidine and tricyclic antidepressant (TCA) therapy may impair the antihypertensive effects of clonidine (Prod Info Catapres(R), 1996). Tricyclic antidepressants increase the release of noradrenaline, presumably through re-uptake blockade. Clonidine reduces the release of noradrenaline by stimulating pre-synaptic alpha-2 adrenoreceptors, whose function is to inhibit noradrenaline release (Briant et al, 1973a; Hicks et al, 1981; Hui, 1983; Glass et al, 1982a). Mianserin, a tetracyclic antidepressant, was not shown to exhibit the impairment of clonidine's antihypertensive effects seen with tricyclic antidepressants (Elliott et al, 1981; Elliott et al, 1983).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Blood pressure should be monitored for an appropriate clinical response. Higher doses of clonidine may be required. An alternative class of antihypertensive agents or an alternative class of antidepressants might be considered.
7) Probable Mechanism: pharmacological antagonism at central alpha-2 receptors
8) Literature Reports

a) The interaction between clonidine and desipramine developed in five hypertensive patients. The results of this double-blind placebo controlled study showed that the introduction of the tricyclic antidepressant led to the loss of blood pressure control in four of the five subjects within two weeks. The rise in the arterial pressure was more prominent in the supine position than in the erect. The average

blood pressure increase in the desipramine period compared to the placebo period was 22/15 mm Hg in the lying position and 12/11 mm Hg standing (Briant et al, 1973).
b) Eleven drug-free patients who met the Research Diagnostic Criteria for Major Depressive Disorder enrolled in a study to determine the effects of desipramine on central adrenergic function. Patients were given a clonidine infusion after 0, 1 and 3 weeks of treatment with desipramine. Results showed that the sedative and hypotensive effects of clonidine were significantly inhibited after three weeks of treatment with desipramine. This interaction was also seen at one week, but did not reach clinical significance. The authors concluded that the effects that were observed during the study were due to an acute drug effect, rather than to a chronic adaptive change (Glass et al, 1982).
c) One case report describes a 65-year-old man who was experiencing perineal pain following the excision of a carcinoma. Pain management of amitriptyline 75 mg nightly and sodium valproate 500 mg three times daily was initiated after slow-release morphine only had a limited effect. A clonidine spinal intrathecal injection of 75 micrograms was given when it was felt that the patient had become tolerant to opioid treatment. Within five minutes, the patient was found to be in severe pain, which resolved within 30 minutes after diamorphine was given. Two mechanisms for this interaction were postulated. In the first, the pain could have been the result of a clonidine-cholinergic interaction. In the second, the tricyclic augmentation of serotoninergic transmission may have unmasked an effect of clonidine at central receptors to enhance nociception (Hardy & Wells, 1988).

3.5.1.X Clorgyline

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982r; Spigset et al, 1993q; Brodribb et al, 1994p; Neuvonen et al, 1993i). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991j). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971u; White & Simpson, 1984p).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of clomipramine with a monoamine oxidase inhibitor (MAOI), such as clorgyline is contraindicated. If clomipramine is replacing treatment with clorgyline, a minimum of 14 days should elapse after clorgyline is discontinued before begin therapy with clomipramine. Similarly, if clomipramine is substituted by clorgyline, a minimum of 14 days should elapse after clomipramine is discontinued and begin therapy with clorgyline (Prod Info clomipramine hydrochloride oral capsule, 2002).
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info clomipramine hydrochloride oral capsule, 2002). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965j; Brachfeld et al, 1963f; Winston, 1971j; Schuckit et al, 1971t; Sargent, 1965f; Spiker & Pugh, 1976j). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965j).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982q).
c) A drug interaction was reported in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993p).
d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion,

fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994o).
e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986d).
f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987i).
g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974e; Winston, 1971j; Schuckit et al, 1971t; White & Simpson, 1984o; Rom & Benner, 1972e). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991i). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991i). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977j; Schuckit et al, 1971t; Ashcroft, 1975i).

3.5.1.Y Conjugated Estrogens

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).
3) Severity: minor
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).
b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched

after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).
d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.Z Dexfenfluramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled

steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AA Dexmethylphenidate

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AB Dextroamphetamine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed

5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AC Dicumarol
1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970g; Williams et al, 1976g). Considerable interindividual differences may be found (Pond et al, 1975g).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased dicumarol metabolism; increased dicumarol absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975f). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970f). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976f). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.AD Dienestrol
1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).
3) Severity: minor

4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).

b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).

d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.AE Diethylpropion

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AF Diethylstilbestrol
1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973m), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972l). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972m) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984l).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose

estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972k).

b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972l). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973l).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973g).

d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980e).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984k).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984f).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980f). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983f).

3.5.1.AG Diphenhydramine

1) Interaction Effect: increased anticholinergic effects (dry mouth, urinary retention)

2) Summary: Concomitant antidepressants with strong anticholinergic effects (e.g., amitriptyline, amoxapine, clomipramine) and antihistamines may increase the possibility of adynamic ileus, urinary retention, or chronic glaucoma. This interaction may be more prominent in elderly patients (Blazer et al, 1983; Arnold et al, 1981).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Patients should be warned that taking antihistamines, including over-the-counter sleeping pills and cold and allergy preparations, may increase the side effects of clomipramine. Patients should be monitored for dry mouth, drowsiness, and problems with urination. Lower dose of diphenhydramine might be considered, particularly in elderly individuals.

7) Probable Mechanism: additive anticholinergic effects

3.5.1.AH Duloxetine

1) Interaction Effect: increased tricyclic antidepressant serum concentrations and potential toxicity

(anticholinergic effects, sedation, confusion, cardiac arrhythmias)
2) Summary: The coadministration of duloxetine with a tricyclic antidepressant is likely to increase bioavailability of the tricyclic agent, increasing the risk of adverse events. Duloxetine is a moderately potent inhibitor of CYP2D6. When a single dose of the CYP2D6 substrate desipramine 50 mg and duloxetine 60 mg twice daily were coadministered, the desipramine AUC increased 3-fold over baseline (Prod Info CYMBALTA(R) delayed-release oral capsules, 2008).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution with the combined use of duloxetine with tricyclic antidepressants (TCAs). If concomitant therapy with duloxetine and a TCA is unavoidable, plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly (Prod Info CYMBALTA(R) delayed-release oral capsules, 2008). Also, monitor patients for signs and symptoms of TCA toxicity (anticholinergic effects, sedation, confusion, and cardiac arrhythmias).
7) Probable Mechanism: duloxetine inhibition of CYP2D6-mediated tricyclic agent metabolism

3.5.1.AI Enalaprilat
1) Interaction Effect: clomipramine toxicity (confusion, insomnia, irritability)
2) Summary: The addition of clomipramine to long-standing enalapril therapy resulted in high blood levels of clomipramine and signs of toxicity (confusion, insomnia, irritability, and mood changes) in 2 cases. Reduction of the clomipramine dose resulted in lower blood levels (Toutoungi, 1992).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for signs of clomipramine toxicity; lower doses may be required with concurrent therapy with enalapril.
7) Probable Mechanism: unknown

3.5.1.AJ Enalapril Maleate
1) Interaction Effect: clomipramine toxicity (confusion, insomnia, irritability)
2) Summary: The addition of clomipramine to long-standing enalapril therapy resulted in high blood levels of clomipramine and signs of toxicity (confusion, insomnia, irritability, and mood changes) in 2 cases. Reduction of the clomipramine dose resulted in lower blood levels (Toutoungi, 1992).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for signs of clomipramine toxicity; lower doses may be required with concurrent therapy with enalapril.
7) Probable Mechanism: unknown

3.5.1.AK Epinephrine
1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions

(severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.AL Esterified Estrogens

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AM Estradiol

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).
3) Severity: minor
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).
b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).
d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed

amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AN Estriol

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AO Estrone

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).
3) Severity: minor
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).
b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).
d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of

18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AP Estropipate

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h; Khurana, 1972h).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out.

The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973d).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AQ Eterobarb

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.AR Ethinyl Estradiol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973c), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972c). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972c) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984c).

3) Severity: minor

4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972b).

b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972b). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973b).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973a).

d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980a).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984b).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984a).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980a). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983a).

3.5.1.AS Etilefrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.AT Fenfluramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AU Fluvoxamine

1) Interaction Effect: clomipramine toxicity (dry mouth, urinary retention, sedation)
2) Summary: Coadministration of fluvoxamine and clomipramine was found to significantly increase plasma levels of clomipramine (Bertschy et al, 1991a). A bidirectional effect was suggested in which fluvoxamine increased clomipramine concentrations (by interfering with N-demethylation) and clomipramine increased fluvoxamine levels (Hartter et al, 1993a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor patients for signs of clomipramine and fluvoxamine toxicity; lower doses of one or both agents may be required with concomitant therapy.
7) Probable Mechanism: decreased clomipramine metabolism
8) Literature Reports
a) Fluvoxamine has been shown to significantly increase plasma levels of amitriptyline and clomipramine and to mildly increase levels of their metabolites nortriptyline and desmethylclomipramine, respectively. This may be due to competitive inhibition of oxidative metabolism in the liver (Bertschy et al, 1991).
b) Metabolism of tricyclic antidepressants coadministered with fluvoxamine was studied in eight depressed patients (four patients received clomipramine). Fluvoxamine was found to interfere with N-demethylation and 8-hydroxylation of clomipramine. The combination of fluvoxamine and clomipramine led to increased plasma levels of clomipramine and decreased concentrations of clomipramine's N-demethylated metabolite, desmethylclomipramine. In addition, plasma levels of fluvoxamine were increased (Hartter et al, 1993).

3.5.1.AV Formoterol

1) Interaction Effect: an increased risk of cardiovascular excitation
2) Summary: Concurrent administration of formoterol with a tricyclic antidepressant (TCA) may lead to potentiation of formoterol's adrenergic effects on the cardiovascular system. Therefore, extreme caution is advised if formoterol is administered to patients who are being treated with a TCA (Prod Info FORADIL(R) AEROLIZER(R) inhalation powder, 2006). Monitor patients closely for adverse cardiovascular effects.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Extreme caution and close observation for adverse cardiovascular effects are warranted when formoterol is administered concurrently with a tricyclic antidepressant (TCA) as the cardiovascular effects of formoterol can be potentiated by TCAs (Prod Info FORADIL(R) AEROLIZER(R) inhalation powder, 2006).
7) Probable Mechanism: potentiation of cardiovascular effects

3.5.1.AW Fosamprenavir

1) Interaction Effect: increased tricyclic agent serum concentrations and potential toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias)
2) Summary: Coadministration of fosamprenavir with a tricyclic antidepressant may provoke increased serum concentrations of the tricyclic antidepressant, causing a potential risk of arrhythmias or other serious adverse effects. Fosamprenavir is a prodrug of amprenavir, an inhibitor of the CYP3A4 isoenzyme in addition to being a CYP3A4 substrate. Tricyclic agents may partially depend on the CYP3A4 pathway for metabolism. Plasma concentrations of the tricyclic agent should be closely monitored in patients also receiving fosamprenavir (Prod Info LEXIVA(R) oral solution, oral tablets, 2009).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: If concomitant therapy with fosamprenavir and a tricyclic antidepressant is unavoidable, plasma concentrations of the tricyclic agent should be closely monitored. Also monitor patients for signs and symptoms of tricyclic toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias) (Prod Info LEXIVA(R) oral solution, oral tablets, 2009).
7) Probable Mechanism: inhibition of CYP3A4-mediated tricyclic agent metabolism

3.5.1.AX Fosphenytoin

1) Interaction Effect: an increased risk of phenytoin toxicity (ataxia, hyperreflexia, nystagmus, tremor)
2) Summary: Fosphenytoin is a prodrug of phenytoin and the same interactions that occur with phenytoin are expected to occur with fosphenytoin (Prod Info Cerebyx(R), 1999). A few case reports have indicated

that imipramine inhibits phenytoin metabolism resulting in increased serum phenytoin concentration (Petti & Campbell, 1975; Perucca & Richens, 1977). Tricyclic antidepressants (TCAs) may lower the seizure threshold in epileptic patients stabilized on anticonvulsants. Theoretically, because phenytoin is an enzyme inducer, the metabolism of antidepressants may be increased resulting in reduced TCA serum levels.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Consider monitoring phenytoin serum levels if a tricyclic antidepressant is added to therapy or if the patient begins to exhibit signs of toxicity (tremor, nystagmus, ataxia, hyperreflexia); lower doses of phenytoin may be required. If phenytoin is added to tricyclic antidepressant therapy, monitor for clinical efficacy of the tricyclic agent.
7) Probable Mechanism: inhibition of phenytoin metabolism

3.5.1.AY Gatifloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Gatifloxacin may prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Although pharmacokinetic studies between gatifloxacin and other drugs which prolong the QT interval have not been performed, an additive effect cannot be excluded. Therefore, the concurrent administration of gatifloxacin and a tricyclic antidepressant is not recommended (Prod Info Tequin(TM), 1999).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of gatifloxacin and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AZ Grepafloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Healthy volunteers who received grepafloxacin during a Phase I study experienced prolongation of the QTc interval. On an outpatient basis, grepafloxacin is contraindicated with other drugs that are known to also prolong the QTc interval or cause torsades de pointes, including tricyclic antidepressants. When appropriate cardiac monitoring can be assured, such as in the hospitalized patient, these two agents should be coadministered with caution (Prod Info Raxar(R), 1999).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The concurrent use of grepafloxacin and tricyclic antidepressants is contraindicated unless appropriate cardiac monitoring can be assured, such as in the hospitalized patient.
7) Probable Mechanism: additive cardiac effects

3.5.1.BA Guanadrel
1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Tricyclic antidepressants inhibit the uptake of guanethidine, and possibly guanadrel, into the adrenergic neuron, resulting in an inhibition of its antihypertensive effect (Mitchell et al, 1967; Ober & Wang, 1973). When a patient is on concomitant tricyclic antidepressant and guanadrel therapy, caution should be exercised when the tricyclic antidepressant is discontinued, since an exaggerated effect of guanadrel may be seen (Prod Info Hylorel(R), 1995).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Blood pressure should be monitored for an appropriate clinical response; higher doses of guanadrel may be required. An alternative class of antihypertensive agents, such as an angiotensin-converting enzyme inhibitor, might be considered.
7) Probable Mechanism: decreased uptake of guanadrel into adrenergic neurons

3.5.1.BB Halofantrine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Halofantrine can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of halofantrine and tricyclic antidepressants is not recommended (Prod Info Halfan(R), 1998; Marshall & Forker, 1982b).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable

6) Clinical Management: The concurrent administration of halofantrine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects

3.5.1.BC Heptabarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BD Hexobarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BE Iproniazid
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982k; Spigset et al, 1993j; Brodribb et al, 1994h; Neuvonen et al, 1993e). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991f). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971m; White & Simpson, 1984i).
3) Severity: major

4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. Consider using a 14 day washout period between treatment with both medicines. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965f; Winston, 1971f; Schuckit et al, 1971l; Spiker & Pugh, 1976f). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965f).

b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982j).

c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993i).

d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987f).

e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991e). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977f; Schuckit et al, 1971l; Ashcroft, 1975e).

3.5.1.BF Isocarboxazid

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: The concurrent administration of isocarboxazid and clomipramine is contraindicated (Prod Info Marplan(R), 1998). Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982g; Spigset et al, 1993h; Brodribb et al, 1994f; Neuvonen et al, 1993c). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991d). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971i; White & Simpson, 1984f).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent use of clomipramine and isocarboxazid is contraindicated. In patients being transferred to isocarboxazid therapy from a dibenzazepine-related entity, allow at least a one-week medication-free interval and then initiate isocarboxazid at one-half of the normal dose for at least the first week of therapy. Also allow one week to elapse between the discontinuation of isocarboxazid and the administration of another MAO inhibitor or dibenzazepine-related entity.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOI) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been

attributed to the combination (Lockett & Milner, 1965d; Brachfeld et al, 1963b; Winston, 1971d; Schuckit et al, 1971h; Sargent, 1965b; Spiker & Pugh, 1976d). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965d).

b) The development of serotonin syndrome was reported due to administration of a TCA after MAOI therapy. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982f).

c) A drug interaction was reported when a 76-year old woman who had been taking clomipramine 50 mg daily for several months was switched to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993g).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994e).

e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986a).

f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987d).

g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974a; Winston, 1971d; Schuckit et al, 1971h; White & Simpson, 1984e; Rom & Benner, 1972a). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991c). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991c). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977d; Schuckit et al, 1971h; Ashcroft, 1975c).

3.5.1.BG Linezolid

1) Interaction Effect: increased risk of serotonin syndrome (hyperthermia, hyperreflexia, myoclonus, mental status changes)

2) Summary: Concomitant use of linezolid and a tricyclic antidepressant, such as clomipramine, is contraindicated in the absence of monitoring for serotonin syndrome. If symptoms occur, consider discontinuation of either one or both of the drugs. Linezolid is a reversible, nonselective inhibitor of monoamine oxidase and may therefore interact with tricyclic antidepressants. Spontaneous reports of serotonin syndrome associated with the co-administration of linezolid and serotonergic agents have been reported (Prod Info ZYVOX(R) IV injection, oral tablets, oral suspension, 2008).

3) Severity: contraindicated

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Concurrent use of linezolid and tricyclic antidepressants, such as clomipramine, is contraindicated unless patient is closely observed for signs and/or symptoms of serotonin syndrome. If concomitant use is clinically warranted, monitor for signs and symptoms of serotonin syndrome, such as neuromuscular abnormalities (including hyper-reflexia, tremor, muscle rigidity, clonus, peripheral hypertonicity, and shivering), autonomic hyperactivity (including tachycardia, mydriasis, diaphoresis, the presence of bowel sounds, and diarrhea), and mental status changes (including agitation and delirium). Serotonin syndrome can be life-threatening. If serotonin syndrome develops, discontinue the offending

agents and provide supportive care and other therapy as necessary (Boyer & Shannon, 2005; Prod Info ZYVOX(R) IV injection, oral tablets, oral suspension, 2008).
7) Probable Mechanism: linezolid inhibition of monoamine oxidase resulting in an increased concentration of serotonin

3.5.1.BH Lisdexamfetamine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BI Lumefantrine

1) Interaction Effect: an increased risk of QT interval prolongation
2) Summary: Lumefantrine is a CYP2D6 inhibitor and may cause QT interval prolongation. Concomitant use of artemether/lumefantrine and a CYP2D6 substrate (eg, amitriptyline, clomipramine, flecainide, and imipramine) can lead to elevated drug levels of the CYP2D6 substrate. As some CYP2D6 substrates can also prolong the QT interval, there is potential for additive QT prolongation. Therefore, artemether/lumefantrine should not be coadministered with CYP2D6 substrates that possess cardiac effects (Prod Info COARTEM(R) oral tablets, 2009).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Artemether/lumefantrine should not be administered concomitantly with CYP2D6 substrates, such as amitriptyline, clomipramine, flecainide, and imipramine, due to the potential additive effect on QT interval prolongation (Prod Info COARTEM(R) oral tablets, 2009).
7) Probable Mechanism: additive effects on QT interval prolongation

3.5.1.BJ Mazindol

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BK Mephentermine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic

agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BL Mephobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BM Mestranol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973c), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972c). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972c) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984c).
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received

imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972b).

b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972b). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973b).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973a).

d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980a).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984b).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984a).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980a). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983a).

3.5.1.BN Methamphetamine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BO Methohexital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BP Methoxamine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.BQ Methylphenidate
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BR Midodrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).

b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.BS Moclobemide

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982i; Spigset & Mjorndal, 1993a; Brodribb et al, 1994g; Neuvonen et al, 1993d). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991e). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971k; White & Simpson, 1984h). An 18-year-old woman suffered irritability, twitching, agitation, myoclonus, and hypertonicity after changing from clomipramine to moclobemide with no washout period (Chan et al, 1998).

3) Severity: contraindicated

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Concomitant use of moclobemide and a tricyclic antidepressant, such as clomipramine, is contraindicated. If clomipramine is replacing treatment with moclobemide, a minimum of two days should elapse after moclobemide is discontinued and clomipramine therapy is begun (Prod Info Manerix(R), 2001). However, the manufacturer of clomipramine recommends that the monoamine oxidase inhibitor (MAOI) be discontinued for at least 14 days before treatment with doxepin is initiated. If moclobemide is replacing treatment with clomipramine, a minimum of 14 days should elapse after clomipramine is discontinued and moclobemide therapy is begun (Prod Info clomipramine hydrochloride oral capsule, 2002).

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965e; Brachfeld et al, 1963c; Winston, 1971e; Schuckit et al, 1971j; Sargent, 1965c; Spiker & Pugh, 1976e). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965e).

b) A clinical study designed to detect an interaction between moclobemide and a tricyclic antidepressant (clomipramine) resulted in severe adverse effects, and the study was terminated. Information about interactions with moclobemide and other tricyclic antidepressants is limited (Prod Info

Manerix(R), 2001).
c) A drug interaction occurred in which a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset & Mjorndal, 1993).
d) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982h).
e) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987e).
f) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974b; Winston, 1971e; Schuckit et al, 1971j; White & Simpson, 1984g; Rom & Benner, 1972b). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991d). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991d). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977e; Schuckit et al, 1971j; Ashcroft, 1975d).
g) A 29-year-old male presented to the emergency department of a hospital one hour after ingesting moclobemide 7.5 g, clomipramine 1 g, and clorazepate 450 mg. He was treated with gastric lavage, charcoal 30 g, and flumazenil, and was admitted to the hospital for observation. One hour later, he began to experience severe tremor, increased body temperature, and tonic-clonic seizures. He died of a cardiorespiratory arrest approximately 145 minutes after his arrival to the hospital. Moclobemide overdoses of 7 g to 8 g produce fatigue, agitation, increased blood pressure, and tachycardia with few other complications. However, in this case, the addition of clomipramine produced a fatal serotonin syndrome (Ferrer-Dufol et al, 1998).
h) A 25-year-old female with recurrent depressive disorder was stabilized on clomipramine 150 mg daily and alprazolam 1.5 to 3 mg daily for seven months when her depressive disorder again reappeared. Clomipramine therapy was discontinued, and moclobemide 300 mg daily was initiated 24 hours later. Moclobemide was rapidly increased to 600 mg daily, and the alprazolam dose remained the same. One week after the start of moclobemide, the patient presented with confusion, mild euphoria, and disinhibition. She reported that within a few hours of starting moclobemide therapy, she experienced an elevation of her mood, nausea, shivering, and flushing. Moclobemide was discontinued, with complete recovery from the drug interaction-induced symptoms eight days later. Because clomipramine has a half-life of 22 to 84 hours, significant amounts of the drug may still have been present when moclobemide therapy was instituted, causing serotonin syndrome (Dardennes et al, 1998).

3.5.1.BT Modafinil
1) Interaction Effect: increased plasma levels of clomipramine and desmethylclomipramine
2) Summary: A narcoleptic patient experienced an increase in her clomipramine levels when modafinil was added to her therapeutic regimen. Hepatic enzymes also increased from 2- to 7-fold, requiring that clomipramine be discontinued (Grozinger et al, 1998a). However, in healthy volunteers, the coadministration of a single dose of clomipramine 50 mg during the first day of a 3-day regimen of modafinil 200 mg daily did not result in an alteration in the pharmacokinetics of either drug (Prod Info Provigil(R), 1998).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor patients receiving modafinil and clomipramine concurrently for signs and symptoms of tricyclic intoxication. Liver enzymes should also be closely followed for marked increases.
7) Probable Mechanism: unknown
8) Literature Reports

a) A 60-year-old narcoleptic female was being treated with clomipramine without complete resolve of her symptoms. At a clomipramine dose of 75 mg under steady-state conditions, her clomipramine (CI) and desmethylclomipramine (DMCI) blood levels were 109 ng/mL and 212 ng/mL, respectively. These levels increased to 129 ng/mL and 208 ng/mL, respectively, when the clomipramine dose was increased to 100 mg. When modafinil 200 mg was instituted, the clomipramine dose was decreased to 75 mg, and the CI/DMCI levels increased to 158/238 ng/mL. With modafinil 400 mg and clomipramine 75 mg, the CI/DMCI levels further rose to 210/449 ng/mL. Hepatic enzymes (GOT, GLDH, GGT, GPT) increased from 2- to 7-fold, necessitating the discontinuation of clomipramine. Three weeks later, the DMCI level was 63 ng/mL, while clomipramine was no longer detectable. Hepatic enzymes also returned to baseline. The patient was determined to be a poor metabolizer with regard to cytochrome P450 2D6 (CYP2D6) isoenzymes, indicating that CYP2D6 was not a factor in this drug interaction (Grozinger et al, 1998).

3.5.1.BU Moxifloxacin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Moxifloxacin has been shown to prolong the QT interval in some patients and should be avoided in those patients receiving agents that also prolong the QT interval, such as tricyclic antidepressants. Although pharmacokinetic studies between moxifloxacin and other drugs which prolong the QT interval have not been performed, an additive effect cannot be excluded. Therefore, moxifloxacin should be used with caution when given concurrently with a tricyclic antidepressant (Prod Info Avelox(TM), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Moxifloxacin should be used with caution when given concurrently with a tricyclic antidepressant.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BV Nefopam

1) Interaction Effect: an increased risk of seizures
2) Summary: Nefopam inhibits the neuronal uptake of norepinephrine and serotonin and increases the risk of seizures, especially in patients with a history of a convulsive disorder. Tricyclic antidepressants also lower the seizure threshold. Therefore, the manufacturer of nefopam advises caution in patients on concurrent tricyclic antidepressant therapy (Pillans & Woods, 1995).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Because of the increased risk of seizures, extreme caution should be exercised in patients receiving nefopam and a tricyclic antidepressant. An alternative analgesic may be considered.
7) Probable Mechanism: additive lowering of seizure threshold

3.5.1.BW Nialamide

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982c; Spigset et al, 1993d; Brodribb et al, 1994b; Neuvonen et al, 1993a). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991b). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971c; White & Simpson, 1984a).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965a; Winston, 1971a; Schuckit et al, 1971b; Spiker & Pugh, 1976a). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965a).
b) In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the

treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982b).

c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993c).

d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987b).

e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991a). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977a; Schuckit et al, 1971b; Ashcroft, 1975a).

3.5.1.BX Norepinephrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).

b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.BY Olanzapine

1) Interaction Effect: an increased risk of seizures

2) Summary: Psychotropic drugs have been shown to reduce the seizure threshold. A case report describes a patient without an underlying seizure disorder who received treatment with olanzapine and clomipramine concomitantly. This combination resulted in seizures which were repeated upon rechallenge with olanzapine and clomipramine. It is advised to use caution when administering olanzapine concomitantly with clomipramine, or any agent known to reduce seizure threshold (Deshauer et al, 2000a).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: It is advised to use caution when administering olanzapine concomitantly with

clomipramine, or other agents known to lower the seizure threshold.
7) Probable Mechanism: unknown
8) Literature Reports
a) A 34-year-old male with schizophrenia and obsessive-compulsive disorder (OCD) without any underlying seizure disorder, presented for treatment following long-term noncompliance. Inpatient olanzapine treatment (20 mg/day) was initiated and positive psychotic symptoms subsequently resolved. Patient was discharged and readmitted because of inability to control symptoms. Clomipramine 250 mg per day was initiated. Within a week, dizziness and myoclonic jerks were reported which quickly progressed to general motor seizures and postictal somnolence (without incontinence). Spike waves and paroxysmal slowing on the EEG was consistent with seizure activity. Clomipramine and olanzapine were subsequently withheld, and the seizures were controlled with diazepam 30 mg per day for three days. This pattern repeated upon re-challenge with the combination of olanzapine and clomipramine. Presumably from the temporal relationship between clomipramine and olanzapine administration and seizure manifestation, it can be suspected that this adverse event is due to an interaction between these two drugs. Clomipramine and olanzapine are both metabolized by the cytochrome P450 isoenzymes 1A2 and 2D6. One theory is that coadministration may result in elevated levels of both compounds. Although the mechanism by which this interaction occurs is not yet known, it is advised to use caution when administering olanzapine concomitantly with clomipramine, or other agents known to lower the seizure threshold (Deshauer et al, 2000).

3.5.1.BZ Oxilofrine
1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CA Oxybutynin
1) Interaction Effect: decreased clomipramine efficacy
2) Summary: Oxybutynin was suspected of inducing the metabolism of clomipramine in an elderly female patient. Subsequent dextromethorphan testing of the patient showed that she was an extensive metabolizer (EM) of cytochrome P450 2D6 (CYP2D6). A pilot study exploring the long- and short-term effects of oxybutynin on the activity of CYP2D6 and another isoenzyme, probably of the CYP3A family, showed that oxybutynin caused a disproportionate increase of hydroxymorphinan compared with dextrorphan. Because the formation of hydroxymorphinan is mainly dependent on the activity of CYP2D6 and CYP3A4, but only the latter is known to be inducible, the authors suggest that oxybutynin is an inducer of a CYP3A subfamily (Grozinger et al, 1999a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Patients receiving concurrent therapy with clomipramine and oxybutynin should be monitored for loss of clomipramine efficacy, including worsening of symptoms. Plasma levels of clomipramine may be helpful in determining if efficacy is being compromised.
7) Probable Mechanism: induction by oxybutynin of cytochrome P450 3A-mediated clomipramine

metabolism
8) Literature Reports
a) A 72-year-old female was receiving clomipramine 150 mg daily for depression with a clomipramine and desmethylclomipramine blood level of 230 ng/mL and 348 ng/mL, respectively. Clomipramine was decreased to 25 mg daily, and fluvoxamine 100 mg daily was added to therapy. Eighteen days later, her clomipramine and desmethylclomipramine levels were 405 ng/mL and 50 ng/mL, respectively. Oxybutynin 5 mg daily was initiated for urinary incontinence, and within one week the clomipramine and desmethylclomipramine levels had decreased to 133 ng/mL and less than 25 ng/mL. They remained low one week later. The patient refused to discontinue oxybutynin to determine if her clomipramine blood levels would again increase (Grozinger et al, 1999).

3.5.1.CB Pargyline
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982a; Spigset et al, 1993a; Brodribb et al, 1994; Neuvonen et al, 1993). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991a). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971a; White & Simpson, 1984).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965; Winston, 1971; Schuckit et al, 1971; Spiker & Pugh, 1976). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982).
c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993).
d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987).
e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977; Schuckit et al, 1971; Ashcroft, 1975).

3.5.1.CC Paroxetine
1) Interaction Effect: clomipramine toxicity (dry mouth, sedation, urinary retention)
2) Summary: Concurrent use of paroxetine with drugs that are metabolized by cytochrome P450 2D6, such

as clomipramine, should be approached with caution (Prod Info Paxil(R), 2003).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: When paroxetine is coadministered with clomipramine, monitor patients for signs and symptoms of clomipramine toxicity (dry mouth, sedation, urinary retention, blurred vision). Clomipramine doses may need to be reduced.
7) Probable Mechanism: decreased cytochrome P450 2D6-mediated clomipramine metabolism

3.5.1.CD Pemoline
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CE Pentobarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from

therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CF Phendimetrazine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CG Phenelzine
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982e; Spigset et al, 1993f; Brodribb et al, 1994d; Neuvonen et al, 1993b). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991c). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used

concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971e; White & Simpson, 1984c).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of clomipramine with a monoamine oxidase inhibitor (MAOI), such as phenelzine, is contraindicated. If clomipramine is replacing treatment with phenelzine, a minimum of 14 days should elapse after phenelzine is discontinued before begin therapy with clomipramine. If clomipramine is substituted by phenelzine, a minimum of 14 days should elapse after clomipramine is discontinued and before phenelzine therapy begins (Prod Info clomipramine hydrochloride oral capsule, 2002). However, the manufacturer of phenelzine recommends that at least 10 days should elapse after clomipramine therapy is discontinued before starting phenelzine (Prod Info NARDIL(R) Tablets, USP, 2005).
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info clomipramine hydrochloride oral capsule, 2002). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965b; Brachfeld et al, 1963; Winston, 1971b; Schuckit et al, 1971d; Sargent, 1965; Spiker & Pugh, 1976b). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965b).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982d).
c) A drug interaction was reported in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993e).
d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994c).
e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986).
f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987c).
g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974; Winston, 1971b; Schuckit et al, 1971d; White & Simpson, 1984b; Rom & Benner, 1972). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991b). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991b). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977b; Schuckit et al, 1971d; Ashcroft, 1975b).

3.5.1.CH Phenindione
1) Interaction Effect: increased risk of bleeding

2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970c; Williams et al, 1976c). Considerable interindividual differences may be found (Pond et al, 1975c).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ration) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased phenindione metabolism; increased phenindione absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975b). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970b). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976b). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.CI Phenmetrazine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little

advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CJ Phenobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CK Phenprocoumon

1) Interaction Effect: increased risk of bleeding

2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970a; Williams et al, 1976a). Considerable interindividual differences may be found (Pond et al, 1975a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.

7) Probable Mechanism: decreased phenprocoumon metabolism; increased phenprocoumon absorption

8) Literature Reports

a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975). This effect was not observed with warfarin.

b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.

c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.CL Phentermine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CM Phenylephrine
1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CN Phenytoin
1) Interaction Effect: an increased risk of phenytoin toxicity (ataxia, hyperreflexia, nystagmus, tremors)
2) Summary: A few case reports have indicated that imipramine inhibits phenytoin metabolism resulting in

increased serum phenytoin concentration (Petti & Campbell, 1975a; Perucca & Richens, 1977a). Tricyclic antidepressants (TCAs) may lower the seizure threshold in epileptic patients stabilized on anticonvulsants. Theoretically, because phenytoin is an enzyme inducer, the metabolism of antidepressants may be increased resulting in reduced TCA serum levels.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Consider phenytoin serum levels if a tricyclic antidepressant is added to therapy or if the patient begins to exhibit signs of toxicity; lower doses of phenytoin may be required. If phenytoin is added to tricyclic antidepressant therapy, monitor for clinical efficacy of the tricyclic agent.
7) Probable Mechanism: inhibition of phenytoin metabolism

3.5.1.CO Primidone
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CP Procarbazine
1) Interaction Effect: neurotoxicity, seizures
2) Summary: Concomitant tricyclic antidepressant and more potent MAOI use has resulted in hyperpyrexia, convulsions, and death. Procarbazine has relatively weak MAOI actions, so while the potential for drug interactions between tricyclic antidepressants and procarbazine exists, clinical data are lacking at this time (Schuckit et al, 1971g; White & Simpson, 1984d). Concurrent use is not recommended (Prod Info Matulane (R), 1997).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant use is not recommended and should probably be initiated only under close medical supervision, and then only if other antidepressant class agents have proven unsuccessful. With more potent MAOIs, recommendations for concurrent use of TCAs have included avoiding large doses of the TCA, using only oral tricyclics, and avoiding imipramine, clomipramine, and desipramine. Procarbazine therapy should not begin until seven days following discontinuation of tricyclic antidepressants and 14 days following the discontinuation of other MAO inhibitors.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Procarbazine is primarily used as an antineoplastic agent, but was originally investigated as a monoamine oxidase inhibitor (Gilman et al, 1985). Animal studies have indicated that procarbazine is a monoamine oxidase inhibitor (MAOI) (DeVita et al, 1965) but appears to be a relatively weak MAOI in man (Gilman et al, 1985). Hypertensive reactions may still result from concomitant administration of tricyclic antidepressants, sympathomimetics, and tyramine-containing foods (Gilman et al, 1985; Ponto et al, 1977c). Concomitant administration of monoamine oxidase (MAO) inhibitors with tricyclic antidepressants has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965c; Brachfeld et al, 1963a; Winston, 1971c; Schuckit et al, 1971f; Sargent, 1965a; Spiker & Pugh, 1976c). Careful examination of such reports indicate unusual circumstances in most cases such as parenteral administration of a tricyclic. The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and

inhibition of catecholamine metabolism (Sjoqvist, 1965c).
b) Procarbazine therapy should not begin until 7 days following discontinuation of tricyclic antidepressants and 14 days following the discontinuation of other MAO inhibitors (AMA Department of Drugs, 1992; Gilman et al, 1985).

3.5.1.CQ Propylhexedrine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973h; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CR Quinestrol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973k), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972j). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972k) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984j).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs.

In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972d).

b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972j). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973j).

c) In one study, women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973e).

d) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973f).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984d).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984e).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980e). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983e).

3.5.1.CS Quinidine

1) Interaction Effect: clomipramine toxicity (dry mouth, sedation)

2) Summary: The concomitant use of quinidine and clomipramine is not recommended. Two studies have demonstrated that concomitant use of quinidine and imipramine or desipramine results in increased serum concentrations of these antidepressants (Brosen & Gram, 1989a; Steiner et al, 1987). A similar interaction may occur with other tricyclic antidepressants including clomipramine.

3) Severity: major

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Monitor for increased antidepressant side effects with concomitant therapy with

quinidine; lower doses of the tricyclic agent may be required. Conversely, if quinidine is discontinued from therapy, monitor for antidepressant efficacy. Tricyclic antidepressant serum levels might be considered in some clinical situations.
7) Probable Mechanism: decreased clomipramine metabolism
8) Literature Reports
a) Quinidine is an inhibitor of the cytochrome P450 2D6 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 3A3/4 isoenzyme is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.
b) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and doses were titrated to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.CT Rasagiline
1) Interaction Effect: severe CNS toxicity
2) Summary: Concomitant use of rasagiline and tricyclic antidepressants should be avoided. Concurrent administration or overlapping therapy with tricyclic antidepressants and non-selective MAOIs has been reported to cause serious, sometimes fatal, reactions; the mechanisms of these reactions are not fully understood. Signs and symptoms include severe CNS toxicity (behavioral and mental status changes, diaphoresis, muscular rigidity, hypertension, and syncope) associated with hyperpyrexia and death. Data from clinical studies, where rasagiline-treated patients (n=115) were concomitantly exposed to tricyclic antidepressants, are insufficient to rule out an interaction. At least 14 days should elapse after discontinuing rasagiline before initiating therapy with a tricyclic antidepressant (Prod Info AZILECT(R) oral tablets, 2006).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concurrent use of rasagiline and a tricyclic antidepressant is not recommended. Wait at least 14 days after discontinuing rasagiline before initiating therapy with a tricyclic antidepressant (Prod Info AZILECT(R) oral tablets, 2006).
7) Probable Mechanism: unknown

3.5.1.CU S-Adenosylmethionine
1) Interaction Effect: an increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: A single case has been reported of serotonin syndrome likely resulting from the combination of S-adenosylmethionine (SAMe) and clomipramine (Iruela et al, 1993a). SAMe was shown to hasten the onset of therapeutic response of imipramine in a clinical trial involving 40 patients, without serotonergic side effects (Berlanga et al, 1992). If therapy is initiated with SAMe and a tricyclic antidepressant, the patient should be monitored closely for early signs of serotonin syndrome. Serotonin syndrome is a condition of serotonergic hyperstimulation and manifests as restlessness, myoclonus, changes in mental status, hyperreflexia, diaphoresis, shivering, and tremor. If the syndrome is not recognized and correctly treated, death can result (Sternbach, 1991).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: S-adenosylmethionine (SAMe) used concomitantly with imipramine was found to decrease depressive symptoms sooner than imipramine alone (Berlanga et al, 1992). One case has been reported of serotonin syndrome likely resulting from concomitant use of SAMe and clomipramine (Iruela et al, 1993). If SAMe and a tricyclic antidepressant are used together, use low doses of each and titrate upward slowly, while monitoring closely for early signs of serotonin syndrome such as increasing anxiety, confusion, and disorientation.
7) Probable Mechanism: additive pharmacologic effects resulting in excessive serotonergic stimulation
8) Literature Reports
a) A 71 year-old female was hospitalized with anxiety, agitation, confusion, and symptoms of serotonin syndrome. She had been taking S-adenosylmethionine 100 milligrams (mg) intramuscularly daily and clomipramine 25 mg daily for 10 days, which was then increased to 75 mg/day. Within 48-72 hours of the increased clomipramine dosage, she became progressively anxious, agitated, and confused. On admission she was verbally unresponsive and stuporous, with heart rate 130 beats/minute, respiratory

rate 30 breaths/minute, temperature 40.5 degrees Celsius, diarrhea, myoclonus, generalized tremors, rigidity, hyperreflexia, shivering, diaphoresis, and dehydration. Temperature increased to 43 degrees Celsius during her hospital stay, with no documented infection. White blood cell count (WBC) was 13,040 mm3, lactic dehydrogenase was 662 units/liter (U/L), creatine phosphokinase was 8920 U/L, serum potassium 2.7 milliequivalents/liter (mEq/L), creatinine 1.1 mg/100 milliliter (mL) (laboratory reference values were not provided). A cranial computed tomography (CT) scan was normal. The patient was not taking neuroleptics. Serum benzodiazepine and tricyclic antidepressant levels were normal. Symptoms resolved gradually with 4 days of hydration and supportive care. The interaction was proposed to be a result of synergistic activity of S-adenosylmethionine and clomipramine (Iruela et al, 1993).

3.5.1.CV Salmeterol

1) Interaction Effect: an increased risk of cardiovascular excitation
2) Summary: Salmeterol should be administered with extreme caution to patients who are being treated with a tricyclic antidepressant, or within two weeks of the discontinuation of a tricyclic antidepressant (Prod Info SEREVENT(R) DISKUS(R) inhalation powder, 2006). Clinically significant changes in systolic and diastolic blood pressure, pulse rate, and electrocardiograms have been seen with the use of salmeterol, and these changes may be exacerbated by the use of a tricyclic antidepressant.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Close observation for adverse cardiovascular effects is warranted when these agents are administered concurrently or if salmeterol is given within two weeks of discontinuation of a tricyclic antidepressant.
7) Probable Mechanism: potentiation of vascular effects

3.5.1.CW Secobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CX Selegiline

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982n; Spigset et al, 1993m; Brodribb et al, 1994l; Neuvonen et al, 1993g). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991h). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971q; White & Simpson, 1984l).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of clomipramine with a monoamine oxidase inhibitor (MAOI), such as selegiline is contraindicated. A minimum of 14 days should elapse after selegiline is discontinued

before therapy with clomipramine is begun. Similarly, a minimum of 14 days should elapse after clomipramine is discontinued and therapy with selegiline is begun (Prod Info clomipramine hydrochloride oral capsule, 2002).

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info clomipramine hydrochloride oral capsule, 2002). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965h; Brachfeld et al, 1963d; Winston, 1971h; Schuckit et al, 1971p; Sargent, 1965d; Spiker & Pugh, 1976h). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965h).

b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982m).

c) A drug interaction was reported in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993l).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994k).

e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986b).

f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987g).

g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974c; Winston, 1971h; Schuckit et al, 1971p; White & Simpson, 1984k; Rom & Benner, 1972c). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991g). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991g). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977h; Schuckit et al, 1971p; Ashcroft, 1975g).

3.5.1.CY Sertraline

1) Interaction Effect: modest elevations of clomipramine serum levels or possible serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: There is limited evidence suggesting that sertraline may inhibit tricyclic antidepressant (TCA) metabolism resulting in higher TCA serum concentrations. Sertraline inhibits cytochrome P450 2D6 enzyme activity and may increase the plasma concentrations of coadministered drugs that are metabolized by this pathway, including the tricyclic antidepressants (Prod Info Zoloft(R), 2002; Preskorn et al, 1994a; Lydiard et al, 1993). Effects of the interaction may have little or no clinical impact, however. Increases in TCA serum levels associated with sertraline coadministration were modest compared with those found when fluoxetine (another selective serotonin reuptake inhibitor) was combined with desipramine (von Moltke et al, 1994). Monitor patients on clomipramine-sertraline therapy for TCA toxicity (dry mouth, urinary retention, CNS

depression). Clomipramine doses may need to be reduced.
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The combined use of tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) may result in the inhibition of the TCA metabolism. A few cases of serotonin syndrome have also been reported with concurrent TCA and SSRI therapy. Caution should be observed when drugs in these two classes are used together.
7) Probable Mechanism: inhibition of clomipramine metabolism
8) Literature Reports
a) The pharmacokinetics of desipramine were studied in 18 healthy male volunteers. Study subjects received only desipramine (50 mg daily) for seven days followed by desipramine with sertraline (50 mg daily) for 21 days. When sertraline was added to desipramine therapy, the mean maximum concentration of desipramine increased by 34% and the area under the concentration-time curve increased by 26%. Trough concentrations of desipramine were close to baseline one week after sertraline was discontinued. The changes in desipramine concentrations were modest and the interaction may not be clinically significant (Preskorn et al, 1994).

3.5.1.CZ St John's Wort
1) Interaction Effect: an increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Theoretically, since St. John's Wort is thought to inhibit serotonin reuptake and may have mild monoamine oxidase inhibitory activity (Singer et al, 1999; Thiede & Walper, 1994), serotonin syndrome could result when St. John's Wort is taken along with a tricyclic antidepressant. This theoretical risk of serotonin syndrome is also based on case reports of serotonin syndrome resulting from concomitant use of selective serotonin reuptake inhibitors with tricyclic antidepressants (Alderman & Lee, 1996), as well as concomitant use of monoamine oxidase inhibitors with tricyclic antidepressants (Brodribb et al, 1994a; Spigset et al, 1993b; Tackley & Tregaskis, 1987a). Coadministration of amitriptyline and St. John's Wort decreased the area under the concentration-time curve of amitriptyline and its metabolite nortriptyline (Roots et al, 2000); if other tricyclic antidepressants are similarly affected by St. John's Wort, the risk of serotonin syndrome may be reduced, yet effectiveness of the tricyclic antidepressant may also be reduced. To maintain maximal effectiveness of the tricyclic antidepressant, as well as avoid any potential risk of serotonin syndrome, avoid concomitant use of St. John's Wort and tricyclic antidepressants.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of St. John's Wort with tricyclic antidepressants.
7) Probable Mechanism: additive pharmacologic effects resulting in excessive serotonergic stimulation

3.5.1.DA Tapentadol
1) Interaction Effect: increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concurrent use of tapentadol and a tricyclic antidepressant may result in serotonin syndrome, which may be life-threatening. Symptoms of serotonin syndrome may include restlessness, hallucinations, loss of coordination, fast heart beat, rapid changes in blood pressure, increased body temperature, overreactive reflexes, nausea, vomiting, and diarrhea (Prod Info tapentadol immediate release oral tablets, 2008).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Coadministration of tapentadol and a tricyclic antidepressant may result in a life-threatening condition called serotonin syndrome. If these agents are used together, monitor the patient closely for symptoms of serotonin syndrome (restlessness, hyperthermia, hyperreflexia, incoordination), especially during treatment initiation and dose increases (Prod Info tapentadol immediate release oral tablets, 2008).
7) Probable Mechanism: additive serotonergic effect

3.5.1.DB Thiopental
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977a; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.DC Tibolone
1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973e), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972e). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972e) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984e).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972d).
b) A case report demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated (Khurana, 1972d). Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973d).
c) A study in which women received clomipramine and oral contraceptives or clomipramine alone was reviewed (Beaumont, 1973b). At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn.
d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980b).

e) Akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984d).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984b).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980b). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983b).

3.5.1.DD Toloxatone

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982l; Spigset et al, 1993k; Brodribb et al, 1994j; Neuvonen et al, 1993f). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991g). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971o; White & Simpson, 1984j).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965g; Winston, 1971g; Schuckit et al, 1971n; Spiker & Pugh, 1976g). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965g).
b) There is minimal risk of a clinically significant pharmacokinetic interaction between amitriptyline and toloxatone, a MAOI-A (Vandel et al, 1993). Seventeen inpatients being treated for major depressive illness were administered amitriptyline 125 mg once daily for two weeks, and the following two weeks they received amitriptyline 125 mg daily and toloxatone 600 mg daily. With combined therapy there was a small, nonsignificant increase in amitriptyline plasma levels. The availability and urinary excretion of amitriptyline and its metabolites were not significantly affected.
c) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991f). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977g; Schuckit et al, 1971n; Ashcroft, 1975f).
d) Serotonin syndrome has been reported with the use of moclobemide, a reversible inhibitor of monoamine oxidase, and a TCA. A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated

with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994i).

3.5.1.DE Tramadol

1) Interaction Effect: an increased risk of seizures
2) Summary: Seizures have been reported in patients using tramadol. Some medications, including tricyclic antidepressants (TCAs), are known to reduce the seizure threshold. The risk of seizures may be enhanced when clomipramine and tramadol therapy are combined (Prod Info Ultram(R), 1998).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution should be used if tramadol is to be administered to patients receiving concomitant TCA therapy. If possible, avoid this combination, especially in patients with underlying conditions that might predispose to seizures.
7) Probable Mechanism: unknown

3.5.1.DF Tranylcypromine

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982p; Spigset et al, 1993o; Brodribb et al, 1994n; Neuvonen et al, 1993h). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991i). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971s; White & Simpson, 1984n).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of clomipramine with a monoamine oxidase inhibitor (MAOI), such as tranylcypromine is contraindicated. If clomipramine is replacing treatment with tranylcypromine, a minimum of 14 days should elapse after tranylcypromine is discontinued and therapy with clomipramine begins. If clomipramine is substituted by tranylcypromine, a minimum of 14 days should elapse after clomipramine is discontinued and tranylcypromine treatment begins (Prod Info clomipramine hydrochloride oral capsule, 2002). However, the manufacturer of tranylcypromine recommends that at least 7 days should elapse before tranylcypromine therapy is replaced by clomipramine. Similarly, if clomipramine therapy is substituted by tranylcypromine, there should be a 7 day washout period. Tranylcypromine should then be given using half the normal starting dosage for, minimally, the first week of therapy (Prod Info Parnate(R), 2001).
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info clomipramine hydrochloride oral capsule, 2002). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965i; Brachfeld et al, 1963e; Winston, 1971i; Schuckit et al, 1971r; Sargent, 1965e; Spiker & Pugh, 1976i). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965i).

b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982o).

c) A drug interaction was reported in which a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993n).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of

moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994m).
e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986c).
f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987h).
g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974d; Winston, 1971i; Schuckit et al, 1971r; White & Simpson, 1984m; Rom & Benner, 1972d). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991h). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991h). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977i; Schuckit et al, 1971r; Ashcroft, 1975h).

3.5.1.DG Valproic Acid

1) Interaction Effect: an increased risk of clomipramine toxicity (agitation, confusion, hallucinations, urinary retention, tachycardia, seizures, coma)
2) Summary: Comedication with clomipramine and valproic acid may increase serum levels of clomipramine resulting in increased side effects. Clomipramine toxicity developed in a patient twelve days after valproic acid therapy was initiated. Metabolism of clomipramine is mediated through N-demethylation, hydroxylation, and glucuronidation, and valproic acid appears to inhibit the enzymes responsible for this mode of metabolism (Fehr et al, 2000a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor serum clomipramine levels to avoid overdosing as a result of elevated concentrations of clomipramine when comedicating with valproic acid. The clomipramine dose may need to be reduced when valproic acid is added to therapy.
7) Probable Mechanism: inhibition of cytochrome P450 2C-mediated metabolism of clomipramine
8) Literature Reports
a) A case report describes a 46-year-old female with personality disorder whose serum clomipramine concentrations became elevated after she began concomitant therapy with valproic acid. Antidepressant therapy with clomipramine and lorazepam was initiated while being hospitalized for treatment of her psychiatric disorder. These two agents were chosen to reduce the frequency of panic attacks and to improve symptoms of suicidal and self-destructive behavior. A target dose of clomipramine 150 mg/day resulted in serum clomipramine levels in the normal range. Lorazepam was initiated at a dose of 2 mg/day After two weeks of therapy valproate was initiated at 1000 mg/day because emotional instability and self-destructive behavior remained unimproved. After five days of therapy the serum levels of clomipramine and desmethylclomipramine increased to 447 ng/mL and 85 ng/mL, respectively. Valproate serum concentration was 63.2 mcg/mL. The valproate dose was subsequently adjusted to 1400 mg/day. Seven days after the increase in valproate dose, clomipramine and desmethylclomipramine serum concentrations were 479 ng/mL and 269 ng/mL respectively. Conversely, the valproate serum level was 55 mcg/mL. The patient noted a feeling of numbness and exaggerated sleep disturbances. After the clomipramine dose was reduced to 75 mg/day, these symptoms resolved. The author concludes that the increase in serum clomipramine concentrations was primarily due to comedication with valproate (Fehr et al, 2000).

3.5.1.DH Vasopressin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants and vasopressin have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Vivactil(R), 1999; McCue et al, 1989; Munger & Effron, 1988; Mauro et al, 1988; Marshall & Forker, 1982c; Goldstein & Claghorn, 1980; Buckhardt et al, 1978; Pinder et al, 1977; Thorstrand, 1976; Singh, 1972). Even though no formal drug interaction studies have been done, the coadministration of drugs known to prolong the QTc interval is not recommended.
3) Severity: major

4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of drugs that prolong the QT interval, such as tricyclic antidepressants and vasopressin, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.DI Venlafaxine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest) and adverse effects of both drugs
2) Summary: Tricyclic antidepressants (TCAs) and venlafaxine have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Effexor(R) XR, 2003; Marshall & Forker, 1982). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as venlafaxine, is not recommended (Prod Info Elavil(R), 1999). In addition, venlafaxine and tricyclic antidepressants (TCAs) may competitively inhibit each other's metabolism which may increase side effects of both drugs (Perry, 2000; Prod Info Effexor(R) XR, 2003; Ellingrod & Perry, 1994). Venlafaxine increased the AUC, Cmax, and Cmin of desipramine by approximately 35%. The AUCs of 2-OH-desipramine increased by 2.5 and 4.5 fold when administered with venlafaxine 37.5 mg and 75 mg every 12 hours, respectively. The pharmacokinetics of imipramine and the 2-hydroxy metabolite were not affected (Prod Info venlafaxine extended release oral tablets, 2008).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Due to the potential for additive effects on the QT interval, the concurrent administration of venlafaxine and tricyclic antidepressants is not recommended.
7) Probable Mechanism: decreased TCA and venlafaxine metabolism; additive effects on QT prolongation
8) Literature Reports
a) When administered with imipramine, the pharmacokinetics of imipramine and the 2-hydroxy metabolite were not affected. Venlafaxine increased the area under the concentration-time curve (AUC), maximum concentration (Cmax), and minimum concentration (Cmin) of desipramine by approximately 35%. The 2-OH-desipramine AUCs increased by 2.5-fold (venlafaxine 37.5 mg every 12 hours) and by 4.5-fold (venlafaxine 75 mg every 12 hours). The clinical significance of this finding is unknown (Prod Info venlafaxine extended release oral tablets, 2008).

3.5.1.DJ Warfarin

1) Interaction Effect: an increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970i; Williams et al, 1976i). Considerable interindividual differences may be found (Pond et al, 1975i).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: In patients being treated concurrently with warfarin and clomipramine, the prothrombin time ratio or international normalized ratio (INR) should be closely monitored to assess the stability of the anticoagulant response. Warfarin dosage adjustments may be required.
7) Probable Mechanism: decreased warfarin metabolism; increased warfarin absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975h). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after eight days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in six healthy volunteers (Vesell et al, 1970h). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976h). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.DK Yohimbine

1) Interaction Effect: increased risk of hypertension
2) Summary: Yohimbine increased blood pressure and decreased orthostatic hypotension experienced by depressed patients treated with clomipramine on a short-term basis (less than 2 weeks of clomipramine treatment, with 4 days of concomitant yohimbine treatment) (Lacomblez et al, 1989a). The effect of yohimbine on orthostatic hypotension induced by clomipramine beyond this time frame is unknown. Levels of yohimbine may continue to increase during the period when clomipramine is accumulating (i.e. at the start of therapy and following any dosage changes). Demethylclomipramine may decrease first pass hepatic metabolism of yohimbine, increasing yohimbine levels and thereby increasing the hypertensive effect of

yohimbine. It was also proposed that patients with depression may have increased sensitivity to the effect of yohimbine on alpha2-receptors (Lacomblez et al, 1989a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor orthostatic and sitting blood pressure in patients taking clomipramine who initiate therapy with yohimbine, as yohimbine may increase blood pressure.
7) Probable Mechanism: inhibition of hepatic metabolism of yohimbine
8) Literature Reports
a) Yohimbine 12 milligrams daily significantly increased blood pressure in a randomized, double-blind, placebo-controlled, crossover study of 12 patients with depression. Patients had been treated with clomipramine 150 mg for a minimum of 48 hours to 1 week maximum and experienced a fall in systolic blood pressure of at least 20 mmHg after 2 and 5 minutes of standing up. Patients received yohimbine 4 mg three times daily for 3 days, and 4 mg once on day 4. Supine blood pressure was significantly increased on day 1 (p between 0.001 and 0.05) and on day 4 (p between 0.01 and 0.05). Standing blood pressure was significantly increased on day 1 (p between 0.01 and 0.05), and on day 4 (p between 0.001 and 0.05). Hypertensive effects lasted 17 to 24 hours after yohimbine administration and were accompanied by an increase in heart rate (Lacomblez et al, 1989).
b) Since yohimbine concentrations are undetectable after 17 to 24 hours, the interaction with clomipramine was suggested to involve more than pharmacokinetic alterations. The hypertensive effect of yohimbine was significantly correlated with plasma yohimbine levels (p equals 0.0025). Plasma levels of yohimbine were significantly correlated with plasma levels of demethylclomipramine, the main metabolite of clomipramine (p less than 0.006), but not with clomipramine levels. The low dose of yohimbine used in this study had no effect on blood pressure in healthy (non-depressed, normotensive) subjects. Demethylclomipramine may decrease first pass hepatic metabolism of yohimbine, increasing yohimbine levels and thereby increasing the hypertensive effect of yohimbine. It was proposed that patients with depression may have increased sensitivity to the effect of yohimbine on alpha2-receptors (Lacomblez et al, 1989).

3.5.2 Drug-Food Combinations

Ethanol

Grapefruit Juice

3.5.2.A Ethanol
1) Interaction Effect: enhanced drowsiness; impairment of motor skills
2) Summary: Ethanol in combination with antidepressants may alter behavior, with the predominant effect being enhanced impairment in psychomotor performance. Almost all studies to date have evaluated the effects of the combination on motor skills, driving behavior and psychomotor skills (Landauer et al, 1969; Patman et al, 1969; Milner & Landauer, 1973a; Seppala et al, 1975; Seppala, 1977). There are no studies evaluating respiratory response with the combination.
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Encourage abstention from alcohol during at least the first few weeks of tricyclic administration to allow patient accommodation to potential CNS depressant effects of the tricyclic.
7) Probable Mechanism: additive CNS depressant activity; impaired hepatic metabolism of the tricyclic antidepressant
8) Literature Reports
a) The studies available indicate that the interaction between amitriptyline (and other antidepressants) in combination with ethanol is unpredictable. They indicate that antidepressants may enhance, prevent, or not affect the CNS depressant actions of ethanol. The most significant effect reported is enhanced CNS depression. However, there are reports that tricyclic antidepressants may actually antagonize the sedative effects of ethanol (Milner & Landauer, 1973).
b) The propensity for interaction may be related to the inherent CNS depressant action of the tricyclic antidepressant, listed in one series in descending order as amitriptyline, doxepin, imipramine, nortriptyline, desipramine, and protriptyline (Marco & Randels, 1981).
c) Imipramine and amitriptyline are the best documented examples of disruptions of metabolism. Clearance of imipramine was 3-fold higher in alcoholics compared with healthy volunteers (Ciraulo et al, 1988).
d) Individual case reports have documented "blackouts" following modest amounts of alcohol in combination with either amitriptyline or imipramine (Hudson, 1981), and reversible extrapyramidal effects (parkinsonian effects, akathisia) with amoxapine (Shen, 1984).

3.5.2.B Grapefruit Juice

1) Interaction Effect: an increased risk of clomipramine toxicity

2) Summary: Clomipramine is metabolized by several different cytochrome P450 pathways, including CYP1A2, 3A4, and 2D6. Grapefruit juice has been shown to inhibit CYP3A4, causing an increase in the concentrations of drugs which require CYP3A4 for metabolism. Two case reports demonstrated that the addition of grapefruit juice to a clomipramine regimen increased the trough plasma concentrations of clomipramine. Whether the inhibition of clomipramine metabolism by grapefruit juice would be sustained over time is not known (Oesterheld & Kallepalli, 1997a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor clomipramine and desmethylclomipramine trough levels in patients receiving grapefruit juice. Also monitor the patient for signs of clomipramine toxicity.

7) Probable Mechanism: inhibition of clomipramine metabolism by grapefruit juice

8) Literature Reports

a) An 8-year-old male patient was being treated with clomipramine 25 mg three times daily for obsessive-compulsive disorder. Trough plasma levels of clomipramine (CMI) and desmethylclomipramine (DMCI) were 73 ng/mL and 144 ng/mL, respectively. When 250 mL of grapefruit juice was administered with each dose of clomipramine, the trough levels of CMI and DMCI increased to 198 ng/mL and 233 ng/mL, respectively, after three days. In another case, a 13-year-old female being treated with clomipramine 125 mg daily had a CMI trough blood level of 48 ng/mL and a DMCI trough blood level of 195 ng/mL. Grapefruit juice 250 mL was administered with each clomipramine dose for three days, and the CMI trough level increased to 69 ng/mL while the DMCI trough level decreased to 170 ng/mL (Oesterheld & Kallepalli, 1997).

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters

A) Clomipramine Hydrochloride

1) Therapeutic

a) Physical Findings

1) DEPRESSION

a) Improvement in mood, affect, and behavior.

b) Improvement in vegetative signs including appetite, sleep pattern, interest in work/recreation, and improvement in weight (if abnormal).

2) OBSESSIVE COMPULSIVE DISORDER (OCD)

a) Reduction in frequency and severity of obsessions and compulsions characteristic of the patient.

b) Improvement in work function, and reduction in amount of time spent with obsessions/compulsions.

2) Toxic

a) Laboratory Parameters

1) Liver function tests

b) Physical Findings

1) Signs of central and peripheral hyperactivity: tremor, seizures, manic- like behavior, increased aggression.

2) Constipation, urinary retention, dry mouth, or blurred vision.

3) Orthostatic hypotension, tachycardia.

4) Sexual dysfunction of both genders: impotence, ejaculation problems, anorgasmia.

5) Monitor patients receiving antidepressants for worsening of depression, suicidality, or unusual changes in behavior, especially at the initiation of therapy or when the dose increases or decreases. Such monitoring should include at least weekly face-to-face contact with patients or their family

members or caregivers during the initial 4 weeks of treatment, then visits every other week for the next 4 weeks, then at 12 weeks, and then as clinically indicated beyond 12 weeks. Families and caregivers should be advised of the need for close observation (ie, daily observation) of patients and communication with the prescriber (Anon, 2004).

6) Patients who experience symptoms of anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, akathisia, hypomania, or mania may be at an increased risk for worsening depression or suicidality. If these symptoms are observed, therapy should be re-evaluated and it may be necessary to discontinue medications when symptoms are severe, sudden in onset, or were not part of the patient's initial symptoms (Anon, 2004).

4.2 Patient Instructions

A) Clomipramine (By mouth)

Clomipramine

Treats obsessive-compulsive disorder, depression, chronic pain, bulimia, sleep disorders, and panic disorder. This medicine is a tricyclic antidepressant (TCA).

When This Medicine Should Not Be Used:
You should not use this medicine if you have had an allergic reaction to clomipramine or to related medicine such as Elavil® or nortriptyline. You should not use this medicine if you have had a recent heart attack or have used an MAO inhibitor (MAOI) such as Eldepryl®, Marplan®, Nardil®, or Parnate® within the past 14 days.

How to Use This Medicine:
Capsule, Tablet

Your doctor will tell you how much of this medicine to use and how often. Your dose may need to be changed several times in order to find out what works best for you. Do not use more medicine or use it more often than your doctor tells you to.
Your doctor may tell you to take the medicine at bedtime, because clomipramine can make you sleepy.
You may take the tablet with or without food. It is best to take the oral capsules with food to decrease stomach upset.
Do not break or chew the capsules. You may open the capsule and mix the medicine beads with soft food (applesauce, pudding). Swallow the mixture without chewing.
It may be 2 to 3 weeks after you start clomipramine before you notice an improvement in your symptoms.
Do not stop taking clomipramine suddenly without asking your doctor.
This medicine should come with a Medication Guide. Read and follow these instructions carefully. Ask your doctor or pharmacist if you have any questions. Ask your pharmacist for the Medication Guide if you do not have one. Your doctor might ask you to sign some forms to show that you understand this information.

If a Dose is Missed:

If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next dose, wait until then to use the medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.
If you take one dose a day at bedtime, you should not use the missed dose the next morning without asking your doctor.

How to Store and Dispose of This Medicine:

Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after you have finished your treatment. You will also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, and herbal products.

Make sure your doctor knows if you are using cimetidine (Tagamet®), clonidine (Catapres®), digoxin (Lanoxin®), guanethidine (Ismelin®), haloperidol (Haldol®), methylphenidate (Ritalin®), or phenothiazine medicine (such as prochlorperazine, Compazine®, Mellaril®, Phenergan®, Thorazine®, or Trilafon®). Tell your doctor if you are also using other medicines to treat depression (such as fluoxetine, sertraline, paroxetine, fluvoxamine, Prozac®, Zoloft®, Paxil®, or Luvox®), medicine to treat seizures (such as phenytoin, phenobarbital, Dilantin®, or Luminal®), certain medicine for heart rhythm problem (such as quinidine, flecainide, propafenone, Quinaglute®, Tambocor®, or Rythmol®), or a blood thinner (such as warfarin or Coumadin®).
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and allergy medicine, narcotic pain relievers, and sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:

Make sure your doctor knows if you are pregnant or breastfeeding, or if you have kidney disease, liver disease, thyroid problems, glaucoma, high blood pressure, heart problems, trouble going to the bathroom (urinating), adrenal gland tumor (such as pheochromocytoma or neuroblastoma), or a history of seizure disorder.
For some children, teenagers, and young adults, this medicine can increase thoughts of suicide. Tell your doctor or your child's doctor right away if you or your child start to feel more depressed and have thoughts about hurting yourselves. Report any unusual thoughts or behaviors that trouble you or your child, especially if they are new or are getting worse quickly. Make sure the doctor knows if you or your child have trouble sleeping, get upset easily, have a big increase in energy, or start to act reckless. Also tell the doctor if you or your child have sudden or strong feelings, such as feeling nervous, angry, restless, violent, or scared. Let the doctor know if you, your child, or anyone in your family has bipolar disorder (manic-depressive) or has tried to commit suicide.
This medicine may make you dizzy or drowsy. Avoid driving, using machines, or doing anything else that could be dangerous if you are not alert.
Make sure any doctor or dentist who treats you knows that you are using this medicine. You may need to stop using this medicine several days before having surgery or medical tests.
This medicine may make your skin more sensitive to sunlight. Use a sunscreen when you are outdoors. Avoid sunlamps and tanning beds.
Your doctor will need to check your progress at regular visits while you are using this medicine. Be sure to keep all appointments.

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, chest tightness, trouble breathing.
Change in how much or how often you urinate, or painful or difficult urination.
Changes in behavior, or thoughts of hurting yourself or others.
Chest pain.
Ear pain or discharge, or ringing in the ears.
Fast, pounding heartbeat.
Fever, chills, cough, sore throat, runny or stuffy nose, and body aches.
Lightheadedness or dizziness when getting up suddenly from a lying or sitting position.
Memory problems, confusion, or depression.
Nervousness, anxiety, agitation, or irritability.
Numbness, tingling, or burning pain in your hands, arms, legs, or feet.
Tremors, or muscle twitching or stiffness.
Trouble sleeping, unusual dreams.
Trouble swallowing.
Unusual bleeding, bruising, or weakness.

If you notice these less serious side effects, talk with your doctor:
Changes in appetite.
Changes in taste.
Changes in vision.
Dry mouth or tooth problems.
Headache or drowsiness.
Menstrual cramps or change in monthly periods.
Muscle, joint, or back pain.
Nausea, vomiting, diarrhea, constipation, or stomach pain or upset.
Problems with sex.
Skin rash or itching.
Sweating.
Tiredness.
Warmth or redness in your face, neck, arms, or upper chest.
Weight changes.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Clomipramine is indicated for the treatment of obsessive compulsive disorder. It is recommended as first-line therapy along with behavioral therapy (Park et al, 1997). Other first-line agents include fluvoxamine, fluoxetine, sertraline, and paroxetine. However, clomipramine may be selected for patients with concomitant insomnia, akathisia, or nausea/diarrhea (Anon, 1997).

B) Clomipramine is not superior to tricyclic antidepressants, including imipramine and amitriptyline, for treating major depression. The drug has been effective for obsessive compulsive behavior associated with depression, although imipramine seems to be equally suited for treating this disorder. Clomipramine appears to be more effective than amitriptyline for relieving chronic pain caused by trigeminal neuralgia and tension headaches, but not post-herpetic neuralgia.

C) Clomipramine should be considered for hospital formulary inclusion for the treatment of obsessive compulsive disorder, with or without major depression (Kelly & Myers, 1990). Clomipramine cannot be recommended for first-line treatment of chronic pain induced by trigeminal neuralgia or tension headaches until additional controlled studies are conducted, but may be considered for those patients refractory to amitriptyline.

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) The exact mechanism of action of clomipramine is not known. The drug is classified as a tertiary amine tricyclic antidepressant with very potent inhibition of serotonin uptake (Bertilsson et al, 1974; Asberg et al, 1977). The active metabolite, desmethylclomipramine, is a potent norepinephrine uptake inhibitor and may retain some serotonin uptake inhibition (Benfield et al, 1980; Ross & Renyi, 1975). Several researchers feel that the effect of clomipramine's serotonin uptake may be essential to the anti-obsessive compulsive activity observed (Flament et al, 1987); (Thoren et al, 1980)(Zohar et al, 1988). Obsessive-compulsive patients with initially high cerebrospinal fluid levels of the serotonin metabolite, 5-hydroxyindole-acetic acid (5-HIAA), demonstrated a positive correlation with the improvement of obsessive-compulsive behavior and the reduction of the cerebrospinal fluid levels of 5-HIAA during clomipramine therapy (Thoren et al, 1980). High pretreatment levels of platelet serotonin were a strong predictor of clomipramine treatment response (Flament et al, 1987). During clomipramine therapy clinical improvement in obsessive-compulsive symptoms was positively correlated with a reduction in platelet serotonin levels.

2) The therapeutic effects of clomipramine in obsessive compulsive disorder are mediated via serotonergic mechanisms (Benkelfat et al, 1989). The plasma ratio of tryptophan (TRP) to other large neutral amino acids (LNAA) were studied in 44 patients with major depression (Moller et al, 1990). The LNAA selected were thought to reflect brain serotonin formation. The patients were subsequently treated with paroxetine (N=27) or clomipramine (N=17) in double-blind fashion on fixed dosage schedules for 4 weeks. Endogenous and nonendogenous patients were comparable with respect to the ratio of TRP/LNAA. The clomipramine group showed a significant inverse correlation between the TRP/LNAA ratio and clinical improvement. Patients with a TRP/LNAA ratio below the mean showed a trend towards greater improvement than patients with a higher ratio, but with comparable serum drug levels. These findings suggest that it may be possible to increase the efficacy of antidepressant treatment in populations of depressed patients by prior selection based on plasma amino acid patterns. The published evidence that supports a link between depression and obsessive-compulsive disorder from a biochemical basis was reviewed (Asberg et al, 1982).

3) The effect of clomipramine (CMI) treatment on serum prolactin (PRL) levels was studied in 18 children and adolescents with obsessive compulsive disorder. PRL was measured at baseline and after 4 and 8 weeks of CMI treatment. Baseline PRL was higher in patients with tics and OCD than in patients with OCD alone. CMI administration significantly increased basal PRL levels. A slight decline in PRL during the last 4 weeks of CMI treatment was positively correlated with a favorable response and negatively correlated with duration of illness. If these PRL changes are related to changes in serotonergic neurotransmission, the results suggest that CMI treatment of OCD produces an adaptive decrease in the responsiveness of serotonergic receptors (Hanna et al, 1991).

4) Cytokine production by peripheral blood mononuclear cells (PBMC) was assessed in 10 patients with major depression (5 male, 5 female) before and after 4 weeks of clomipramine (CMI) treatment and in age- and gender-matched controls (Weizman et al, 1994). A significant reduction in interleukin-1B (IL-1B), interleukin-2 (IL-2) and interleukin-3-like activity (IL-3-LA) was observed in untreated depressed patients when compared to controls. IL-1B and IL-3-LA synthesis was significantly increased after treatment with CMI. The suppression of cytokine production by PBMC in depressed patients may be associated with the depression per se, or may be related to depression-related hyperactivity of the hypothalamic-pituitary-adrenal axis. The authors did not discuss the role of serotonergic drugs (clomipramine) in possible reversal of cytokine suppression.

B) REVIEW ARTICLES

1) Treatment guidelines for obsessive compulsive disorders including the use of clomipramine have been published (Goodman, 1999; Ellingrod, 1998; Anon, 1997a; Park et al, 1997a; Flament & Bisserbe, 1997; Rasmussen & Eisen, 1997; Jackson et al, 1994; Jenike, 1992).

2) Comprehensive review articles on CLOMIPRAMINE have been prepared (Peters et al, 1990; McTavish & Benfield, 1990).

3) The worldwide use of CLOMIPRAMINE was summarized (Trimble, 1990).

4) The pharmacokinetics of CLOMIPRAMINE are summarized in a review (Balant-Gorgia et al, 1991).

5) Drug-interactions of antidepressants are reviewed in German language (Zapotoczky & Simhandl, 1995).

4.5 Therapeutic Uses

Clomipramine

Clomipramine Hydrochloride

4.5.A Clomipramine

Anorexia nervosa

Cataplexy - Narcolepsy

4.5.A.1 Anorexia nervosa

Self-injurious behavior

Steinert myotonic dystrophy syndrome

Trichotillomania

4.5.B.1 Anorexia nervosa

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Ineffective
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Found to be no more effective than placebo in producing weight gain in patients with anorexia nervosa

c) Adult:

1) In a double-blind, placebo-controlled trial of 16 female ANOREXIA NERVOSA patients, CLOMIPRAMINE 50 milligrams/day was found no more effective than placebo in producing weight gain (Lacey & Crisp, 1980). Placebo or oral CLOMIPRAMINE 50 milligrams was administered once daily to anorexic patients until their predetermined target weight was attained. Patients on CLOMIPRAMINE had increased appetite, hunger and calorie consumption during the early part of the study; however, this had no impact on the final outcome. Patients on placebo took a mean of 72 days to attain their target weight, while those on CLOMIPRAMINE took a mean of 76 days. Two patients on CLOMIPRAMINE and 1 patient on placebo did not complete the study. At a 4-year follow-up, measurement outcomes of

nutritional status, sexual adjustment, socioeconomic adjustment and mental state showed no significant differences between the 2 groups (Crisp et al, 1987a). Patients treated with CLOMIPRAMINE and placebo- treated patients were at a mean of 94% and 93% of target weight, respectively.

4.5.B.2 Autistic disorder

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Effective in one study

c) Adult:

1) CLOMIPRAMINE (CMI) was superior to placebo and desipramine (DMI) on ratings of autistic symptoms such as anger, and compulsive, ritualized behaviors in a 10-week, double-blind crossover comparison of CMI and placebo and CMI and DMI (Gordon et al, 1993a).

4.5.B.3 Chronic pain

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Possibly effective for chronic low back pain in selected patients

c) Adult:

1) In an open study, 23 out of 30 patients with chronic low back pain responded to clomipramine treatment. Clomipramine 25 milligrams (mg) was increased to 150 mg/day intravenously during a 10-day hospital stay. After discharge, clomipramine 150 mg/day orally was used for 20 days. Patients with lower initial mean scores on the Minnesota Multiphasic Personality Inventory (MMPI) for hypochondria, depression, and hysteria were more likely to respond to treatment (p less than 0.02, p less than 0.05, p less than 0.02, respectively). These study findings may assist in proper patient selection for beneficial clomipramine therapy, however further placebo-controlled studies are recommended (Fouquet et al, 1997).

2) In 2 case reports, patients with schizophrenia and obsessive-compulsive symptoms had their chronic back pain alleviated by clomipramine (Kurokawa & Tanino, 1997). Doses used ranged from 30 to 75 milligrams. The authors believe that the back pain was related to serotonin dysfunction.

4.5.B.4 Delusional disorder

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Appears effective in the treatment of some types of delusional disorders including DELUSIONAL DISORDER, SOMATIC TYPE and BODY DYSMORPHIC DISORDER

c) Adult:

1) In a double-blind, cross-over trial clomipramine was more effective than desipramine in patients with body dysmorphic disorder (BDD)(Hollander et al, 1999). Patients (n=29) with distress or impairment in functioning due to BDD were randomized to receive first either clomipramine, a selective serotonin reuptake inhibitor, or desipramine, a selective norepinephrine reuptake inhibitor (specifically an active placebo), for 8 weeks each. Patients initially received 25 milligrams (mg)/day and were increased to a maximum of 250 mg/day or the highest tolerated dose. Mean dosages attained were 138 mg/day for clomipramine and 147 mg/day for desipramine. Assessments were done using a BDD modified version of the Yale-Brown Obsessive Compulsive Scale (BDD-YBOCS), a modified National Institute of Mental Health Global Obsessive-Compulsive Scale (BDD-NIMH), and the Clinical Global Impression Scale specific to BDD symptoms (BDD-CGI). Clomipramine was superior to desipramine on all 3 of the outcome measures. On the BDD-YBOCS there was a 65% improvement rate with clomipramine and a 35% rate with desipramine (p=0.09). On the BDD-NIMH the response rate was 70% with clomipramine and 30% with desipramine (p=0.02). For the BDD-CGI, clomipramine was also significantly better than desipramine (p=0.01). Also of significance was that patients who were more delusional appeared to improve more with clomipramine therapy (BDD-CGI, p=0.007). Adverse effects were similar for both drugs. This is the first study demonstrating the effectiveness of clomipramine for BDD.

2) Four patients with delusional disorder of the somatic type showed clinical improvement with

clomipramine therapy (Wada et al, 1999). All patients persistently complained that something was moving inside their bodies although nothing was found after extensive evaluations. All repeatedly visited physicians complaining of symptoms with 1 patient receiving a possibly unnecessary surgery. Another patient was unresponsive to multiple therapies including sulpiride, nemonapride, mosapramine, levomepromazine, risperidone, fluphenazine, pimozide, and clocapramine. The dosage of clomipramine ranged from 60 to 120 milligrams daily and the time to improvement ranged from 27 to 52 days. Further studies including comparisons with pimozide are needed.

4.5.B.5 Depression

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Oral and intravenous clomipramine have been successfully used to treat dysthymia and major depression (Faravelli & Pallanti, 1987)
Intravenous therapy has had no advantage over oral therapy (Faravelli & Pallanti, 1987)
Early improvement in severe depressive symptoms may be achieved by using loading doses of oral or intravenous CLOMIPRAMINE

c) Adult:

1) Five days after pulse-therapy with oral or intravenous clomipramine, symptoms of depression significantly improved in 22 inpatients. Patients were given either an evening infusion of 150 milligrams of clomipramine and placebo tablets or 150 milligrams of oral clomipramine and an isotonic saline infusion. Twenty-four hours later, this was repeated using 200 milligrams of clomipramine. Pulse-therapy with oral and intravenous clomipramine showed no difference in efficacy or side effects in treating depression. In this double-blind randomized trial results were based on the Hamilton Depression, Raskin, and Beck scales (Pollock et al, 1989).

2) Clomipramine was significantly (p equals 0.02) more effective than placebo in improving mood in 21 depressed patients with probable Alzheimer's disease. Results were based on the Hamilton Depression scores. Clomipramine- treated patients showed a significantly (p less than 0.01) lower Mini-Mental State score than placebo; no significant drug effects were seen on the Independence measure scores. Patients received 6 weeks of clomipramine or placebo in a double-blind crossover design. During the first 6 week period, 9 of 11 clomipramine-treated patients experienced a complete remission while the same effect occurred in only 3 of 10 placebo-treated patients. Clomipramine was administered at 25 mg for 1 week, 50 mg for week 2, 75 mg for week 3, and 100 mg for weeks 4 to 6 (Petracca et al, 1996).

d) Pediatric:

1) A single pulse dose of clomipramine 200 milligrams intravenously was administered in a double-blind, placebo-controlled trial of 16 depressed adolescents, (14-to 18-years-old), demonstrating dramatic and rapid reduction in depressive symptoms at day 6 post-clomipramine infusion, based upon decreases in Hamilton Depression Rating Scale score ($p = 0.04$) and Clinical Global Impression severity score ($p = 0.003$). The clomipramine effect (88% study response rate) may persist for up to 8 weeks in some patients. The authors suggest that gradually administered clomipramine is less effective than pulse intravenous clomipramine due to the pulse regimen's rapid enhancement of serotonergic transmission (Sallee et al, 1997).

4.5.B.6 Disorder of ejaculation

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Useful in the treatment of ejaculatory disorders

c) Adult:

1) Daily dosing with clomipramine was successful in treating premature ejaculation in men who were unresponsive to clomipramine 25 milligrams (mg) on an "as needed" basis. Four men who, in an earlier study, were nonresponders to clomipramine 25 mg "as needed" participated in a 12 week study in which they took clomipramine 0, 10, 20, and 30 mg daily, each dose for 3 weeks. Latencies were significantly longer with the 30-mg per day dose than with the previous 25-mg regimen. Ejaculatory control, sexual arousal, and penile rigidity were not significantly affected by treatment. All subjects reported satisfaction with the treatment. Side-effects were mild and generally transient. Of the 3 men who opted to continue clomipramine treatment, 1 chose 30 mg as needed, and 2 chose 20 mg daily (Rowland et al, 2001).

2) Clomipramine 25 milligrams, as needed, effectively increased ejaculatory latency in men with primary premature ejaculation. In a prospective, double-blind, placebo controlled, crossover study,

patients with primary premature ejaculation (n=8), premature ejaculation and erectile dysfunction (n=6), and controls (n=8) were randomly given clomipramine for a 3 week period and placebo for 3 a week period. Each was to be used 12 to 24 hours before sexual activity. Patients with ejaculatory latency increased their time to ejaculation from approximately 2 to 8 minutes (p=0.035). No significant effects occurred in controls and men with premature ejaculation and erectile dysfunction (Haensel et al, 1996).
3) CLOMIPRAMINE (CMI) was useful in the treatment of PREMATURE EJACULATION (Segraves et al, 1993). Twenty patients with premature ejaculation were randomly allocated to treatment with CLOMIPRAMINE or placebo in a double-blind study. Mean estimated time to ejaculation after vaginal penetration increased to 6.1 minutes on CMI 25 mg and to 8.4 minutes on CMI 50 mg. These estimated times were significantly different from estimated time to ejaculation while on placebo. The results suggest that low-dose CMI may be useful in the treatment of premature ejaculation.
4) Two of 3 cases of RETROGRADE EJACULATION were successfully treated with oral CLOMIPRAMINE 25 milligrams twice a day. Two of the 3 patients responded with normal ejaculation within 5 days and subsequent conception, while the third patient only partially improved (Eppel & Berzin, 1984).

4.5.B.7 Obsessive-compulsive disorder

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, yes (10 years and older)
Efficacy: Adult, Effective; Pediatric, Effective
Recommendation: Adult, Class IIa; Pediatric, Class IIa
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Indicated for the treatment of obsessions and compulsions associated with obsessive compulsive disorder

c) Adult:

1) Double-blind, placebo-controlled trials have demonstrated the efficacy of CLOMIPRAMINE in relieving some obsessive compulsive symptoms (Greist et al, 1990; DeVeaugh-Geiss et al, 1989; Pato et al, 1988; Flament et al, 1985a; Marks et al, 1980a). Some researchers feel that patients with a depressive component will do better with CLOMIPRAMINE. Other researchers believe that behavioral therapy is also required to alleviate ritualistic behavior. Large long-term studies have been difficult to conduct because of the apparent low incidence of this disorder. In a meta-analysis, it was concluded that the most common treatments for obsessive-compulsive disorder include CLOMIPRAMINE, FLUOXETINE, and exposure-based behavior therapy (Cox et al, 1993). Results from 25 appropriate treatment studies from 1975 to 1991 revealed that all three treatments were significantly effective for most of the outcome variables (overall severity, anxiety, depression). Exposure was not significantly effective for reducing depressed mood.
2) A 24-year-old female with a 3-year history of obsessive compulsive disorder (OCD) experienced a 90% resolution of symptoms in 4 weeks following inpatient behavior therapy and treatment with clomipramine 50 milligrams (mg) gradually increased to 150 mg daily. Patient symptoms included fear of contamination from touching various items she considered dirty and excessive hand washing (30-50 times per contact with a dirty object). The symptoms began to adversely affect her social and academic life, and depression developed. She failed an outpatient behavior program and treatment with fluoxetine 40 mg to 60 mg daily prior to being admitted to an inpatient behavior program. Clomipramine therapy was started at 50 mg daily and was gradually increased to 150 mg daily; therapy was well tolerated with the exception of periodic sedation. Upon discharge, her compulsive rituals were 90% improved and she was maintained on clomipramine 25 mg daily. No relapses of OCD or severe depression occurred during a 5-year follow-up period (Al-Sughayir, 2000).
3) A 93-year-old woman with a long-standing history of obsessive-compulsive disorder that worsened after developing Alzheimer's disease was helped by clomipramine therapy (Trappler, 1999). Her obsessions consisted of needing to know and remember trivial events with a compulsion of making excessive lists of these events. She had previously failed trials of fluoxetine and buspirone. She began clomipramine 25 milligrams (mg) daily and was increased over 10 days to 50 mg. After 9 weeks her score on the Yale-Brown Obsessive-Compulsive Scale dropped from 29 to 3. The author notes that clomipramine was effective and well-tolerated in this very old patient.
4) A combination of CLOMIPRAMINE and FLUOXETINE was effective in 4 cases of OCD where either drug used alone was ineffective. No increased side effects resulted (Browne et al, 1993).
5) There was no significant difference in treatment outcome with CLOMIPRAMINE between those patients with at least one personality disorder and those with no personality disorders. The effect of Axis II diagnosis on the outcome of treatment with CLOMIPRAMINE was determined in 55 patients with obsessive-compulsive disorder (Baer et al, 1992). Patients with paranoid, schizoid, or schizotypal personality disorders (DSM-III) had significantly higher obsessive-compulsive disorder severity scores at baseline, and the number of personality disorders was strongly related to baseline severity of obsessive compulsive symptoms. At the conclusion of this 12-week study, the presence of schizotypal, borderline, and avoidant personality disorders, along with the total number of personality disorders, did predict poorer treatment outcome.

6) Using standard OCD assessment tools, it was shown that CLOMIPRAMINE (CMI) was significantly more effective than placebo (38 to 44% response vs 3 to 5% response). Two double-blind studies at 21 centers evaluated the efficacy and safety of up to 300 mg/d of CMI vs placebo in 520 patients with OCD. TCA-like side effects were reported for CMI. Although uncommon, seizures and elevated aminotransferase values are potentially serious side effects of CMI (Anon, 1991).
7) Ten patients with DSM-III-R obsessive compulsive disorder (OCD) who were being treated chronically with CLOMIPRAMINE (CMI) in a mean dosage of 270 milligrams/day, were studied to determine the minimum dose of CMI needed to maintain therapeutic benefit. Gradual, open dosage reduction resulted in a mean dosage of 165 milligrams/day, a reduction of 105 milligrams/day (approximately 40%). This decrease in dosage was accompanied by no significant change in three OC measures, as determined by the paired t-test. These results suggest that even though OCD patients were not able to discontinue medication completely, they were able to do well at lower doses than those used initially in the treatment of the disorder (Pato et al, 1990).

d) Pediatric:
1) Continued CLOMIPRAMINE (CMI) treatment seems necessary for children and adolescents. The need for continued CLOMIPRAMINE (CMI) treatment in children and adolescents with obsessive compulsive disorder (OCD) was evaluated in a double-blind DESIPRAMINE substitution study. Twenty-six children and adolescents with severe primary OCD receiving long-term CMI maintenance treatment (mean 17 months) entered an 8-month study. All patients received CMI for the first 3 months, then half received CMI and half were given DESIPRAMINE (DMI) for the next 2 months, then all subjects were given CMI for the last 3 months. Eighty-nine percent of the substituted versus 18% of the non-substituted group relapsed during the 2-month comparison period. However, even subjects who continued uninterrupted CMI treatment experienced OC symptoms which varied in severity over time (Leonard et al, 1991a).
2) In a case series, 7 children and adolescents (9-to 23-years-old) with obsessive compulsive disorder, benefited from combination therapy of clomipramine and a selective, serotonin reuptake inhibitor (Figueroa et al, 1998). The combination therapy appeared to augment the effectiveness of monotherapy. Clomipramine was used in doses of 25 to 100 milligrams. The serotonin reuptake inhibitors used included: fluoxetine, sertraline, paroxetine, and fluvoxamine. In 2 cases, once the combination was effective, one of the drugs was successfully discontinued. Two cases of QTc interval prolongation occurred.

4.5.B.8 Obsessive-compulsive disorder, Intravenous therapy

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Appears effective in the treatment of obsessive-compulsive disorder even in some patients refractory to oral clomipramine
Intravenous clomipramine is not FDA approved

c) Adult:
1) Intravenous clomipramine was more effective than placebo in the treatment of obsessive-compulsive disorder (OCD) in patients refractory to oral clomipramine (Fallon et al, 1998). In a double-blind 4-week study, OCD patients refractory to oral clomipramine were randomized to receive 1-hour infusions of 500 milliliters of 0.9% isotonic sodium chloride solution containing either clomipramine (n=28) or placebo (n=23). Clomipramine was titrated over 14 infusions from 25 milligrams (mg) daily to 250 mg daily. Oral clomipramine was started in all patients after the infusions. Patients were evaluated using the Clinical Global Impression (CGI) scale. After the seventh infusion, no patients showed improvement. After infusion 14, 6 (20.7%) clomipramine patients were responders on the CGI versus none in the placebo group (p less than 0.02). At 1 week after the infusions, 9 out of 21 (43%) clomipramine patients were responders according to the CGI (not all patients were evaluated at this time point). Again there were no responders in the placebo group. At 1 month after the infusion, 9 out of 16 patients were rated as overall intravenous clomipramine responders. Further study is needed comparing the intravenous route to the oral route of therapy.
2) Intravenous pulse loading of clomipramine was beneficial in 6 out of 7 patients with obsessive compulsive disorder. Patients were randomized to receive either oral loading of clomipramine (n=8) or intravenous loading (n=7). The intravenous loading consisted of clomipramine 150 milligrams (mg) given intravenously over 90 minutes, followed by clomipramine 200 mg intravenously, 24 hours later. Trimethobenzamide hydrochloride 250 mg was given before each dose to reduce nausea. The oral loading consisted of clomipramine 150 mg on day 1 and 200 mg given on day 2. Oral clomipramine 150 mg was started in all patients 4.5 days after the second dose and increased by 25 mg every fourth day to 250 mg/day. Using the Yale-Brown scale, 6 out of 7 patients in the intravenous group had responded before the oral dosing was started while only 1 in the oral dose group had responded (p=0.009). After 8 weeks, there was no difference in the 2 groups, both had 4 responders (p=0.38). Pulse intravenous loading may be an effective method for quickly testing patient responsiveness to clomipramine therapy

(Koran et al, 1997).
3) A 25-year-old woman with schizophrenia and ego-dystonic checking and cleaning rituals benefited from intravenous clomipramine (Poyurovsky & Weizman, 1998). Her schizophrenia was stabilized with perphenazine 8 milligrams (mg) daily. She had failed trials of fluvoxamine and fluoxetine for her obsessive-compulsive disorder (OCD). Further deterioration of her OCD led to hospitalization where a course of intravenous clomipramine 75 mg was added to her perphenazine. The infusion was repeated the next day. Five days later her Yale-Brown Obsessive Compulsive score had dropped from 19 to 4. She was maintained on clomipramine 150 mg daily and has had no recurrence of her OCD symptoms over the last 6 months.

4.5.B.9 Panic disorder

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Reported to be effective in the treatment of panic attacks and AGORAPHOBIA

c) Adult:
1) Low-dose clomipramine 60 mg/day was as effective as high-dose clomipramine 150 mg/day in the treatment of phobias, anxiety, and panic attacks in a multi-center study (Caillard et al, 1999). In an 8-week study, patients were randomized to clomipramine 150 milligrams (mg)/day (n=56), clomipramine 60 mg/day (n=51), or placebo (n=51). Doses were titrated over 2 weeks. At the end of 8 weeks, phobias as evaluated on the Cottraux Scale were significantly improved in both clomipramine groups as compared to placebo (p=0.002). For anxiety, both clomipramine groups were significantly better than the placebo group as measured on the anxiety subscale of the Cottraux Anxiety Scale (p=0.002). For panic attacks, the average number of attacks during the previous week was not significantly different in either of the clomipramine groups or for placebo. However, the number of DSM-III-R symptoms of panic attacks was decreased in both clomipramine groups but not in the placebo group (p=0.03). There was no difference seen between the 2 clomipramine therapies in these 3 areas. The author notes that differences may have become evident if a longer treatment period had been used.
2) In a randomized, placebo-controlled, 10-week study, exercise was found to be effective for the treatment of panic disorder, however, clomipramine was even more effective. Forty-six patients with panic disorder were assigned to either regular aerobic exercise (running), clomipramine (increasing doses over three weeks up to 112.5 milligrams/day), or placebo capsules. The dropout rate was 31% for the exercise group, 27% for the placebo group, and 0% for the clomipramine group. On the Bandelow Panic and Agoraphobia Scale, Observer-Rated, clomipramine and exercise improved anxiety symptoms more effectively than placebo (p less than 0.001, p less than 0.05, respectively). Improvements in the clomipramine group were seen as early as 4 weeks while exercise improvements were not seen until the 8th week. Patients receiving clomipramine or placebo experienced more side effects (dry mouth, sweating, mild tremor, dizziness, tachycardia, nausea, constipation, diarrhea) than those in the exercise group. Additional studies are warranted to investigate exercise in the treatment of anxiety disorders, perhaps in combination with drug treatment (Broocks et al, 1998).
3) Despite lowering the initial starting dose of clomipramine to 10 milligrams (mg)/day to maximize compliance, a study involving 58 patients with panic disorder (with or without agoraphobia) resulted in a 45% dropout rate due to adverse reactions occurring mostly during the first two weeks of treatment. Of those completing the study, 84% were markedly or moderately improved. The initial dose was clomipramine 10 mg at bedtime and increased slowly to 20 mg/day after 4 days, then by 10 mg at 1-to 2-week intervals up to 80 mg after 8 weeks. Patients could receive up to 250 mg daily if the drug was tolerated, with the mean daily dosage being 96.9 mg after 13 weeks of treatment. The primary adverse reactions reported were increased nervousness and agitation (Papp et al, 1997).
4) Clomipramine (10 milligrams (mg) for three days and 20 mg for four days) and fluvoxamine (50 mg/day for seven days) were both effective in decreasing the hypersensitivity to 35% carbon dioxide, supporting the serotonergic effect of these drugs to decrease panic attacks through modification of carbon dioxide sensitivity. Thirty-nine panic disorder patients were enrolled in a double-blind, randomized, placebo-controlled study, where each patient was given the 35% carbon dioxide challenge on days 0, 3, and 7. Patients on clomipramine and fluvoxamine showed significant reduction in sensitivity over placebo after seven days as seen by the percent change on a visual analogue for anxiety scale (p=0.027) (Perna et al, 1997a).
5) Clinical improvement was modest on agoraphobia in panic disorder patients who failed to respond to exposure-based behavioral treatment and were treated then with CLOMIPRAMINE (CMI) (Hoffart et al, 1993). Eighteen patients with panic disorder with agoraphobia who had not responded to previous inpatient behavioral treatment entered a 12-week, placebo- controlled, double-blind crossover study of CLOMIPRAMINE at maximum doses of 150 milligrams/kilogram for 3 weeks. Patient outcome was assessed on measures of phobic avoidance, agoraphobic cognitions, panic, state and trait anxiety, subjective anxiety, and depression. Seventeen of 18 patients completed the study. One patient (placebo group) dropped out after 6 weeks after developing acute gastric pain. On most outcome measures,

patients had significantly lower symptom scores at posttest in the active drug period than at posttest in the placebo period. However, while this study showed short-term efficacy of CLOMIPRAMINE for agoraphobic patients who did not respond to behavioral treatment, its ability to produce lasting benefits remains to be proven.
6) CLOMIPRAMINE in low doses (25 to 75 milligrams daily) was reported effective in the treatment of panic ANXIETY and agoraphobia in outpatients in an uncontrolled 8-week clinical trial (Gloger et al, 1989). Of 17 patients treated, panic attacks were abolished completely in 13, and markedly decreased in 4 others. In 7 agoraphobic patients, avoidance behavior disappeared in 5. Overall mean doses were 45 milligrams daily, with 8 patients (6 panic and 2 agoraphobic) receiving 25 milligrams daily or less (mean, 18.76 milligrams). There was a trend towards the need for higher doses in agoraphobia (mean, 56 milligrams) as opposed to panic disorder (mean, 40 milligrams). Well-controlled clinical trials are required to confirm these findings and determine the optimal dose of CLOMIPRAMINE in panic disorder and agoraphobia.
7) Oral CLOMIPRAMINE was significantly superior to placebo on measures of DEPRESSION, DYSPHORIA, and on several indexes of PHOBIC SYMPTOMS in an 8-week double-blind, placebo-controlled study of 94 agoraphobic women as diagnosed by DSM-III guidelines (Johnston et al, 1988a). CLOMIPRAMINE was started at 25 milligrams/day which was slowly increased up to a maximum of 300 milligrams/day as tolerated. At the end of the study the mean daily dose of CLOMIPRAMINE was 83 milligrams. Adverse effects associated with CLOMIPRAMINE use included dry mouth, high energy levels, constipation, and increased sweating.

4.5.B.10 Pervasive developmental disorder

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
May be effective in adults with pervasive developmental disorders (PDDs)

c) Adult:
1) Clomipramine was found to be effective in 18 of 35 adult patients (55%) with pervasive developmental disorders (PDDs) (18 patients with autistic disorder, 6 with Asperger's disorder, 11 with PDD not otherwise specified). In an open-label study, clomipramine was started at 50 milligrams (mg) at bedtime and increased by 50 mg every 3 or 4 days to a maximum dosage of 250 mg daily within 3 weeks and continued for a minimum of 9 additional weeks. Based on the Clinical Global Impression scale, 18 patients were "much" or "very much" improved (p less than 0.001). In those 18 patients, clomipramine significantly reduced total repetitive thoughts and behavior (p less than 0.001), aggression (p less than 0.001), and some aspects of social relatedness such as eye contact and verbal responsiveness (p less than 0.001). Improvements were not related to a specific subtype of PDD. Three patients had seizures during treatment (two having a prior seizure history), prompting the authors to recommend a selective serotonin uptake inhibitor in these patients (Brodkin et al, 1997).

4.5.B.11 Premenstrual syndrome

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Effective in reducing the symptoms of Premenstrual Syndrome in small studies

c) Adult:
1) Intermittent administration of low-dose CLOMIPRAMINE (25 to 75 milligrams/day) during the luteal phase only for the treatment of premenstrual syndrome was effective (N=29), and the onset of clinical effect was shorter than when clomipramine was used to treat depression, panic disorder, or obsessive-compulsive disorder (Sunblad et al, 1993).
2) CLOMIPRAMINE (CMI) was effective in reducing symptoms of Premenstrual Syndrome (PMS) in a placebo-controlled trial. Forty non-depressed women with severe premenstrual irritability and/or dysphoria and fulfilling DSM-IIIR diagnostic criteria for late luteal phase dysphoric disorder were treated daily for 3 menstrual cycles with either CMI (25 to 75 milligrams/d) or placebo. Both groups had 20 patients. The response rate in the placebo group was 40% compared with 80% for the CMI group. The possible role of serotonin in the pathophysiology of PMS is discussed (Sundblad et al, 1992).
3) Subjects reported a dramatic reduction in premenstrual complaints with clomipramine therapy. CLOMIPRAMINE was administered orally as 25 to 50 milligrams/day for 5 consecutive menstrual cycles to 5 non-depressed women with severe premenstrual irritability and sadness (Eriksson et al, 1990).

4.5.B.12 Self-injurious behavior

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Useful in certain types of self-injurious behaviors such as severe NAIL BITING

c) Adult:
1) In an open clinical trial, CLOMIPRAMINE was useful for chronic stereotypic and self-injurious behaviors in 11 consecutive patients with concomitant development disorders (Garber et al, 1992). Patients received CLOMIPRAMINE in a mean dosage of 70 milligrams/d (range 25 to 125 mg/d). Ten patients (91%) had marked decreases in rates of target behaviors as early as 2 days after starting treatment and as late as 1 month. No seizures occurred despite the inclusion of six patients with previous histories of epileptic events, and improvement was evident regardless of level of mental retardation. These findings support the use of serotonergic medications in this population and the need for further research.
2) CLOMIPRAMINE has been helpful in reducing SELF-MUTILATING BEHAVIOR in a 25-year-old female patient with obsessive compulsive disorder. Excessive nail-biting and arm-burning with cigarettes was successfully curtailed after 4 months of treatment with CMI at doses of 250 milligrams per day (Lipinski, 1991).
3) CLOMIPRAMINE (CMI) was significantly more effective than DESIPRAMINE (DMI) in decreasing severe nail-biting in 25 adult subjects with severe morbid ONYCHOPHAGIA. During a 10-week double-blind, crossover trial CMI at 120 milligrams/day was superior to DMI at 135 mg/d as determined by nail-biting rating scale assessments. It is hypothesized that similar biological systems mediate a spectrum of "grooming" behaviors, including onychophagia, trichotillomania, and obsessive compulsive disorder (Leonard et al, 1991a).

4.5.B.13 Steinert myotonic dystrophy syndrome

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Has improved some symptoms associated with myotonic dystrophy

c) Adult:
1) CLOMIPRAMINE (CMI) has improved grip myotonia in patients with myotonic dystrophy in a placebo-controlled double-blind, crossover study. Fifteen of 17 patients completed the two 33-day treatment periods separated by a 30-day washout period. Grip myotonia was determined by a standardized test and was video-taped for later analysis. Results showed that mean relaxation time after CLOMIPRAMINE was significantly shorter than after placebo (Antonini et al, 1990).

4.5.B.14 Trichotillomania

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Ineffective
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Effective for short-term treatment of trichotillomania

c) Adult:
1) In a 9-week study comparing cognitive-behavioral therapy (CBT), clomipramine, and placebo in the treatment of trichotillomania, CBT significantly reduced symptoms from pretreatment to posttreatment, whereas clomipramine and placebo did not. Twenty-three patients were randomized to receive either CBT, clomipramine (50 mg at bedtime titrated as tolerated to 250 mg at bedtime), or placebo and were evaluated on a weekly basis by either a psychiatrist (clomipramine and placebo patients) or a behavioral psychologist (CBT patients). Of the 16 patients that completed the trial, severity and impairment of trichotillomania were significantly reduced ($p=0.002$ and $p=0.006$, respectively) in the CBT group (n=5); however, significant differences were not noted in the clomipramine (n=6) or the placebo (n=5) groups. Clomipramine did produce more changes in pretreatment and posttreatment evaluations ($p=0.061$) than placebo; however, given the low power of the study conventional levels of significance were not achieved. Documented side effects of moderate or severe intensity included tremor, sedation, dry mouth, constipation, memory difficulty, and nausea (Ninan, 2000).
2) Four consecutive patients treated for trichotillomania (hair-pulling) with CLOMIPRAMINE reported initial dramatic reductions in symptoms. However, three of the four patients had relapsed completely at

3-month follow-up, although all four were taking previously effective dosages of the drug. The fourth patient relapsed for about 2 weeks but regained initial treatment benefits. Daily dosage used was 150 milligrams (1), 100 milligrams (2), and 50 milligrams (1) (Pollard et al, 1991).

4.6 Comparative Efficacy / Evaluation With Other Therapies

Albuterol

Amineptine

Amitriptyline

Buspirone

Citalopram

Desipramine

Diazepam

Dixyrazine

Dothiepin

Doxepin

Fluoxetine

Fluvoxamine

Haloperidol

Imipramine

Lithium

Lofepramine

Maprotiline

Metoprolol

Mianserin

Milnacipran

Moclobemide

Nortriptyline

Oxaprotiline

Paroxetine

Pentazocine

Phenelzine

Sildenafil

Venlafaxine

4.6.A Albuterol

4.6.A.1 Depression

a) In depression, albuterol 6 milligram/day was superior to clomipramine 150 milligram/day, both given by intravenous infusion. Ten patients received each drug; symptoms were evaluated by 2 blind observers at days 0, 5, and 15, using the Hamilton rating scale. With albuterol, global improvement on day 5 was significantly superior to clomipramine. This improvement included mood retardation, anxiety, and insomnia. On day 15, the improvement in the albuterol group was only slightly increased over the clomipramine group. Eight of 10 patients in the albuterol group, and 5 of 10 patients in the clomipramine group demonstrated a clear improvement. An additional 2 patients responded to clomipramine 1 week later (Lecrubier et al, 1980).

4.6.B Amineptine

4.6.B.1 Depression

a) Amineptine and clomipramine were found to have similar antidepressant activity in 62 depressed patients during a 6-week, randomized, double-blind study (Lemoine et al, 1981). Patients were diagnosed with psychotic, non-psychotic, or melancholic depression by the investigators; however, the diagnostic criteria were not described. The Hamilton Rating Scale for Depression was used to evaluate therapeutic effects. Oral daily doses of amineptine 100 to 300 milligrams (mean 180 mg) or clomipramine 50 to 150 milligrams (mean 84 mg) were administered during the trial. Improvement in depression symptoms were seen in both groups and no apparent differences in antidepressant activity could be determined. Fifteen patients did not complete the study: 4 on amineptine and 11 on clomipramine.

4.6.C Amitriptyline

Chronic pain

Obsessive-compulsive disorder

4.6.C.1 Chronic pain

a) Clomipramine appeared to be better than amitriptyline in treating chronic trigeminal neuralgia and tension headache pain; however, amitriptyline was more effective in treating postherpetic neuralgia during a 3-month, randomized, single-blind study with 67 chronic pain sufferers (Carasso et al, 1979). Oral clomipramine was dosed between 20 and 75 milligrams daily in 3 divided doses, while oral amitriptyline was dosed between 30 and 110 milligrams daily in 3 divided doses. Severe sedation was the most commonly reported adverse effect with amitriptyline. The most severe adverse effect with clomipramine was motor agitation, which was experienced by 4 of 35 (10%) patients. Anticholinergic effects were experienced with both drugs.

4.6.C.2 Obsessive-compulsive disorder

a) Oral clomipramine produced a statistically significant reduction in the number or severity of obsessive-compulsive symptoms over amitriptyline on the Psychiatric Questionnaire for Obsessive-Compulsive Disorder (Ananth et al, 1981). Twenty patients with chronic obsessive-compulsive disorder were randomized to receive either clomipramine or amitriptyline in a 4-week, double-blind study. Both drugs were started at 75 milligrams/day and increased up to 300 mg/day as tolerated. The clomipramine-treated group demonstrated improvement over amitriptyline on depression and anxiety scales. The most common adverse effects experienced by both groups included dizziness, drowsiness, and dry mouth. Three patients failed to complete the study: 1 from each group due to syncope and 1 from amitriptyline due to an inadequate response.

4.6.D Buspirone

4.6.D.1 Obsessive-compulsive disorder

a) A double-blind study comparing buspirone and clomipramine in the tretment of obsessive-compulsive disorder (OCD) was performed (Pato et al, 1991). Eighteen of 20 study entrants completed the trial, which included an initial 2-week placebo washout period, a 2-week titration phase (in which doses were increased as tolerated to a daily maximum of 60 mg buspirone or 250 mg clomipramine), and a 4-week dose maintenance phase; subjects then received half the maximum tolerated dose for 4 days, followed by 3-1/2 weeks of placebo. Although the study was conducted in a crossover fashion, with the alternate treatment

given after the 3-1/2 week placebo washout, the trial results were analyzed as a parallel design because subjects did not return to baseline status by the beginning of the second active treatment period. The authors reported similar efficacy of the 2 active treatments, with at least half of the patients in each group evidencing a minimum of 20% improvement in several measures of OCD and one of depression. However, the small sample size may have obscured differences in efficacy. The authors noted that response was not correlated with dose of clomipramine (mean 225 +/- 49 mg/day) or of buspirone (mean 58 +/- 7 mg/day), or with previous use of benzodiazepines. Buspirone warrants further study as a possible treatment for OCD.

4.6.E Citalopram

4.6.E.1 Depression

a) Clomipramine (a tricyclic antidepressant with potent 5-HT reuptake inhibiting properties) 150 milligrams once daily was statistically superior to citalopram 40 milligrams once daily in the treatment of endogenously depressed patients in a 5-week double-blind study (n=75). Clomipramine appeared to have a faster onset and was particularly more effective in improving sleep disturbances, although other depressive symptoms were also improved to a greater degree with this agent compared to citalopram. In the subgroup of patients with nonendogenous depression in this study (n=27), a similar trend was observed in favor of clomipramine; however, the number of patients treated was too small to enable an effective comparison. Orthostatic symptoms, dry mouth, and perspiration were seen only with clomipramine, whereas nausea, vomiting, and headache were more common with citalopram (Anon, 1986). Flaws in this study were that fixed doses of each agent were employed and the duration of 5 weeks may have been too short. The onset of full antidepressant effects of citalopram may take 5 to 6 weeks. Titrating the dose of each agent based on clinical response would enable a more effective comparison in that optimal doses for specific patients could be achieved. A further comparison of these agents with flexible dosing regimens is warranted.

4.6.E.2 Efficacy

a) A small, 5-week, double-blind study reported significant orthostatic hypotensive effects (systolic pressure) in depressed patients treated with clomipramine 150 milligrams once daily but not citalopram 40 milligrams once daily. Diastolic blood pressure was also significantly reduced, although to a lesser extent, with clomipramine, whereas this change did not occur in citalopram-treated patients (Christensen et al, 1985).

b) Similar findings were reported in a clinical efficacy comparison of clomipramine and citalopram (Anon, 1986), and these results are consistent with other clinical data suggesting the lower propensity of citalopram to induce cardiovascular effects compared to tricyclic antidepressants (Milne & Goa, 1991).

4.6.F Desipramine

Autistic disorder

Diabetic neuropathy

Nail biting

Obsessive-compulsive disorder

Paraphilia

Trichotillomania

4.6.F.1 Autistic disorder

a) Clomipramine was superior to both desipramine and placebo for treatment of autistic behavior such as stereotypies, anger, and compulsive, ritualized behavior. Clomipramine and desipramine were both superior to placebo, and had equivalent effects in reducing hyperactivity of patients with autistic disorder (Gordon et al, 1993).

4.6.F.2 Diabetic neuropathy

a) Clomipramine and desipramine both significantly reduced symptoms of diabetic neuropathy as determined by investigators and self-rating compared to placebo (Sindrup et al, 1990). In this double-blind, placebo-controlled, 3-way crossover study, 19 patients were randomized to 2 weeks of treatment with oral desipramine 50 or 200 milligrams/day, clomipramine 50 or 75 milligrams/day, or placebo. Washout between treatment periods was not mentioned. Both agents significantly reduced neuropathy symptoms (pain, paresthesia, dysesthesia, numbness, nightly deterioration, and sleep disturbances) compared to placebo. No significant difference between active treatments was observed. The most common adverse events, which occurred with equal frequency in each active treatment group, included dry mouth, sweating, orthostatic dizziness, and fatigue.

4.6.F.3 Nail biting

a) Clomipramine was superior to desipramine in the treatment of onychophagia in a 10-week, double-blind, crosover study. Of the 25 patients enrolled, only 14 complete the study perhaps due to lack of other psychiatric disturbance (Leonard et al, 1991a).

4.6.F.4 Obsessive-compulsive disorder

a) Clomipramine was significantly more effective than desipramine for treating obsessive compulsive disorder. In a 10-week, double-blind, crossover study forty-eight children and adolescents (ages 6 to 18 years) received clomipramine (mean dose 150 milligrams/day) then desipramine (153 milligrams/day). Sixty-four percent of the patients who received clomipramine for the first time demonstrated a relapse during desipramine therapy. None of the subjects studied exhibited a greater than 20% improvement as measured by the Global OCD Scale during a 2-week, single-blind trial before receiving active treatment. Unlike desipramine, clomipramine decreased obsessive compulsive ratings and depression ratings measured on the Hamilton and NIMH Depression scales (Leonard et al, 1989).
b) Oral clomipramine was superior to desipramine in a comparative, crossover, double-blind study in childhood obsessive-compulsive disorder (Leonard et al, 1989). Twenty-one adolescents were treated for 5 weeks with each drug in increasing doses to a maximum of 3 mg/kg. The results showed a striking superiority of clomipramine over desipramine and the clinical effects were not attributed to a nonspecific antidepressant effect. In a group of 26 obsessive compulsive patients on clomipramine who entered a double-blind drug substitution study using desipramine, clomipramine was superior to desipramine (Leonard et al, 1991).

4.6.F.5 Paraphilia

a) Clomipramine and desipramine had similar efficacy in the treatment of paraphilias in a small, double-blind, crossover study. Eight of 15 patients completed the study in which each patient received a mean maximal daily dose of clomipramine 162.5 milligrams (range 75 to 250 mg) and desipramine 212.5 milligrams (range 100 to 250 mg) for 5 weeks after a 2-week placebo phase. Four of the 8 were also clinically depressed, and there was a great deal of variety in the paraphilias demonstrated by this patient population. As measured by the Schedule for Affective Disorders and Schizophrenia, Lifetime Version, severity of paraphilic symptoms were significantly decreased by both clomipramine (p less than or = 0.005) and desipramine (p less than or = 0.002) as compared with placebo (Kruesi et al, 1992).

4.6.F.6 Trichotillomania

a) Clomipramine was superior to desipramine in the treatment of trichotillomania (hair pulling) during a 10-week, double-blind, crossover study involving 13 women (Swedo et al, 1989). In this study, capsules containing 50 mg of either clomipramine or desipramine were administered; initial doses were 50 milligrams daily, increasing over 3 weeks to a maximum dose of 3 milligrams/kilogram/day (250 mg daily). Mean maximal doses were 180 mg daily for clomipramine and 173 mg daily for desipramine. Clomipramine was superior to desipramine by a physician's rating scale and a trichotillomania-impairment scale. Symptom severity was reduced more with clomipramine as compared to desipramine and clomipramine patients were better able to resist the urge to pull hair as opposed to desipramine patients. Clomipramine appears to be a specific antitrichotillomanic agent; this disorder may be related to an obsessive-compulsive disorder.

4.6.G Diazepam

4.6.G.1 Agoraphobia

a) Clomipramine was significantly superior to diazepam in the treatment of 33 agoraphobic patients during a 12-week, multicentered, randomized, double-blind study (Allsopp et al, 1984). The patients were diagnosed with agoraphobia or social phobia of at least a 1-month duration. Both drugs were administered orally in low doses initially; the doses were then increased to 25 to 150 milligrams in 3 divided daily doses for clomipramine and to 10 to 30 milligrams in 3 divided daily doses of diazepam. Headaches were experienced more in the diazepam group, while dry mouth and drowsiness were more prevalent in the clomipramine group. By the end of the study, clomipramine demonstrated significant improvement over diazepam in total scores for situational anxiety, interference in life-style, and accompanied travel distance on an agoraphobia inventory.

4.6.H Dixyrazine

4.6.H.1 Panic disorder

a) Dixyrazine plus clomipramine was more effective than clomipramine alone in reducing the number of panic attacks. In a 12-week study, 45 patients with panic attacks (with or without agoraphobia) were treated with clomipramine titrated up to 250 milligrams (mg) per day plus either dixyrazine 50 mg per day or placebo. Patients treated with dixyrazine plus clomipramine showed a larger reduction in the Hamilton Anxiety Rating Scale (HARS-P) scores for panic attacks from week 6 to week 12 than the patients in the placebo group (p less than 0.05). The reduction of the number of panic attacks and the increase in patients daily functioning were also significantly greater in the dixyrazine- clomipramine group (p less than 0.05) (Feet & Gotestam, 1994).

4.6.I Dothiepin

4.6.I.1 Depression

a) Although dothiepin and clomipramine were equally capable of diminishing depressive symptoms in a randomized, double-blind, parallel-group comparison of the two tricyclic antidepressants over 6 weeks, adverse events affected 50% more patients in the clomipramine group (n=45) than in the dothiepin group (n=47), and overall more than one-quarter of patients in the clomipramine group withdrew because of such adverse effects as dry mouth, dizziness, and somnolence (Welch et al, 1997).

4.6.J Doxepin

4.6.J.1 Dysthymia

a) Results were equivocal in a study that compared clomipramine and doxepin (75 milligrams/day of either) in a group of 66 patients with neurotic depression. Patient-rated measures did not show a superior agent. Clomipramine was rated better by physician-rated measures. There were no significant differences in side effects (Kornhaber & Horwitz, 1984).

b) Doxepin (25 milligrams three times a day) and clomipramine (25 milligrams three times a day), were more effective than L-tryptophan (500 mg three times a day) in 42 neurotically-depressed patients. The findings of the study were that doxepin and clomipramine resulted in more responses than L-tryptophan, therapeutic blood levels of clomipramine and doxepin were much smaller than those found in endogenously depressed patients, that responders had a significantly higher blood level of the two than non-responders at 21 days, and that the response to clomipramine, but not doxepin, parallelled its accumulation in the blood. (Linnoila et al, 1980).

4.6.K Fluoxetine

4.6.K.1 Obsessive-compulsive disorder

a) Treatment with fluoxetine (FLX) was compared with treatment with clomipramine (CMI) in two groups of patients with obsessive compulsive disorder (OCD) using two different experimental designs. In the first group of 11 patients with OCD studied using a randomized, double-blind, crossover design, treatment with FLX (20 to 80 milligrams/d) for 10 weeks was found to produce therapeutic effects similar to that obtained with CMI (50 to 250 milligrams/d) for 10 weeks. There were significantly fewer total side effects reported during FLX than CMI treatment. Drug tapering and placebo substitution in the 4-week crossover interval phase led to substantial relapses in OCD symptoms and depression. In addition, response to the second drug took as long as response to the first drug, despite a putative common mechanism of action of serotonin uptake inhibition. A second group of 21 patients with OCD that had been previously stabilized on CMI with at least partial benefit were crossed over to FLX in double blind fashion. After 10 weeks of FLX, most patients manifested behavioral rating scores of OCD and depressive symptoms that were comparable with pre-crossover ratings completed during CMI treatment. A significant exacerbation in OCD and depression ratings as well as a similar lag in therapeutic efficacy were also noted in this second cohort of patients with OCD. Platelet serotonin concentrations were reduced 95% during both CMI and FLX treatment periods. These results suggest that FLX may represent a viable alternative to CMI in the treatment of OCD, although more studies with larger sample sizes are needed (Pigott et al, 1990).

b) Clomipramine (CMI) and fluoxetine (FLX) were shown to be equally effective in the treatment of 120 patients with DSM-III major unipolar depressive disorder over a 6-week period. Adverse effects were more frequent with CMI. Those that did occur with FLX tended to disappear during the course of the study (Noguera et al, 1991).

4.6.L Fluvoxamine

Anxiety

Cataplexy

Depression

Obsessive-compulsive disorder

Panic disorder

4.6.L.1 Anxiety

a) Fluvoxamine and clomipramine were comparable in reducing anxiety symptoms in patients with agoraphobia with panic attacks (APA), generalized anxiety disorders (GAD), and obsessive-compulsive

disorders (OCD) as classified by DSM-III during a randomized, double-blind study (Westenberg et al, 1987). Of the 50 patients in this study, 39 diagnosed with APA, 5 with GAD, and 6 with OCD. Patients were randomly assigned to receive either clomipramine, up to 150 milligrams/day, or fluvoxamine, up to 100 milligrams/day, for the 6-week study. Both drugs demonstrated significant improvement in anxiety symptoms after drug therapy when compared to pretreatment.

4.6.L.2 Cataplexy

a) Both fluvoxamine and clomipramine improved cataplexy, but not narcolepsy, in 18 patients with these diseases during a cross-over study (Schachter & Parkes, 1980). It was not revealed if either the patients or researchers were blinded to drug therapy. It should be noted that 15 of the 18 patients were receiving clomipramine 25 to 100 milligrams/daily at the start of the trial, and may have been accustomed to the adverse effects of clomipramine. Also, if the patients were not blinded to drug therapy, some patients may have associated more adverse effects with a new drug, fluvoxamine. Patients were randomly allocated to receive fluvoxamine or clomipramine for a 3-week interval. After a 1-week drug-free period, the patients crossed over to the other drug. The daily dosing range for both drugs ranged from 25 to 200 milligrams/day. All patients were clinically assessed by observers on 5 occasions. The observers' impression was that fluvoxamine caused a moderate reduction in the frequency of attacks of cataplexy and sleep paralysis in most subjects. Fluvoxamine abolished cataplexy in 4 patients and sleep paralysis in 2 patients; only 12 of the 18 patients completed the fluvoxamine-treatment period. The observers felt that clomipramine was more effective than fluvoxamine in preventing both cataplexy and sleep paralysis. Clomipramine abolished cataplexy in 4 patients and sleep paralysis in 5 patients.

4.6.L.3 Depression

a) SUMMARY: Several double-blind, short-term studies have demonstrated fluvoxamine to be as effective as clomipramine in the treatment of depression (De Wilde et al, 1983; Klok et al, 1981). Anticholinergic adverse effects appear to be less common with fluvoxamine therapy.

b) Fluvoxamine and clomipramine were compared for antidepressant activity in a 6-week, randomized, double-blind study of 43 outpatients with major depression (De Wilde et al, 1983). Oral fluvoxamine 100 to 300 milligrams or oral clomipramine 50 to 150 milligrams was administered once daily in the evening. Assessments of the HAM-D (Hamilton Rating Scale for Depression) during the study and at the end failed to demonstrate any significant differences in antidepressant activity between the 2 drugs. The incidence of anticholinergic adverse effects were slightly more significant in the clomipramine-treated group.

c) Clomipramine and fluvoxamine appeared to be equally effective in the treatment of depression for 36 female inpatients during a 4-week, randomized, double-blind study (Klok et al, 1981). Patients were randomized to receive either oral clomipramine or oral fluvoxamine 50 milligrams 3 times daily. Diazepam 10 to 30 mg/day for severe agitation and/or anxiety was the only other psychotropic agent administered. Significant improvements in the Hamilton Rating Scale for Depression, the Clinical Global Impression, and the Zung Self-Rating Depression scale were seen in both treatment groups. Anticholinergic adverse effects appeared more frequently in the clomipramine-treated patients, while gastrointestinal effects were more prevalent in the fluvoxamine group.

d) Fluvoxamine and clomipramine appeared to have similar clinical efficacy in the treatment of endogenous depression for 30 unipolar and bipolar inpatients during a 4-week, randomized, double-blind study (De Wilde et al, 1983). Both drugs were administered orally in doses of 150 to 300 milligrams/day in 3 divided doses. At the end of the study, the fluvoxamine-treated patients demonstrated a 73% improvement on the Hamilton Rating Scale for Depression, while the clomipramine-treated patients had a 62% improvement. In the bipolar patients, 3 of 4 on fluvoxamine responded, while only 1 of 5 on clomipramine demonstrated a good response on the CGI Global Change Scale. Overall, the differences in efficacy between the 2 drugs were not statistically significant. Adverse anticholinergic effects were significantly more prevalent in the clomipramine-treated group.

e) Both clomipramine and fluvoxamine produced significant improvements on the Hamilton Rating Scale for Depression (HAM-D) in 32 patients with mixed depression during a 4-week, randomized, double-blind study (Dick & Ferrero, 1983). The average daily dosage was 130 milligrams and 132.8 milligrams for fluvoxamine and clomipramine, respectively. The mean percentage improvement on the HAM-D for the fluvoxamine-treated patients was 63.8%, and for the clomipramine-treated patients it was 66.3%.

4.6.L.4 Obsessive-compulsive disorder

a) Fluvoxamine (150 to 125 milligrams/day) and clomipramine (100 to 250 milligrams/day were equally effective in the treatment (10 weeks) of 66 outpatients with obsessive compulsive disorder. Both treatments were well-tolerated. Fluvoxamine produced fewer anticholinergic adverse effects and caused less sexual dysfunction than clomipramine, but caused more headache and insomnia (Freeman et al, 1994). under OBSESSIVE COMPULSIVE DISORDER add:

b) In a randomized, double-blind study of 26 patients with obsessive compulsive disorder without comorbid diseases, fluvoxamine and clomipramine, each titrated from an initial dose of 50 milligrams (mg) in the evening up to a maximum of 300 mg daily within two weeks, were equally effective (38% improvement over baseline with fluvoxamine versus 40% for clomipramine). Efficacy was assessed according to the Yale-Brown Obsessive Compulsive Scale and Clinical Global Impression Scale. Fluvoxamine was better tolerated, with less anticholinergic adverse effects while clomipramine had a quicker onset of action. Further studies are needed to demonstrate a time-related effect that might differentiate these drugs (Milanfranchi et

al, 1997).

4.6.L.5 Panic disorder

a) Clomipramine (10 milligrams (mg) for three days and 20 mg for four days) and fluvoxamine (50 mg/day for seven days) were both effective in decreasing the hypersensitivity to 35% carbon dioxide, supporting the serotonergic effect of these drugs to decrease panic attacks through modification of carbon dioxide sensitivity. Thirty-nine panic disorder patients were enrolled in a double-blind, randomized, placebo-controlled study, where each patient was given the 35% carbon dioxide challenge on days 0, 3, and 7. Patients on clomipramine and fluvoxamine showed significant reduction in sensitivity over placebo after seven days as seen by the percent change on a visual analogue for anxiety scale (p=0.027) (Perna et al, 1997).

4.6.M Haloperidol

4.6.M.1 Autistic disorder

a) Among subjects who completed full therapeutic trials of haloperidol and clomipramine for treatment of autistic disorder, the two drugs were comparable; however, haloperidol was superior to clomipramine on an intent-to-treat basis, because of the large proportion of patients who were unable to complete clomipramine treatment due to side effects and behavior problems. In a double- blind, placebo-controlled crossover study, 36 subjects with a DSM- IV diagnosis of autism were given placebo, haloperidol, and clomipramine for periods of 7 weeks each. Clomipramine was begun at 25 milligrams (mg) at bedtime for 2 days and increased to 25 mg twice a day for 2 days, 25 mg 3 times a day for 2 days, and finally 50 mg twice a day. Haloperidol was begun at 0.25 mg at bedtime for 2 days and increased to 0.25 mg twice a day for 2 days, 0.25 mg 3 times a day for 2 days, and finally 0.5 mg twice a day. For both drugs, adjustments of the final dose could be made as clinically indicated. During week 7 of each period, drug dosages were tapered in preparation for the next treatment. Percentages of subjects completing each trial were 70% for haloperidol, 38% for clomipramine, and 66% for placebo. In the haloperidol trials, 7 of 10 discontinuations were for side effects (fatigue or lethargy, dystonia, depression) and the remainder for behavior problems. With clomipramine, 12 of 20 discontinuations were for side effects (fatigue or lethargy, tremors, tachycardia, insomnia, diaphoresis, nausea or vomiting, and decreased appetite) and the remainder for behavior problems. In the placebo trials, 10 of 11 discontinuations were for behavior problems. On an intent-to-treat basis, significant improvement in irritability (p less than 0.05) and hyperactivity (p less than 0.05) was seen with haloperidol only (versus baseline). No differences among treatments were observed for stereotypic behavior, lethargy, or inappropriate speech. When data only from patients completing full therapeutic trials were assessed, both haloperidol and clomipramine were superior to baseline with regard to irritability and stereotypy (Remington et al, 2001).

4.6.N Imipramine

Depression

Obsessive-compulsive disorder

4.6.N.1 Depression

a) Clomipramine was as effective as imipramine in treating depression in 24 patients during a 44-day, randomized, double-blind study (McClure et al, 1973). The patients were diagnosed with psychotic depression independently by 2 psychiatrists. Oral imipramine or oral clomipramine was administered 3 times daily in 50 milligrams doses. Throughout the study periodic assessments using the Hamilton Depression Rating Scale and the Beck Depression Inventory demonstrated a significant reduction in depression from baseline for both drugs; however, a significant difference in antidepressant effects between drugs could not be seen. Minor and transient anticholinergic adverse effects were noted in all patients and included blurred vision, dry mouth, increased sweating, hand tremor, and dizziness. Three patients dropped out of the study, but none of these was due to adverse effects.

4.6.N.2 Obsessive-compulsive disorder

a) SUMMARY: Clomipramine is superior to imipramine in the treatment of obsessive-compulsive disorder.
b) Oral clomipramine was slightly superior to oral imipramine in improving symptoms of obsessive-compulsive disorder (Volavka et al, 1985). A 12-week, double-blind study of 23 patients according to DSM-III with secondary depression diagnosed was conducted to compare the 2 drugs. Both drugs were started at 50 milligrams/day; this was gradually increased to 300 mg/day as tolerated. Seven patients did not complete the study: 4 because of adverse effects (2 from each group), 2 because of unsatisfactory therapeutic response with imipramine, and 1 for no apparent reason. Both drugs produced improvement in depressive symptoms; however, only clomipramine demonstrated improvement in obsessive symptoms when compared to baseline. Typical anticholinergic adverse effects were experienced by both treatment groups with no significant differences between the two. It is difficult to accurately evaluate the clinical response in this study

because of the small number of patients and the methods used for statistical analysis.
c) Both oral clomipramine and oral imipramine were effective in improving symptoms in obsessive-compulsive disorder patients who met DSM-III criteria (Mavissakalian et al, 1985). The study was a 12-week, double-blind trial that compared the efficacy of clomipramine and imipramine in treating obsessive-compulsive disorders. Both drugs were begun at 25 to 50 milligrams/day; this was increased to 300 mg/day as tolerated. At the end of the trial, the mean daily dose of both drugs was 220 mg. Two of 3 clomipramine-treated patients and 2 of 5 imipramine-treated patients were classified as responders. For both drugs, maximal improvement in depression was evident at 4 weeks, while maximal improvement in obsessive-compulsive symptoms was not seen until 8 weeks. The responders also had higher pretreatment depression scores than did nonresponders, which corresponded with the results of another study (Marks et al, 1980). Because of the small sample size, differences (n=8) in efficacy between clomipramine and imipramine could not be determined.
d) The relationship between the antiobsessional and antidepressant effects of tricyclic drugs was studied in primary obsessive-compulsive disorder. Study 1 consisted of a controlled 12-week trial with clomipramine (n=7) and placebo (n=5); study 2 analyzed the pooled data from 15 uniformly selected patients who were treated with either clomipramine or imipramine. Although the antiobsessional and antidepressant effects of the drugs covaried, antidepressant action was not a prerequisite for antiobsessional effects. Clomipramine, and probably imipramine, possess specific antiobsessive effects that are at least partially independent of the antidepressant effects (Mavissakalian et al, 1985).

4.6.O Lithium

4.6.O.1 Depression
a) The effects of lithium and clomipramine (CMI) on signs and symptoms were compared in 22 patients with major depression (Linder et al, 1989). They also compared effects of the two drugs on serum calcium and magnesium. Evaluation of response using the Comprehensive Psychopathological Rating Scale (CPRS) and side effects was made after a 5 to 7 day placebo period, at 2 weeks and at 4 weeks of treatment. After 2 weeks of treatment, the rated scores dropped for more than half of the CPRS items. After 4 weeks, the scores for all but one item were reduced in both groups and after 4 weeks global scores were also reduced. There was no significant difference between lithium patients and CMI patients in response at 2 and 4 weeks. Lithium treatment was associated with fluctuations in calcium and magnesium levels in plasma but there were no changes in CMI patients. Serum prolactin increased during CMI treatment but was unaffected by lithium treatment. There was no correlation between rating scores and drug blood levels, serum prolactin, calcium or magnesium.

4.6.P Lofepramine

4.6.P.1 Depression
a) A meta-analysis of 4 studies comparing lofepramine (n=79) with clomipramine (n=79) concluded that lofepramine was superior to clomipramine in efficacy and tolerance (Kerihuel & Dreyfus, 1991). Overall, there was a significant difference between the number of lofepramine-treated patients (62%) and clomipramine-treated patients (37%) who improved during the 6-week trials. Fewer patients reported side effects with lofepramine than clomipramine (54% vs 65%; p less than 0.15). Lofepramine doses ranged from 70 to 210 milligrams/d, and clomipramine doses ranged from 50 to 150 milligrams/d.
b) Oral lofepramine 70 milligrams twice daily was slightly superior to oral clomipramine 50 milligrams twice daily in a 6-week, randomized, double-blind study involving 60 depressed patients. Lofepramine-treated patients demonstrated a significantly greater improvement on the Hamilton Depression Scale than clomipramine by the end of the study. Statistical significance between the 2 drugs could not be determined in the Self-Rating Depression Scale. Typical mild anticholinergic effects were experienced by both groups, with no significant differences between the drugs (Dimitriou et al, 1984).

4.6.Q Maprotiline

Depression

Pain, Idiopathic

4.6.Q.1 Depression
a) Maprotiline and clomipramine were equally effective in a 4-week, randomized, double-blind study in 12 depressed patients (Ridges, 1977). All patients were endogenously depressed; however, diagnosis criteria was not discussed. Both drugs were started orally at 75 milligrams/day; this was increased to 225 mg/day after 2 weeks if 150 mg/day was inadequate. The Hamilton Depression Rating Scale was used to assess therapeutic efficacy. At the end of the study, both drugs improved depression symptoms to a similar degree and no difference in efficacy could be distinguished. The clomipramine-treated patients appeared to improve sooner than the maprotiline-treated patients. Adverse effects were generally mild and similar for both drugs:

dry mouth, constipation, and tremor. Because of the small number of patients and short duration of the study, further studies are required to adequately compare the 2 drugs in the treatment of depression.

4.6.Q.2 Pain, Idiopathic

a) Oral clomipramine (mean 97 milligrams/day) was more effective in reducing the overall idiopathic pain syndrome symptoms than oral maprotiline (mean 100 milligrams/day) during a 6-week, randomized, double-blind study of 52 patients (Eberhard et al, 1988). An overall improvement was seen in 63% of the clomipramine-treated patients and in only 36% of the maprotiline-treated patients. Clomipramine produced improvements in pain, memory disturbances, concentration difficulties, inner tension, sadness, and bodily discomfort. The most common adverse effect for both drugs was dry mouth, while sweating was more prevalent with clomipramine. Eight clomipramine patients withdrew from the study because of adverse effects compared to only 1 maprotiline-treated patient.

4.6.R Metoprolol

4.6.R.1 Migraine

a) Metoprolol, in oral doses up to 100 milligrams/day, was superior to oral clomipramine (up to 100 milligrams/day) and placebo in 63 migraine headache sufferers during a 16-week, randomized, double-blind, crossover study (Langohr et al, 1985). All patients were diagnosed with common or classic migraines according to the Ad Hoc Committee on Classification of Headache. The drugs were administered at 4-week intervals, with 4-week washout periods before crossover. Metoprolol was the only agent that significantly reduced both the frequency and duration of migraine attacks. When compared to placebo, clomipramine had no influence on migraine attacks. Adverse effects from clomipramine caused 18 patients to discontinue treatment. The most commonly reported adverse effects with clomipramine included insomnia, sweating, tiredness, and constipation.

4.6.S Mianserin

Depression

Headache

Pain

4.6.S.1 Depression

a) SUMMARY: Comparative clinical trials with mianserin and clomipramine fail to demonstrate any significant differences in antidepressant activity. Clomipramine may produce more adverse effects than mianserin.

b) Oral mianserin 60 mg daily and oral clomipramine 150 mg daily were compared for antidepressant activity during a 4-week, multicenter, randomized, double-blind study of 145 depressed patients (Pinder et al, 1980). At the end of the trial, both drugs produced significant but indistinguishable improvement in depression. The clomipramine patients demonstrated a slightly significant increase in adverse effects that were mild and included dry mouth, hypotension, and tremor. Ten patients, 4 on mianserin and 6 on clomipramine, did not complete the study because of drug-related problems; these included adverse effects, clinical deterioration, and increased suicidal risk.

c) A 5-week, randomized, double-blind study compared the safety and efficacy of mianserin and clomipramine in 42 patients with primary unipolar depression according to the International Classification of Diseases (Anon, 1968; Levin, 1982). Patients were started on either oral mianserin 30 milligrams or oral clomipramine 75 milligrams once daily; both doses were doubled beginning in the second week. Both groups demonstrated significant improvement in depression symptoms; however, the mianserin group demonstrated slightly more improvement after 5 weeks of therapy. Adverse effects were similar in both groups, but more prevalent in the clomipramine group, and included dry mouth, tremor, tachycardia, dizziness, excitement, and nasal congestion. Tachycardia and excitement were only present in the clomipramine group. One mianserin patient and 5 clomipramine patients withdrew from the study because of adverse effects.

d) The antidepressant activity of oral mianserin 30 to 60 milligrams daily and oral clomipramine 75 to 150 milligrams daily was compared in 62 mildly depressed patients during a 4-week, randomized, double-blind study (Dunbar et al, 1985). No significant difference in antidepressant activity could be demonstrated between the 2 drugs. Similar anticholinergic adverse effects were experienced by both groups; however, clomipramine patients reported more tremor, dry mouth, tachycardia, and dizziness and 2 withdrew from the study because of adverse effects.

4.6.S.2 Headache

a) Mianserin, clomipramine, and placebo were studied in a double-blind, parallel group comparison involving 82 patients with chronic tension headaches. Both mianserin and clomipramine produced

improvements in pain scores in light of a significant placebo response after 6 weeks of therapy with either oral clomipramine 75 to 150 milligrams/day or mianserin 30 to 60 milligrams/day (Langemark et al, 1990).

4.6.S.3 Pain

a) No significant difference was found among oral clomipramine (75 to 150 milligrams/day), mianserin (30 to 60 milligrams/day), and placebo in a study of 253 patients with chronic idiopathic pain syndrome. Improvement rate was about 40% after 6 weeks when using a 50% or better reduction in pain level. In patients who fulfilled checklist criteria for minor-to-major depression (30% of patients), clomipramine was superior to mianserin and placebo, with an improvement rate of 75% after 7 weeks. Both mianserin and clomipramine were superior to placebo in patients with low back pain. No difference among the 3 treatments was found in patients with burning mouth syndrome or abdominal pain (Loldrup et al, 1989).

4.6.T Milnacipran

4.6.T.1 Depression

a) Milnacipran offers no efficacy advantage over tricyclic antidepressants. Milnacipran 50 to 100 mg twice daily has been comparable to or less effective than imipramine 100 to 150 mg daily, amitriptyline 150 mg daily, and clomipramine 75 to 150 mg daily in the treatment of major depressive disorders; primary endpoints were improvements on the Hamilton and Montgomery-Asberg scales (Tignol et al, 1998; Leinonen et al, 1997; Kasper et al, 1996; Anon, 1997b; Von Frenckell et al, 1990; Ansseau et al, 1989). A more rapid onset of action has been observed with clomipramine and amitriptyline (Leinonen et al, 1997; Ansseau et al, 1989).

b) Greater improvement of CGI-3 scores (therapeutic index, incorporating efficacy and tolerance) was reported with milnacipran in a manufacturer-prepared meta analysis of tricyclic antidepressant comparative trials (Anon, 1997b; Kasper et al, 1996), and this appears in manufacturer product information. However, statistical significance between treatments was not demonstrated (Anon, 1997b).

4.6.U Moclobemide

4.6.U.1 Depression

a) SUMMARY: Clomipramine and moclobemide have been similarly effective in the treatment of depression; a faster onset of action and lower incidence of adverse effects have been reported with moclobemide in some studies. Drop-out rates due to clinical worsening and suicidality were more likely with moclobemide than clomipramine in one study.

b) Clomipramine in doses of 75 to 200 milligrams daily has been as effective as moclobemide 300 to 600 milligrams daily in treating endogenous and non-endogenous depression in most controlled studies (Dierick et al, 1990; Civeira et al, 1990; Lecrubier & Guelfi, 1990). One study (Larsen et al, 1989) reported that moclobemide, imipramine, and placebo were all associated with similar clinical improvement in patients with non-endogenous depression. Lack of statistical superiority of these agents over placebo in this report may have been a reflection of the small number of patients treated (20 in each group). In a larger controlled trial (n=191), moclobemide and clomipramine produced similar and significant improvement in non-endogenously depressed patients; however, placebo was not incorporated into this study (Stabl et al, 1989).

c) An advantage for moclobemide with regard to tolerability (particularly its lesser anticholinergic effects) was reported in some of these studies. However, a similar adverse effect profile for moclobemide and clomipramine emerged in others (Civeira et al, 1990).

d) The onset of antidepressant effect was quicker with moclobemide (10 days) as compared to clomipramine (13 days) in some studies (Lecrubier & Guelfi, 1990).

e) Antidepressant and adverse effects of moclobemide (MCB) (400 milligrams/day) and clomipramine (CMI) (150 milligrams/day) were compared in a double-blind, randomized, inpatient, fixed-dose study with weekly ratings and drug level measurements. After 1 week on single-blind treatment, 115 patients with major depression who met inclusion criteria were begun on active treatment for 6 weeks. MCB drop-outs (N=20) were primarily due to clinical worsening and suicidality (N=9) whereas CMI drop-outs were related primarily to adverse effects (N=6) with none due to clinical worsening. End-point analysis using the Hamilton Depression Scale showed a significant difference favoring CMI over MCB (Anon, 1993).

4.6.V Nortriptyline

4.6.V.1 Pain

a) Twenty-four patients with central pain completed a randomized, crossover, placebo-controlled study of the efficacy and tolerability of clomipramine and nortriptyline. Results showed strong predominance of active drugs over placebo and a significantly more effective analgesic effect of clomipramine over nortriptyline. The analgesic effect of both tricyclic compounds is independent of any antidepressant effect (Panerai et al, 1990).

4.6.W Oxaprotiline

4.6.W.1 Depression

a) Oral oxaprotiline 150 milligrams/day and oral clomipramine 150 milligrams/day were compared for

efficacy in the treatment of 38 depressed patients during a 4-week, randomized, double-blind study (Wolfersdorf et al, 1987). All patients were diagnosed as having either endogenous or psychogenous (psychotic) depression according to ICD (International Classification of Diseases) criteria and were divided equally between the 2 drug therapy groups. After 2 weeks of therapy, both drugs demonstrated equal improvement in depression as assessed by a trained therapist; however, after 4 weeks, the clomipramine group was slightly more improved as determined by the Hamilton Depression Rating Scale and the Self-Rating Scale of Depression. Adverse effects were generally mild and similar for both drugs; they included tremor, sweating, agitation, headaches, and dizziness. Three patients withdrew from the study: 1 from each group due to perceived lack of efficacy and the third due to a venous thrombosis that was not felt to be drug-related.

4.6.X Paroxetine

Depression

Obsessive-compulsive disorder

4.6.X.1 Depression

a) In a large (n=1002) clinical trial, treatment with paroxetine or clomipramine produced similar decreases in anxiety and depression scores; however, adverse effects occurred in significantly (p=0.025) more patients treated with clomipramine than paroxetine (Ravindran et al, 1997). Statistically significant differences between treatments were NOT found on the Montgomery-Asberg Depresssion Rating Scale (MADRS) or Clinical Anxiety Scale (CAS), but a trend in favor of paroxetine was observed for the Clinical Global Impressions (CGI) score at 6 and 12 weeks (p=0.015). Patients entered into this trial had depression with anxiety which was treated in a primary care setting. Paroxetine 20 milligrams (mg) daily was used initially but the protocol permitted an increase to 40 mg daily, if needed, after 4 weeks. Clomipramine titration proceeded as follows: (1) 25 mg in the evening for 3 days; (2) 50 mg in the evening for 4 days; (3) 75 mg daily (25 mg in the morning and 50 mg in the evening); and (4) after 4 weeks, the dose could be increased to 150 mg/day. Based on this study, paroxetine and clomipramine have comparable efficacy but the incidence of adverse effects (AE) including serious AE is lower in patients treated with paroxetine.
b) Paroxetine 30 milligrams once daily was as effective as clomipramine 25 milligrams three times daily in the treatment of major depressive disorder in a 6-week, double-blind study involving 79 elderly patients (60 years of age or older) (Guillibert et al, 1989). Anticholinergic effects and somnolence occurred to a greater degree with clomipramine, whereas nausea and vomiting were observed more frequently with paroxetine.
c) Clomipramine demonstrated a significantly better therapeutic effect than paroxetine using categorical response measures and group averages of rating scores during a double-blind, randomized, inpatient study of 120 depressed patients (Anon, 1990). Patients were randomized to receive either paroxetine 30 milligrams/day or clomipramine 150 milligrams/day for this 6-week study. At the end of week 4, 27 patients were rated as nonresponders and were terminated from the study. Of thses 27 patients, 23 were in the paroxetine group.

4.6.X.2 Obsessive-compulsive disorder

a) In a 12-week, comparative study, paroxetine was as effective as clomipramine for treating obsessive compulsive disorder. Patients were randomly assigned to receive placebo (n=99), paroxetine 10 milligrams (mg) (n=201), or clomipramine 25 mg daily (n=99); the dose of active treatments was titrated to a maximum of 60 mg and 250 mg for paroxetine and clomipramine, respectively. No statistically significant differences were found in the primary efficacy measures, the Yale-Brown Obsessive-Compulsive Scale or the National Institute of Mental Health Obsessive-Compulsive Scale, between paroxetine or clomipramine; however, both drugs were significantly better than placebo. Adverse effects requiring treatment withdrawal occurred in fewer patients treated with paroxetine (9%; p=0.033) than clomipramine (17%). Limitations of the study are the relatively short duration, and the potential loss of blinding due to differences in adverse effects (Zohar et al, 1996).

4.6.Y Pentazocine

4.6.Y.1 Postoperative pain

a) Clomipramine was as effective as pentazocine for relieving postoperative pain. Forty patients (30 to 50 years old) received either intramuscular clomipramine 50 mg or pentazocine 30 mg a half an hour after the end of anesthesia for hysterectomies or laparotomies. No significant difference was observed between either agent for analgesia (Tiengo et al, 1987).

4.6.Z Phenelzine

4.6.Z.1 Obsessive-compulsive disorder

a) Clomipramine and phenelzine had similar efficacy in a double-blind clinical trial conducted in 30 patients

suffering from DSM-III obsessive-compulsive disorder. The study period was 12 weeks and the maximum doses used (from the fifth week on) were 225 milligrams/d for clomipramine (14 patients) and 75 milligrams/d for phenelzine (12 patients); four patients dropped out. Obsessive symptoms improved significantly in both drug groups, but there was no significant difference between groups. Depressive symptoms responded faster than obsessive symptoms (Vallejo et al, 1992).

4.6.AA Sildenafil

4.6.AA.1 Premature ejaculation

a) According to a double-blind, randomized, cross-over study (n=31), as-needed SILDENAFIL was superior in the treatment of premature ejaculation compared with CLOMIPRAMINE, PAROXETINE, SERTRALINE, and PAUSE-SQUEEZE technique. Clomipramine, paroxetine, and sertraline had generally similar efficacy and safety. Paroxetine exhibited improved efficacy and satisfaction over pause-squeeze, while efficacy and satisfaction were similar to pause-squeeze for clomipramine and sertraline. Median intravaginal ejaculation latency time (IVELT) increased significantly to 4 minutes (min), 4 min, 3 min, 15 min, and 3 min from baseline 1 min for clomipramine, paroxetine, sertraline, sildenafil, and pause-squeeze, respectively (all p less than 0.0001). Paroxetine was superior to pause-squeeze with respect to IVELT (p=0.04) and sexual satisfaction (p=0.025). A significant positive correlation occurred between ejaculation latency and sexual satisfaction. No significant differences in adverse effects were found among the 4 drugs. Three patients dropped out due to side effects, including sildenafil (2) and clomipramine (1; also lack of efficacy in this patient). Three additional patients dropped out due to lack of efficacy related to clomipramine, paroxetine, sertraline, and/or pause-squeeze. Medications were administered as needed 3 to 5 hours before planned intercourse and not more than twice a week. Doses were clomipramine 25 milligrams (mg), paroxetine 20 mg, sertraline 50 mg, and sildenafil 50 mg (Abdel-Hamid et al, 2001).

4.6.AB Venlafaxine

4.6.AB.1 Depression

a) Venlafaxine 105 milligrams/day (average dose) tended to be more effective than clomipramine 105 milligrams/day (average dose) for the treatment of depression in a 6-week study with 102 patients; however, the difference was not statistically significant (Holliday & Benfield, 1995). Patients were assessed using the Hamilton Depression Rating Scale, Montgomery-Asberg Depression Rating Scale, and the Clinical Global Impressions scale. Venlafaxine was associated with fewer anticholinergic side effects and a greater incidence of headache/nausea than clomipramine.

588. Product Information: ANAFRANIL(R) oral capsule, clomipramine hydrochloride oral capsule. Mallinckrodt Inc, St Louis, MO, 2005.
589. Product Information: ANAFRANIL(R) oral capsules, clomipramine hcl oral capsules. Mallinckrodt,Inc, Hazelwood, MO, 2007.
590. Product Information: ANAFRANIL(R) oral capsules, clomipramine hcl oral capsules. Mallinckrodt,Inc, Hazelwood, MO, 2007a.
591. Product Information: AZILECT(R) oral tablets, rasagiline oral tablets. Teva Pharmaceuticals, Kfar Saba, Israel, 2006.
592. Product Information: Agenerase(R), amprenavir. Glaxo Wellcome Inc., Research Triangle Park, NC, 2000.
593. Product Information: Anafranil(R), clomipramine hydrochloride capsules. Novartis Pharmaceuticals Corp, East Hanover, NJ, 2001c.

594. Product Information: Anafranil(R), clomipramine hydrochloride. Mallinckrodt Inc, St Louis, MO, USA, 2001.
595. Product Information: Anafranil(R), clomipramine. Mallinckrodt, St. Louis, MO, 2001a.
596. Product Information: Anafranil(R), clomipramine. Mallinckrodt, St. Louis, MO, 2001b.
597. Product Information: Avelox(TM), moxifloxacin hydrochloride. Bayer Corporation, West Haven, CT, 2000.
598. Product Information: BROVANA(TM) inhalation solution, arformoterol tartrate inhalation solution. Sepracor,Inc, Marlborough, MA, 2006.
599. Product Information: COARTEM(R) oral tablets, artemether lumefantrine oral tablets. Novartis Pharmaceuticals Corporation, East Hanover, NJ, 2009.
600. Product Information: CYMBALTA(R) delayed-release oral capsules, duloxetine hcl delayed-release oral capsules. Eli Lilly and Company, Indianapolis, IN, 2008.
601. Product Information: Catapres(R), clonidine. Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT, 1996.
602. Product Information: Cerebyx(R), fosphenytoin sodium injection. Parke-Davis, Division of Warner-Lambert, Morris Plains, NJ, 1999.
603. Product Information: DAYTRANA(TM) transdermal system, methylphenidate transdermal system. Shire US Inc., Wayne, PA, 2006.
604. Product Information: DEXEDRINE(R) sustained-release oral capsules, oral tablets, dextroamphetamine sulfate sustained-release oral capsules, oral tablets. GlaxoSmithKline, Research Triangle Park, NC, 2006.
605. Product Information: Effexor(R) XR, venlafaxine hydrochloride extended-release. Wyeth Laboratories, Philadelphia, PA, 2003.
606. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999.
607. Product Information: FORADIL(R) AEROLIZER(R) inhalation powder, formoterol fumarate inhalation powder. Schering Corporation, Kenilworth, NJ, 2006.
608. Product Information: GenESA(R), arbutamine hydrochloride. Gensia Automedics, Inc., San Diego, CA, 1997.
609. Product Information: Halfan(R), halofantrine hydrochloride. Research Triangle Park, NC, 1998.
610. Product Information: Hylorel(R), guanadrel. Fisons Corporation, Rochester, NY, 1995.
611. Product Information: LEXIVA(R) oral solution, oral tablets, fosamprenavir calcium oral solution, oral tablets. GlaxoSmithKline, Research Triangle Park, NC, 2009.
612. Product Information: Manerix(R), Moclobemide. Hoffmann-La Roche Limited, Mississauga, Ontario, Canada, 2001.
613. Product Information: Marplan(R), isocarboxazid. Roche Laboratories Inc., Nutley, NJ, 1998.
614. Product Information: Matulane(R), procarbazine. Roche Laboratories Inc., Nutley, NJ, 1997.
615. Product Information: NARDIL(R) Tablets, USP, phenelzine sulfate tablets, USP. Parke-Davis, New York, NY, 2005.
616. Product Information: NUVIGIL(TM) oral tablets, armodafinil oral tablets. Cephalon,Inc, Frazer, PA, 2007.
617. Product Information: Parnate(R), tranylcypromine sulfate tablets. GlaxoSmithKline, Research Triangle Park, NC, 2001.
618. Product Information: Paxil(R), paroxetine hydrochloride. GlaxoSmithKline, Research Triangle Park, NC, 2003.
619. Product Information: Propulsid(R), cisapride. Janssen Pharmaceutica Inc., Titusville, NJ, 2000.
620. Product Information: Provigil(R), modafinil. Cephalon, Inc., West Chester, PA, 1998.
621. Product Information: Raxar(R), grepafloxacin hydrochloride. Glaxo Wellcome Inc., Research Triangle Park, NC, 1999.
622. Product Information: Reyataz(TM), atazanavir. Bristol-Myers Squibb Company, Princeton, NJ, 2003.
623. Product Information: SEREVENT(R) DISKUS(R) inhalation powder, salmeterol xinafoate inhalation powder. GlaxoSmithKline, Research Triangle Park, NC, 2006.
624. Product Information: Strattera(TM), atomoxetine. Eli Lilly and Company, Indianapolis, IN, 2002.
625. Product Information: Tequin(TM), gatifloxacin. Bristol-Myers Squibb Company, Princeton, NJ, 1999.
626. Product Information: Ultram(R), tramadol hydrochloride. Ortho-McNeil Pharmaceutical, Raritan, NJ, 1998.
627. Product Information: VYVANSE(TM) oral capsules, lisdexamfetamine dimesylate oral capsules. New River Pharmaceuticals,Inc, Blacksburg, VA, 2007.
628. Product Information: Vascor(R), bepridil hydrochloride. Ortho-McNeil Pharmaceuticals, Raritan, NJ, 2000.
629. Product Information: Vivactil(R), protriptyline. Merck & Co Inc, Westpoint, PA, 1999.
630. Product Information: ZYVOX(R) IV injection, oral tablets, oral suspension, linezolid IV injection, oral tablets, oral suspension. Pharmacia & Upjohn Company, New York, NY, 2008.
631. Product Information: Zoloft(R), sertraline hydrochloride. Roerig Division of Pfizer Inc, New York, NY, 2002.
632. Product Information: clomipramine hydrochloride oral capsule, clomipramine hydrochloride oral capsule. Taro Pharmaceuticals USA, Inc, Hawthorne, NY, 2002.
633. Product Information: tapentadol immediate release oral tablets, tapentadol immediate release oral tablets. Ortho-McNeil-Janssen Pharmaceuticals Inc, Raritan, NJ, 2008.

DRUGDEX® Evaluations

CLOZAPINE

0.0 Overview

1) Class
- **a)** This drug is a member of the following class(es):
  Antipsychotic
  Dibenzodiazepine

2) Dosing Information
- **a)** Adult
  - **1)** Schizoaffective disorder - Suicidal behavior, Recurrent
    - **a)** initial, 12.5 mg ORALLY 1-2 times a day, then continued with daily dosage increments of 25-50 mg/day, if well-tolerated, to achieve a target dose of 300-450 mg/day (in 2-3 divided doses) by the end of 2 weeks
    - **b)** maintenance: dosage adjustments should be made no more than 1-2 times per week, in increments not to exceed 100 mg; MAX daily dosage is 900 mg/day
  - **2)** Schizophrenia, Treatment-resistant
    - **a)** initial, 12.5 mg ORALLY 1-2 times a day, then continued with daily dosage increments of 25-50 mg/day, if well-tolerated, to achieve a target dose of 300-450 mg/day (in 2-3 divided doses) by the end of 2 weeks
    - **b)** maintenance: dosage adjustments should be made no more than 1-2 times per week, in increments not to exceed 100 mg; MAX daily dosage is 900 mg/day
  - **3)** Schizophrenia - Suicidal behavior, Recurrent
    - **a)** initial, 12.5 mg ORALLY 1-2 times a day, then continued with daily dosage increments of 25-50 mg/day, if well-tolerated, to achieve a target dose of 300-450 mg/day (in 2-3 divided doses) by the end of 2 weeks
    - **b)** maintenance: dosage adjustments should be made no more than 1-2 times per week, in increments not to exceed 100 mg; MAX daily dosage is 900 mg/day
- **b)** Pediatric
  - **1)** safety and effectiveness in pediatric patients have not been established

3) Contraindications

a) agranulocytosis or severe granulocytopenia, clozapine-induced, history; increased risk of subsequent episodes (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

b) concomitant use with other drugs having a known potential to cause agranulocytosis or suppress bone marrow function (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

c) hypersensitivity to clozapine or any other component of this drug (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

d) myeloproliferative disorders, preexisting (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

e) paralytic ileus, preexisting (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

f) severe central nervous system depression or comatose states from any cause; preexisting (Prod Info CLOZARIL (R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

g) uncontrolled epilepsy or other predisposing factors, preexisting; may increase risk of seizure (Prod Info CLOZARIL(R) Tablets, 2005)

4) Serious Adverse Effects

a) Agranulocytosis
b) Bowel obstruction
c) Cardiac arrest
d) Colitis, Necrotizing
e) Death
f) Drug-induced eosinophilia
g) Fecal impaction
h) Gastrointestinal hypomotility
i) Hepatitis
j) Hyperglycemia
k) Ischemic bowel disease
l) Leukopenia
m) Myocarditis, 5 cases/100,000 patient years
n) Neuroleptic malignant syndrome
o) Neutropenia
p) Orthostatic hypotension
q) Pancreatitis
r) Paralytic ileus
s) Perforation of intestine
t) Pericardial effusion
u) Pulmonary embolism

v) Respiratory arrest
w) Seizure
x) Sudden cardiac death
y) Syncope
z) Tardive dyskinesia
aa) Thrombocytopenia
ab) White blood cell finding, Decreased

5) Clinical Applications
a) FDA Approved Indications
1) Schizoaffective disorder - Suicidal behavior, Recurrent
2) Schizophrenia, Treatment-resistant
3) Schizophrenia - Suicidal behavior, Recurrent

1.0 Dosing Information

Drug Properties

Storage and Stability

Adult Dosage

Pediatric Dosage

1.1 Drug Properties

A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product Index)
B) Synonyms
Clozapine
C) Physicochemical Properties
1) Molecular Weight
a) 326.83 (Canada, 1997)
2) Solubility
a) Systemic: Very slightly soluble in water (Prod Info Clozapine, 98).

1.2 Storage and Stability

A) Oral route
1) Storage temperatures for clozapine tablets should not exceed 86 degrees F (30 degrees C) (Prod Info Clozaril(R), 2002).
2) Store clozapine oral disintegrating tablets at 25 degrees Celsius (77 degrees Fahrenheit) with excursions permitted to 15 to 30 degrees Celsius (59 to 86 degrees Fahrenheit) (Prod Info Fazaclo(TM), 2003).
B) Extemporaneous Formulation - Oral route
1) A 20-milligram per milliliter (mg/mL) suspension prepared from crushed tablets in a pediatric mixture base (containing syrup, carboxymethylcellulose, methylhydroxybenzoate and propylhydroxybenzoate) was found to be chemically stable for 18 days at room temperature. However, an expiration date of 7 days was recommended due to lack of microbial testing (Ramuth et al, 1996).

1.3 Adult Dosage

Normal Dosage

Dosage in Geriatric Patients

1.3.1 Normal Dosage

Intramuscular route

Oral route

Parkinson's disease - Psychotic disorder

Tardive dyskinesia

1.3.1.A Intramuscular route

1) Short-term intramuscular administration of clozapine effectively managed 59 treatment-resistant schizophrenic patients whose refusal to take oral medications precipitated an acute exacerbation. Patients had previously received oral clozapine at a mean dose of 307 milligrams/day. The average parenteral dose was 202 milligrams/day for a duration of 3 to 8 days. All patients improved and 90% became compliant with oral clozapine. In addition to the desired sedative effect, parenteral clozapine was associated with constipation (12%), headache (10%), dry mouth (7%) and injection site reactions (5%) (Lokshin et al, 1999).
2) In clinical trials, patients have been treated with clozapine intramuscularly in daily doses of up to 600 milligrams/day. The usual range is 150 to 300 milligrams daily (Ayd, 1974c).

1.3.1.B Oral route

1) The recommended initial dose of clozapine for treatment-resistant schizophrenia and recurrent suicidal behavior is 12.5 milligrams (mg) (one-half 25 mg tablet) once or twice daily (Prod Info Clozaril(R), 2002; Prod Info Fazaclo(TM), 2003). If tolerated, daily dosage increments of 25 to 50 mg may be added to achieve a target dose of 300 to 450 mg/day by the end of 2 weeks. Subsequent increases should be made no more than 1 to 2 times weekly in increments not exceeding 100 mg. For maintenance therapy, the lowest dose of clozapine to maintain remission should be used.
In schizophrenia, initial doses of oral clozapine have been suggested (Taniguchi & Icaza, 1996):

day 1	12.5 milligrams twice daily
day 2	25 milligrams in the AM
day 3	25 milligrams twice daily
day 4	25 milligrams in the AM, 50 milligrams at bedtime
day 5	50 milligrams twice daily
day 6	50 milligrams in the AM, 75 milligrams at bedtime
day 7 and 8	50 milligrams in the AM, 100 milligrams at bedtime
days 9 and 10	100 milligrams twice daily
days 11 and 12	50 milligrams in the AM, 200 milligrams at bedtime
days 13 and 14	100 milligrams in the AM, 200 milligrams at bedtime

Target doses of 300 to 450 milligrams/day are usually achieved by the end of 2 weeks. Cautious titration and a divided dosage schedule are necessary to minimize the risks of hypotension, seizures, and sedation.
2) If therapy is interrupted for two days or more, clozapine should be reinitiated at a dose of 12.5 milligrams once or twice daily. If well-tolerated, titration to the therapeutic dose may proceed more rapidly than recommended for initial therapy. Patients previously experiencing untoward reactions with initial therapy should be retitrated with caution even following 24 hours off of the drug (Prod Info Clozaril(R), 2002; Prod Info Fazaclo(TM), 2003).
3) In a double-blind trial conducted at a state psychiatric hospital (n=50), daily doses of 300 to 600 milligrams were generally superior to 100 milligrams/day. The study sample was severely and chronically ill with refractory schizophrenia or schizoaffective disorder (mean age: 45 years, mean illness duration: 25 years, mean length of current hospitalization: 8.6 years). Subjects were slowly titrated to one of three target doses (100, 300 or 600 milligrams/day) and treated for 16 weeks. Nonresponders at the target dose were crossed over to a different target dose for an additional 16-week period, with a third 16-week trial at the remaining target dose for continuing nonresponders. Only 10% (n=2 on 300 milligrams/day, n=3 on 600 milligrams/day) of this sample met response criteria. At the 16-week timepoint, the 600 milligrams/day dose was statistically superior to the lower doses (p less than 0.05). After 48 weeks, both 300 milligrams/day and 600 milligrams/day were statistically equivalent, with 100 milligrams/day being inferior to both (p less than 0.0001). In an open-label extension, four additional subjects responded to higher doses (800 to 900 milligrams/day) (Simpson et al, 1999).
4) To minimize the overall risk of adverse effects with clozapine, investigators recommend using the lowest possible effective dose with very gradual dose titration (Miller, 2000a; Naber, 1999a).
5) One author reports that therapeutic doses of clozapine range from 50 to 800 milligrams daily. Most patients appear to respond to doses of 200 to 400 milligrams daily. In most patients 3 divided doses at intervals of 4 to 6 hours appear to be effective; however, because of the sedating effects of clozapine, it may be advantageous to either give low doses in the morning and at midday with the bulk of the total daily dose in the evening, or to give the entire daily dose in the evening (Ayd, 1974c).

1.3.1.C Parkinson's disease - Psychotic disorder

See Drug Consult reference: THERAPY OF PSYCHOTIC DISTURBANCES IN PARKINSONIAN PATIENTS

1.3.1.D Tardive dyskinesia

See Drug Consult reference: TARDIVE DYSKINESIA - DRUG THERAPY

1.3.1.E IMPORTANT NOTE

1) Clozapine should NOT be dispensed without appropriate white blood cell count monitoring (Prod Info Clozaril(R), 2002).

2) A 1-week supply of clozapine tablets may be supplied to the patient at the initiation of therapy for emergency use such as weather or holidays (Prod Info Clozaril(R), 2002).

1.3.1.F DISCONTINUATION OF TREATMENT

1) Gradually reduce the dose over a 1- to 2-week period. If abrupt discontinuation is required, carefully monitor the patient for recurrence of psychotic and cholinergic rebound symptoms such as diarrhea, nausea, vomiting, and headache (Prod Info Clozaril(R), 2002; Prod Info Fazaclo(TM), 2003).

1.3.1.G MAXIMUM DOSE

1) Many patients with schizophrenia will respond to clozapine doses between 300 and 600 milligrams/day, but if necessary, the dose can be increased to 600 to 900 milligrams/day. Due to an enhanced risk of adverse effects, the dose should not exceed 900 milligrams/day and patients should be periodically re-evaluated to assess whether continued therapy is appropriate or whether a reduction in dose is possible (Prod Info Clozaril(R), 2002; Prod Info Fazaclo(TM), 2003).

1.3.1.H ORAL DISINTEGRATING TABLETS - PATIENT INSTRUCTIONS

1) Oral disintegrating tablets are supplied as blister packs and should not be opened until ready for use. Peel back foil to expose tablet; do NOT push the tablet through the foil. Just prior to use, remove the tablet from the blister unit and immediately place the entire tablet in the mouth; allow the tablet to disintegrate and then swallow with saliva. Water is not needed to take clozapine oral disintegrating tablets (Prod Info Fazaclo (TM), 2003).

1.3.4 Dosage in Geriatric Patients

A) Clinical studies of clozapine did not include sufficient numbers of subjects aged 65 and over to determine whether they respond differently from younger subjects. However, elderly patients may have an increased risk for agranulocytosis and should be carefully monitored during therapy (Prod Info Clozaril(R), 2002).

B) Elderly patients may be particularly susceptible to the anticholinergic effects of Clozaril (clozapine), such as urinary retention and constipation (Prod Info Clozaril(R), 2002).

C) Many elderly patients with Parkinson's disease cannot tolerate an initial clozapine dose of 25 milligrams because of side effects including sedation and orthostasis. An initial dose of 6.25 or 12.5 milligrams should be considered in elderly psychotic patients with Parkinson's disease (Wolk & Douglas, 1994).

D) Low-dose initial treatment for geriatric patients is recommended (12.5 milligrams given once on the first day) with subsequent increases not exceeding 25 mg daily (Prod Info Clozaril(R) Australia, 1996).

1.4 Pediatric Dosage

Normal Dosage

Dosage in Other Disease States

1.4.1 Normal Dosage

1.4.1.A Oral route

1) Safety and effectiveness for use in children has not been established (Prod Info Clozaril(R), 2002); (Prod Info Clozaril(R) Australia, 1996).

2) In an open trial of 11 adolescents (ages 12 to 17 years) with childhood-onset schizophrenia refractory to other neuroleptic agents, clozapine was given as an initial dose of 12.5 to 25 milligrams/day and increased every 4 days by one or two times the starting dose (Frazier et al, 1994). The dose was advanced based on clinical response and the emergence of adverse effects to a maximal possible dose of 900 milligrams/day. The mean dose at week 6 of the trial was 370.5 milligrams/day.

1.4.5 Dosage in Other Disease States

A) INFECTIOUS/INFLAMMATORY/HYPERSENSITIVITY PROCESSES

1) If an infectious, hypersensitivity, or inflammatory process is suspected, clozapine plasma levels should be closely monitored and the clozapine dose may need to be reduced by up to 50% (de Leon & Diaz, 2003; Haack et al, 2003).

1) Initial Response

a) Schizophrenia, Oral: 3 months (Wilson, 1996).

1) In a small number of patients, clinical improvement may be delayed up to 12 months (Wilson, 1996).

2.2 Drug Concentration Levels

A) Time to Peak Concentration

1) ORAL: 2.3 to 3 hours (range, 1 to 6 hours) (Prod Info Fazaclo(TM), 2003; Guitton et al, 1998; Prod Info Clozaril(R), 2002p; Cheng et al, 1988).

B) Schizophrenia, 350 to 420 micrograms/Liter (not clearly defined) (Olesen, 1998); (Freeman & Oyewumi, 1997).

1) Plasma levels show a significant degree of variation (Kurz et al, 1998). Levels are higher in women and increase with age in all patients (Lane et al, 1999).

2) Clozapine and norclozapine levels should only be quantified in plasma since serum levels underestimate blood levels (Kaladjian et al, 1999). Plasma and saliva levels of clozapine do not correlate (r=0.56) (Dumortier et al, 1998).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

2.3.1 Absorption

A) Effects of Food

1) No effect (Prod Info Clozaril(R), 2002p; Prod Info Fazaclo(TM), 2003).

B) Clozapine tablets and solution are equally bioavailable (Prod Info Clozaril(R), 2002p).

C) Clozapine orally disintegrating tablets (Fazaclo (TM)) are bioequivalent to clozapine tablets (Clozaril (R)) (Prod Info Fazaclo(TM), 2003).

2.3.2 Distribution

A) Distribution Sites

1) Protein Binding

a) 97% (Prod Info Clozaril(R), 2000; Prod Info Fazaclo(TM), 2003).

2) OTHER DISTRIBUTION SITES

a) Red blood cells

B) Distribution Kinetics

1) Volume of Distribution

a) 6 L/kg (Guitton et al, 1998).

2.3.3 Metabolism

A) Metabolism Sites and Kinetics

1) Extrahepatic presystemic routes (Cheng et al, 1988), extensive (Prod Info Clozaril(R), 2002p; Ayd, 1974b; Stock et al, 1977).

a) Metabolites are eliminated in the urine, principally in unconjugated form (Prod Info Clozaril(R), 2002p; Ayd, 1974b; Stock et al, 1977).

b) The average hepatic extraction ratio is 0.2 (Cheng et al, 1988).

c) The cytochrome P-450 enzyme system is involved in the metabolism of the parent compound to the major metabolites desmethylclozapine (both CYP1A2 and CYP3A4) and clozapine N-oxide (CYP3A4) (Eiermann et al, 1997; Jerling et al, 1997).

B) Metabolites

1) N-desmethylclozapine, active (Guitton et al, 1998; Gerson et al, 1994a).

a) N-desmethylclozapine, the major metabolite of clozapine, is a potent 5-HT(1C) receptor antagonist and has affinity for the D(2) and 5-HT(2) receptors. It is further metabolized to an unstable compound that is toxic to hemopoietic precursors of both myeloid and erythroid lineages (Guitton et al, 1998; Gerson et al, 1994a).

2) Hydroxylated and n-oxide derivatives, inactive (Guitton et al, 1998; Prod Info Clozaril(R), 2002p).

2.3.4 Excretion

A) Kidney

1) Renal Excretion (%)

a) 50% (Prod Info Clozaril(R), 2002p; Prod Info Fazaclo(TM), 2003).

1) Excreted in urine as the demethylated, hydroxylated, and n-oxide derivatives, only trace amounts of unchanged drug are detected in urine (Prod Info Clozaril(R), 2002p; Prod Info Fazaclo (TM), 2003).

2) Feces, 30% (Prod Info Clozaril(R), 2002p; Prod Info Fazaclo(TM), 2003).

a) Approximately 30% of a dose is excreted in the feces as the demethylated, hydroxylated, and n-oxide derivatives; only trace amounts of unchanged drug are detected in the feces (Prod Info Clozaril (R), 2002p; Prod Info Fazaclo(TM), 2003).

B) Total Body Clearance

1) 38 to 41 L/hr (Olesen, 1998; Guitton et al, 1998)

C) Other

1) OTHER EXCRETION

a) Blood clearance, 250 mL/min (Cheng et al, 1988).

2.3.5 Elimination Half-life

A) Parent Compound

1) ELIMINATION HALF-LIFE, 8 hours (range 4 to 12 hours), with single dose (Prod Info Clozaril(R), 2002p; Guitton et al, 1998; Prod Info Fazaclo(TM), 2003).

a) Elimination half-life is 12 hours (range, 4 to 66 hours) with multiple dosing (Prod Info Fazaclo(TM), 2003).

B) Metabolites

1) N-desmethylclozapine, 13.2 hours (Guitton et al, 1998)

2) N-oxide metabolite, 7 hours (Guitton et al, 1998)

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING

1) Oral (Tablet; Tablet, Disintegrating)

Agranulocytosis

Because of a significant risk of agranulocytosis, a potentially life-threatening adverse event, clozapine should be reserved for use in (1) the treatment of severely ill patients with schizophrenia who fail to show an acceptable response to adequate courses of standard antipsychotic drug treatment, or (2) for reducing the risk of recurrent suicidal behavior in patients with schizophrenia or schizoaffective disorder who are judged to be at risk of reexperiencing suicidal behavior.

Patients being treated with clozapine must have a baseline white blood cell (WBC) count and absolute neutrophil count (ANC) before initiation of treatment as well as regular WBC counts and ANCs during treatment and for at least 4 weeks after discontinuation of treatment.

Clozapine is available only through a distribution system that ensures monitoring of WBC counts and ANCs according to the schedule described below prior to delivery of the next supply of medication.

Seizures

Seizures have been associated with the use of clozapine. Dose appears to be an important predictor of seizure, with a greater likelihood at higher clozapine doses. Caution should be used when administering clozapine to patients having a history of seizures or other predisposing factors. Patients should be advised not to engage in any activity where sudden loss of consciousness could cause serious risk to themselves or others.

Myocarditis

Analyses of postmarketing safety databases suggest that clozapine is associated with an increased risk of fatal myocarditis, especially during, but not limited to, the first month of therapy. In patients in whom myocarditis is suspected, clozapine treatment should be promptly discontinued.

Other Adverse Cardiovascular and Respiratory Effects

Orthostatic hypotension, with or without syncope, can occur with clozapine treatment. Rarely, collapse can

be profound and be accompanied by respiratory and/or cardiac arrest. Orthostatic hypotension is more likely to occur during initial titration in association with rapid dose escalation. In patients who have had even a brief interval off clozapine (ie, 2 or more days since the last dose) treatment should be started with 12.5 mg once or twice daily.

Since collapse, respiratory arrest and cardiac arrest during initial treatment has occurred in patients who were being administered benzodiazepines or other psychotropic drugs, caution is advised when clozapine is initiated in patients taking a benzodiazepine or any other psychotropic drug.

Increased Mortality in Elderly Patients with Dementia-Related Psychosis

Elderly patients with dementia-related psychosis treated with antipsychotic drugs are at an increased risk of death. Analysis of seventeen placebo-controlled trials (modal duration of 10 weeks), largely in patients taking atypical antipsychotic drugs, revealed a risk of death in drug-treated patients of between 1.6 to 1.7 times the risk of death in placebo-treated patients. Over the course of a typical 10-week controlled trial, the rate of death in drug-treated patients was about 4.5%, compared to a rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths appeared to be either cardiovascular (eg, heart failure, sudden death) or infectious (eg, pneumonia) in nature. Observational studies suggest that, similar to atypical antipsychotic drugs, treatment with conventional antipsychotic drugs may increase mortality. The extent to which the findings of increased mortality in observational studies may be attributed to the antipsychotic drug as opposed to some characteristic(s) of the patients is not clear. Clozapine is not approved for the treatment of patients with dementia-related psychosis (Prod Info FAZACLO(R) orally disintegrating tablets, 2008; Prod Info CLOZARIL(R) oral tablets, 2008; Novartis Pharmaceuticals,Corporation, 2008).

3.1 Contraindications

A) agranulocytosis or severe granulocytopenia, clozapine-induced, history; increased risk of subsequent episodes (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

B) concomitant use with other drugs having a known potential to cause agranulocytosis or suppress bone marrow function (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

C) hypersensitivity to clozapine or any other component of this drug (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

D) myeloproliferative disorders, preexisting (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

E) paralytic ileus, preexisting (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

F) severe central nervous system depression or comatose states from any cause; preexisting (Prod Info CLOZARIL (R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

G) uncontrolled epilepsy or other predisposing factors, preexisting; may increase risk of seizure (Prod Info CLOZARIL(R) Tablets, 2005)

3.2 Precautions

A) agranulocytosis may occur; monitoring recommended (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

B) cardiovascular and/or pulmonary disease; possible increased risk for adverse cardiovascular and/or respiratory events (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

C) concurrent use of benzodiazepines or other psychotropic medications (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

D) elderly patients with dementia-related psychosis (unapproved use); increased risk of death; most deaths were attributed to cardiovascular events (eg, heart failure or sudden death) or infections (eg, pneumonia (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

E) myocarditis, including fatalities, has been reported; consider discontinuing therapy; rechallenge not recommended (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

F) orthostatic hypotension, with or without syncope may occur (Prod Info CLOZARIL(R) Tablets, 2005)

G) seizures, history or predisposing factors ; dose-related risk of seizures associated with clozapine therapy (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

H) cardiomyopathy may occur (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

I) concurrent general anesthesia administration (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

J) deep vein thrombosis or respiratory symptomatology may occur; consider presence of pulmonary embolism (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

K) diabetes mellitus or at risk of diabetes mellitus; increased risk for severe hyperglycemia (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

L) eosinophilia has been rarely reported; therapy interruption may be necessary (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

M) fever, possibly benign, may occur; evaluate to rule out sign of infection, sign of agranulocytosis, or neuroleptic malignant syndrome (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

N) glaucoma, narrow angle; condition may be exacerbated due to anticholinergic properties (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

O) hepatic disease; increased risk of hepatitis (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
P) hyperglycemia (some extreme cases associated with ketoacidosis or hyperosmolar coma or death) has been reported (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
Q) increased duration of treatment and/or higher cumulative doses; increased risk of tardive dyskinesia (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
R) intestinal peristalsis impairment, ranging from constipation to intestinal obstruction, fecal impaction and paralytic ileus, including fatal cases, have been reported during postmarketing use (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
S) Jewish background; associated with more cases of agranulocytosis than general US population (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
T) leukopenia, moderate, initial episode; increased risk for subsequent episodes of agranulocytosis (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
U) neuroleptic malignant syndrome, potentially fatal, has been reported in association with antipsychotic therapy; immediately discontinue drug has occurred (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
V) phenylketonurics; Fazaclo(R) 12.5-mg, 25-mg, and 100-mg orally disintegrating tablets contain 0.87 mg, 1.74 mg, and 6.96 mg phenylalanine per tablet, respectively (Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
W) prostatic enlargement; condition may be exacerbated due to anticholinergic properties (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
X) suicide risk (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)
Y) tardive dyskinesia, potentially irreversible, may occur (Prod Info CLOZARIL(R) oral tablets, 2008; Prod Info FAZACLO(R) orally disintegrating tablets, 2008)

3.3 Adverse Reactions

3.3.1 Cardiovascular Effects

Abnormal ECG

Cardiac complication

Cardiac dysrhythmia

Cardiomyopathy

Edema

Hypertension

Hypotension

Orthostatic hypotension

Phlebitis

Sudden cardiac death

Tachyarrhythmia

3.3.1.A Abnormal ECG

1) Premature ventricular contractions are temporally associated with clozapine and occur with patients at a frequency less than 1%. A minority of patients experience ECG repolarization changes including ST segment depression and flattening of T-waves or inversion of T-waves; clinical significance is unclear. All of these effects normalize after clozapine is discontinued (Prod Info Clozaril(R), 2002).

3.3.1.B Cardiac complication

1) In clinical trials, several patient cases have experienced ischemic changes, myocardial infarction, and sudden death with clozapine therapy. Additionally, postmarketing evaluation revealed cases of myocarditis, pericarditis and/or pericardial effusions; causality was complicated because of serious preexisting cardiac disease (Prod Info Clozaril(R), 2002).

2) Pancreatitis followed by pericardial effusion occurred in a 17-year-old, male, patient who was receiving clozapine for the treatment of paranoid schizophrenia. Following 23 days of treatment during which time the clozapine dose was titrated from 25 mg/day to 175 mg/day, the patient experienced mild epigastric pain and had elevated levels of pancreas amylase and lipase. A diagnosis of pancreatitis was made and the clozapine was discontinued. One day later, the clozapine was resumed at 100 mg/day and the epigastric pain disappeared within 3 days. Amylase and lipase levels returned to normal after 19 days. Four days after decreasing the dose, the patient experienced inspiratory chest pain, increasing pain in both shoulders, and had a heart rate of 120 beats/min. A CT scan of the chest revealed a pericardial effusion. The clozapine was again discontinued and the patient recovered following cardiocentesis that removed 250 mL of slightly hemorrhagic fluid (Wehmeier et al, 2003).

3.3.1.C Cardiac dysrhythmia

1) Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include bradycardia. Other effects reported from postmarketing experience and a case report include atrial fibrillation and ventricular fibrillation; a causal relationship with clozapine could not be determined (Prod Info Clozaril (R), 2002; Low et al, 1998).

2) A 69-year-old male with chronic paranoid schizophrenia developed atrial fibrillation and possible congestive heart failure after having his clozapine titrated to 325 mg/day over 3 weeks. This was confirmed upon rechallenge (Low et al, 1998).

3.3.1.D Cardiomyopathy

1) In the US, the reported rate of cardiomyopathy in clozapine-treated patients is 8.9 per 100,000 person-years compared to a rate of 9.7 per 100,000 person-years in the general US population (1999 National Hospital Discharge Survey data). Eighty percent of the patients with cardiomyopathy treated with clozapine were less than 50 years of age. The duration of clozapine treatment prior to the diagnosis of cardiomyopathy was greater than 6 months in 65% of the patients. Dilated cardiomyopathy was the most frequently reported type. Signs and symptoms suggestive of cardiomyopathy include: exertional dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea and peripheral edema. If cardiomyopathy is confirmed, clozapine should be discontinued unless the benefit to the patient clearly outweighs the risk (Prod Info Clozaril(R), 2002).

2) A total of 82 reports of myocarditis associated with clozapine use have been received from the USA, Canada, UK, and Australia. The incidence of myocarditis was 5, 16.3, 43.2, and 96.6 cases per 100,000

patient years, respectively. This is 17 to 322 times higher than the rate of myocarditis in the general population. In 51 (62%) of these cases, myocarditis occurred during the first month of treatment. There were 31 (38%) fatalities in this group with 25 of the 31 patients showing evidence of myocarditis at autopsy (Prod Info Clozaril(R), 2002).
3) Twenty-eight cases of myocarditis, including 18 deaths, and 41 cases of cardiomyopathy, including 10 deaths, were reported to the Food and Drug Administration in clozapine recipients over a 10-year period (La Grenade et al, 2001). Additionally, postmarketing evaluation revealed cases of congestive heart failure; causality was complicated because of serious preexisting cardiac disease (Prod Info Clozaril(R), 2002).
4) Plasma and red-cell selenium concentrations were significantly (p less than 0.01) lower in schizophrenic patients treated with clozapine (n=54) compared to patients with mood disorders (n=36), schizophrenic patients not treated with clozapine (n=41) and a healthy control group (n=56). The plasma and red-cell selenium concentrations (micromoles/L) were 1.28 +/- 0.33, 1.47 +/- 0.57; 1.39 +/- 0.29, 1.70 +/- 0.4; 1.47 +/- 0.41, 1.7 +/- 0.48; and 1.49 +/- 0.3, 1.8 +/- 0.58 for the four groups, respectively. Selenium deficiency has been associated with cardiomyopathy and with myocarditis and these same adverse effects are also known to occur with clozapine treatment. Although it could not be determined by this study whether clozapine causes selenium deficiency or if treatment-resistant schizophrenic patients (who are often treated with clozapine) are selenium deficient prior to treatment, the authors suggested that it may prove beneficial to provide selenium supplementation to schizophrenic patients receiving clozapine (Vaddadi et al, 2003).
5) Based on reports to the Food and Drug Administration, those who developed myocarditis and survived were generally treated for a shorter time (median 2 weeks vs 4 weeks) and took a lower daily dose (median 225 mg vs 450 mg) than those who died. However in patients with cardiomyopathy, the median dose (450 mg vs 500 mg) and the duration of therapy (8 months vs 10 months) were similar in those who survived and those who died (La Grenade et al, 2001).
6) Voluntary postmarketing reports to the Adverse Drug Reactions Advisory Committee of Australia over 6 years included 15 cases of myocarditis and 8 cases of cardiomyopathy among 8000 registered clozapine recipients (0.29%). Objective evidence confirmed the diagnosis in all 23 cases (87% male, mean age 36 years, clozapine dose range 100 to 725 mg/day). The median onset of myocarditis was 15 days, with subsequent early death in 5 cases in which autopsy revealed florid myocardial inflammatory infiltrates (eosinophilic in 3, lymphocytic in 1, mixed in 1). Recovery was documented in 5 patients, while the outcome of the remaining 5 was unknown. Five of 8 cardiomyopathy cases manifested during months 2 to 6 of therapy, while the remaining 3 cases occurred much later (30 to 36 months after initiation). One case was fatal after 2 years; 2 patients were stable to improved; the final outcome was unknown in 5 cases. The investigators discovered no confounding factors to account for these cardiac complications (Kilian et al, 1999).
7) A case of cardiomyopathy, possibly related to clozapine, occurred in a 26-year-old woman with no prior cardiac history. Following a total of 5 months of therapy with clozapine 700 mg/day, the patient developed malaise, dyspnea, and edema. Echocardiography demonstrated cardiomyopathy with a low ventricular ejection fraction. The patient improved following discontinuation of clozapine and institution of digoxin therapy. Because baseline echocardiography studies were not performed, it is difficult to determine a causal relationship, or if therapy with clozapine aggravated a previously undiagnosed cardiac problem (Leo et al, 1996).

3.3.1.E Edema

1) Edema and periorbital edema temporally associated with clozapine has been reported and occurs at a frequency 1% or less (Prod Info Clozaril(R), 2002). In a case report, a 24-year-old woman treated with clozapine 400 mg daily for 6 weeks, developed pedal edema and peri-orbital puffiness. After the dosage was reduced to 200 mg over 10 days the edema gradually disappeared (Durst et al, 2000).

3.3.1.F Hypertension

1) Hypertension and chest pain/angina have been reported in 1% to 4% of patients(Prod Info Clozaril(R), 2002).
2) Four obese patients developed a pseudopheochromocytoma syndrome while being treated with clozapine for serious refractory psychiatric disturbances. All patients manifested hypertension and profuse sweating. Urinary catecholamine concentrations were elevated in all 4 patients. Pheochromocytoma was excluded. In 2 cases, catecholamine concentrations normalized and clinical features improved or resolved with withdrawal of the drug. Clozapine dose was reduced in one patient, and treatment was continued unchanged in one patient because of spontaneous lowering of his blood pressure. The author suggested that concurrent sulpiride may have contributed to clinical symptoms in 2 patients (Krentz, 2001).
3) A 34-year-old male with paranoid schizophrenia developed moderate hypertension, tachycardia, pallor, and irritability after the initiation of clozapine (confirmed upon re-challenge). Propranolol 180 mg/day in divided doses was used successfully to control his blood pressure while clozapine was increased to 350 mg/day (George & Winther, 1996). In a similar case, a 19-year-old man developed tachycardia and hypertension and was successfully treated with atenolol (Ennis & Parker, 1997).
4) A 27-year-old man with catatonic schizophrenia treated with clozapine 300 mg developed hypertension. Blood pressure increased to 146/106 (previously 110/70 to 120/80). Amlodipine 5 mg daily controlled the high blood pressure. Upon further testing, it was noted that urinary adrenaline and noradrenaline were also elevated mimicking a pheochromocytoma-type reaction. Clozapine was eventually withdrawn over 10 weeks (Li et al, 1997).

3.3.1.G Hypotension

1) Hypotension and syncope were reported with an incidence greater than 5% of patients, usually after the first dose or during dosage escalation. Rarely, the collapse can be profound and may be accompanied by respiratory arrest and/or cardiac arrest (Prod Info Clozaril(R), 2002).

2) A 51-year-old male maintained on clozapine 600 mg/day suffered from refractory hypotension following coronary artery bypass graft surgery. The initial postoperative systolic blood pressure reading was 50 mL of mercury (mmHg), necessitating vasoconstrictor (methoxamine and metaraminol) and inotropic (dopamine) support. Even with the addition of epinephrine, systolic pressure was only 60 mmHg. A 3-day norepinephrine infusion was required to maintain blood pressure. The alpha-1 blockade and resultant vasodilatation induced by clozapine was the likely etiology (Donnelly & MacLeod, 1999).

3.3.1.H Orthostatic hypotension

1) Orthostatic hypotension with or without syncope can occur during clozapine therapy; usually occurring during initial titration in association with rapid dose escalation. In rare cases (approximately 1 case per 3000 patients), collapse can be profound and may be seen with respiratory arrest and/or cardiac arrest. Collapse and respiratory arrest have occurred with initial doses as low as 12.5 mg. If patients have been off clozapine therapy for 2 days or more, reinitiate with 12.5 mg once or twice daily. Some patients experiencing collapse, respiratory arrest, or cardiac arrest also received benzodiazepines or other psychotropic drugs. Elderly patients, particularly those with compromised cardiac functioning, may be more susceptible to these effects (Prod Info Clozaril(R), 2002; Kane, 1996a).

2) In clinical trials (n=842), greater than 5% of patients experienced syncope (Prod Info Clozaril(R), 2002).

3.3.1.I Phlebitis

1) Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include phlebitis, thrombophlebitis, cyanosis, and epistaxis (Prod Info Clozaril(R), 2002).

3.3.1.J Sudden cardiac death

1) In a large, retrospective, cohort study that included a primary cohort of 93,300 users of antipsychotic drugs and 186,600 non-users of antipsychotic drugs, there was an increased risk of sudden cardiac death in adult participants 30 to 74 years of age (mean age of 45.7 years) who were using clozapine compared to those who were not using antipsychotic drugs (incidence-rate ratio, 3.67; 95% confidence interval (CI), 1.94 to 6.94; p less than 0.001). In participants being treated with atypical antidepressants (clozapine, olanzapine, quetiapine, risperidone), the incidence-rate ratio for sudden cardiac death increased from 1.59 (95% CI, 1.03 to 2.46) for those using low doses to 2.86 (95% CI, 2.25 to 3.65) for those using high doses (p=0.01) (Ray et al, 2009).

3.3.1.K Tachyarrhythmia

1) Incidence: 25%

2) Tachycardia has been observed in approximately 25% of patients receiving clozapine and may be sustained. The sustained tachycardia is present in all positions monitored; the average increase in pulse is 10 to 15 beats per minute. Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include palpitations (Prod Info Clozaril(R), 2002; Wolf & Otten, 1991).

3) A 44-year-old man with chronic schizophrenia developed ventricular tachycardia after 2 weeks of clozapine therapy. He presented with a fever (38.5 degrees Celsius), pallor, and lethargy. Macular rashes appeared on his forearms and feet. Electrocardiogram showed ST elevation in leads V2 and V3. He was treated with lidocaine and amiodarone via a central line. Atrial fibrillation also developed lasting for 24 hours (Varma & Achan, 1999).

3.3.2 Dermatologic Effects

Cellulitis

Dermatological finding

Rash

Sweating symptom

3.3.2.A Cellulitis

1) Summary

a) A 37-year-old male developed right arm cellulitis and progressively increasing eosinophil count after 5 days of clozapine therapy and a left-sided pleural effusion after 12 days. Clozapine was discontinued and he improved with antibiotics. A later trial of clozapine 25 milligrams daily resulted in recurrence of

symptoms (Chatterjee & Safferman, 1997).

3.3.2.B Dermatological finding

1) Summary

a) Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include PRURITUS, PALLOR, ECZEMA, ERYTHEMA, BRUISE, DERMATITIS, PETECHIAE, and URTICARIA. Voluntary postmarketing reports included STEVENS-JOHNSON SYNDROME, ERYTHEMA MULTIFORME, PHOTOSENSITIVITY, and VASCULITIS. However, a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

2) Rash has occurred with some frequency in patients during clozapine therapy. Adverse effects temporally associated with clozapine and occurring at a lower frequency include pruritus, pallor, eczema, erythema, sweating, bruising, dermatitis, petechiae, and urticaria. Reports of other rare adverse effects include Stevens-Johnson syndrome, erythema multiforme, photosensitivity, and vasculitis.

3.3.2.C Rash

1) Summary

a) In clinical trials, rash occurred in 2% of patients (n=842) during clozapine therapy (Prod Info Clozaril (R), 2002).

2) Incidence: 2%

3) LITERATURE REPORTS

a) A well-circumscribed, erythematous, papular pruritic rash spread over the torso and extremities of a 37-year-old female approximately 9 days after clozapine initiation and titration to 150 milligrams/day. An initial skin biopsy revealed possible furunculosis, but a later biopsy was consistent with a drug hypersensitivity reaction. The rash was preceded by fever to 39.9 degrees Celsius, headache, neck stiffness and chest pain, evolving into bilateral pleural effusions. All signs and symptoms began to subside shortly after clozapine's discontinuation (Stanislav & Gonzalez-Blanco, 1999).

3.3.2.D Sweating symptom

1) Summary

a) A 31-year-old male developed increased sweating with clozapine therapy. Biperiden, titrated to 6 milligrams per day, resulted in prompt cessation of generalized sweating (Richardson et al, 2001).

2) Incidence: 6%

3.3.3 Endocrine/Metabolic Effects

Acid-base balance - finding

Body temperature finding

Diabetes mellitus

Diabetic ketoacidosis

Disorder of fluid AND/OR electrolyte

Excessive salivation

Hyperlipidemia

Hyperprolactinemia

Lactic acidosis

Metabolic syndrome

Selenium deficiency

Sweating

Weight gain

3.3.3.A Acid-base balance - finding

1) Refractory lactic acidosis and diabetic ketoacidosis have been reported with clozapine use.

3.3.3.B Body temperature finding

1) Adverse effects temporally associated with clozapine and occurring at a frequency of less than 1% include chills, hot flashes, and hypothermia (Prod Info Clozaril(R), 2002).

3.3.3.C Diabetes mellitus

1) Summary

a) Hyperglycemia, glucose intolerance, and new-onset diabetes have been reported with clozapine therapy. Clozapine therapy may modify glucose-insulin homeostasis by increasing insulin secretion, either by a direct effect on the pancreatic beta cells or via induction of peripheral insulin resistance, and impairing growth hormone secretion (Rigalleau et al, 2000; Melkersson et al, 1999; Popli et al (1997). One study found patients receiving clozapine tended to have diabetes type 2 or impaired glucose tolerance more often than a control group of patients receiving depot neuroleptics (Hagg et al, 1998). The manufacturer reports that severe hyperglycemia, sometimes leading to ketoacidosis, hyperosmolar coma, or death, has been reported in patients with no prior history of hyperglycemia, but that a causal relationship could not be definitively established (Prod Info Clozaril(R), 2004). A case-control study investigated the possible association between clozapine use and development of diabetes mellitus; it found no significant relationship (Wang et al, 2002).

2) Literature Reports

a) A case-control study found no significant association between clozapine use and development of diabetes mellitus. Using data from the New Jersey (NJ) Medicaid program (covering the period January 1, 1990 to June 30, 1995), NJ Medicare, and NJ Pharmaceutical Assistance to the Aged and Disabled program, 7227 cases of newly treated diabetes were compared to 6780 controls. Both groups represented patients having psychiatric diagnoses recorded in the previous 6 months. In the group with newly diagnosed diabetes, 1.3% were using clozapine. In the control group (ie, patients with psychiatric diagnoses but not newly diagnosed with diabetes), 1.7% were using clozapine (p=0.073). The adjusted odds ratio (OR) of developing diabetes with clozapine use was 0.98. There was no increased risk associated with higher clozapine doses or longer duration of clozapine therapy. By comparison, persons in the control group using non-clozapine antipsychotic medication had a modest but significantly increased risk of developing diabetes (OR 1.13). The antipsychotic agents particularly associated with an increased risk for diabetes were chlorpromazine (adjusted OR 1.31) and perphenazine (adjusted OR 1.34). The data also showed that there was an increased risk of developing diabetes among those using prochlorperazine (adjusted OR 1.21) and an oral corticosteroid (Wang et al, 2002).

b) A Chinese male schizophrenia patient developed hyperglycemia, hyperlipemia, and periodic paralysis while taking clozapine. Symptoms resolved when clozapine was withdrawn and recurred when clozapine treatment was reestablished. Symptoms appeared at clozapine doses as low as 37.5 milligrams (mg) per day. Other drugs were not as effective as clozapine for treating his mental state. His mental state was finally stabilized with a combination of clozapine 25 mg/day and haldol 20 mg/day, without elevations of blood glucose or lipids (Wu et al, 2000).

c) Three cases of new-onset diabetes were reported in Caucasian men who were on clozapine for 3 to 6 months. They had a distinct presentation including weight loss, ketosis (one ketoacidosis), severe hyperglycemia requiring insulin therapy, and relative insulin deficiency. In all cases, insulin was discontinued one month after the clozapine was stopped (Rigalleau et al, 2000).

d) Clozapine therapy may modify glucose-insulin homeostasis by increasing insulin secretion, either by a direct effect on the pancreatic beta cells or via induction of peripheral insulin resistance, and impairing growth hormone secretion. In a study of 28 patients (median age: 42) on classical antipsychotics and 13 patients (median age: 35) on clozapine for schizophrenia and related psychotic disorders, body mass index (BMI), fasting serum glucose, fasting serum insulin, and insulin-like growth factor binding protein-1 (IGFBP-1) did not differ statistically between groups. Age-correlated insulin-like growth factor-1 (IGF-1) was significantly lower in clozapine recipients, which investigators speculated may be due to decreased growth hormone secretion. A higher percentage of clozapine users (46% versus 21%, p=NS) had above normal insulin levels, but only one subject had abnormal glucose levels. BMI was elevated in 54% and 46% of the classical and clozapine groups, respectively. Findings unique to clozapine users were lack of correlations between IGFBP-1 and insulin and between IGFBP-1 and BMI; a negative correlation between IGF-1 and IGFBP-1; and a positive correlation between serum drug concentration and insulin. These data, and their relationship to the risk of developing or exacerbating diabetes mellitus, require further confirmation (Melkersson et al, 1999).

e) Patients receiving clozapine tended to have diabetes type 2 or impaired glucose tolerance more often than a control group of patients receiving depot neuroleptics (Hagg et al, 1998). Patients at a psychiatric clinic receiving either clozapine or depot neuroleptics were recruited for a diabetes screening. None of the patients had a previous diagnosis or evidence of diabetes mellitus. After screening, 13 out of 60 patients (22%) treated with clozapine were diagnosed with type 2 diabetes or impaired glucose tolerance while only 6 out of 63 (10%) in the depot neuroleptic group received these diagnoses. The difference did not reach statistical significance (p=0.06).

f) Severe hyperglycemia (blood glucose 585 milligrams/deciliter) was reported in a 37-year-old Jewish male after 11 weeks of clozapine therapy. This was accompanied with refractory lactic acidosis,

agranulocytosis, fever, candidiasis and fatal myocardial failure (Koren et al, 1997).

g) Four adults developed increasing glucose intolerance following the initiation of clozapine therapy (Popli et al, 1997). Two of the patients developed severe diabetic ketoacidosis. The other 2 patients developed an exacerbation of their preexisting, well-controlled, diabetes mellitus within 2 weeks of initiation of clozapine therapy. The authors, in their limited experience (treated 147 patients over 10 years), noted a 2.7% incidence of clinically significant changes in glucose tolerance during clozapine therapy.

h) Two cases of patients developing diabetes mellitus and 2 cases of exacerbation of preexisting, but well controlled diabetes mellitus, in patients starting clozapine therapy were reported (Popli et al, 1997).

See Drug Consult reference: ATYPICAL ANTIPSYCHOTIC AGENTS - EFFECT ON GLUCOSE AND RISK OF DIABETES

3.3.3.D Diabetic ketoacidosis

1) Summary

a) Four case reports have noted the development of ketoacidosis with therapeutic use of clozapine therapy (Avram et al, 2001; Colli et al, 1999; Ai et al, 1998; Pierides, 1997).

2) Literature Reports

a) A 33-year-old male, without past or family history of diabetes mellitus, developed diabetic ketoacidosis after taking clozapine 50 milligrams twice a day for 8 months (Avram et al, 2001).

b) A 31-year-old Caucasian man developed ketoacidosis 3 months after beginning clozapine 200 milligrams daily (Colli et al, 1999). His blood sugars rapidly normalized after the discontinuation of clozapine. A repeat trial of clozapine resulted in increased blood sugars within 72 hours.

c) A 30-year-old Afro-Caribbean man treated with clozapine 150 milligrams twice daily for 5 months developed ketoacidosis (Ai et al, 1998). Initially he was treated with insulin until clozapine was discontinued. He was then switched to an oral hypoglycemic agent. Eight months after discontinuing the clozapine, the patient still required an oral agent.

d) Hyperglycemia, hyperkalemia and ketoacidosis (pH 7.09) developed after 1 week of initiating and titrating clozapine from 25 milligrams/day (mg/day) to 300 mg/day in a 50-year-old male with chronic refractory schizophrenia. Presenting symptoms included lethargy, thirst, chest pain, and dyspnea. The patient improved with clozapine withdrawal and insulin therapy (Pierides, 1997).

3.3.3.E Disorder of fluid AND/OR electrolyte

1) In voluntary postmarketing reports adverse effects of hyperuricemia and hyponatremia occurred during clozapine therapy. A causal relationship could not be determined (Prod Info Clozaril(R), 2002).

3.3.3.F Excessive salivation

1) Incidence: 31% (Prod Info Clozaril(R), 2002)

2) In clinical trials, increased salivation was reported in 31% of patients (n=842). Salivation may be profuse particularly during sleep but may be diminished with a dosage reduction (Prod Info Clozaril(R), 2002). .

3.3.3.G Hyperlipidemia

1) Summary

a) There have been case reports of significant hyperlipidemia associated with clozapine use (Ball et al, 2005; Wu et al, 2000), in one case precipitating acute pancreatitis (Ahmed et al, 2009).

2) Literature Reports

a) In a case report, a 47 year old male treated for 2 years with clozapine for treatment-resistant schizophrenia developed xanthomas associated with significant dyslipidemia which developed into acute pancreatitis. Following discontinuation of clozapine therapy, his metabolic parameters normalized. When rechallenged with clozapine, significant dyslipidemia reoccurred within 10 weeks. The patient had no personal or family history of abnormal lipids or elevated blood glucose prior to clozapine initiation. He was maintained on clozapine 450 mg daily with an average plasma level of 490 ng/mL and presented with xanthomas, fasting cholesterol 772.2 mg/dL, fasting triglyceride 4886.1 mg/dL, and a normal fasting glucose. Clozapine therapy was continued with the addition of statin therapy for the next 11 years. The patient was admitted with acute pancreatitis, cholesterol 1404 mg/dL, triglyceride 14,418 mg/dL, and fasting glucose of 147.6 mg/dL. Discontinuation of clozapine resulted in normalization of metabolic parameters within 3 weeks. When psychotic symptoms deteriorated, clozapine was reintroduced and titrated up to 400 mg daily. Within 10 weeks, the cholesterol level increased to 417.3 mg/dL, triglyceride 3008.2 mg/dL, and fasting glucose 167.4 mg/dL. Clozapine discontinuation normalized levels within 10 days (Ahmed et al, 2009).

b) New-onset hyperlipidemia was reported in the case of a 42-year-old schizophrenic patient treated with clozapine. At a dose of 300 mg/day, corresponding total cholesterol (TC) was increased at 256 mg/dL and triglycerides (TG) at 285 mg/dL. At clozapine doses of 500 mg/day, TG increased to greater than 400 mg/day. Lipid-lowering drug therapy did not adequately improve the lipid profile. The highest levels measured were TC 477 mg/dL and TG 4758 mg/dL. With sporadic clozapine compliance, TC measured 213 mg/dL, TG 298 mg/dL and low density lipoprotein cholesterol (LDL-C) 146 mg/dL. Clozapine was discontinued, and aripiprazole initiated and titrated to 45 mg/day. After 3 weeks, TC measured 107 mg/dL, TG 49 mg/dL and LDL-C 47 mg/dL (Ball et al, 2005).

c) A Chinese male schizophrenia patient developed hyperglycemia, hyperlipidemia, and periodic

paralysis while taking clozapine. Symptoms resolved when clozapine was withdrawn and recurred when clozapine treatment was reestablished. Symptoms appeared at clozapine doses as low as 37.5 milligrams (mg) per day. Other drugs were not as effective as clozapine for treating his mental state. His mental state was finally stabilized with a combination of clozapine 25 mg/day and haloperidol 20 mg/day, without elevations of blood glucose or lipids (Wu et al, 2000).

3.3.3.H Hyperprolactinemia

1) Summary

a) With clozapine therapy, resolution of chronic hyperprolactinemia was observed in 2 female patients (Dickson et al, 2000). Clozapine does not cause sustained increases in serum prolactin levels as the traditional neuroleptics do. One author theorized that due to both the resolution of impaired sexual functioning secondary to hyperprolactinemia and improved social interactions secondary to clozapine treatment, higher birth rates may occur with clozapine therapy(Dickson & Edwards, 1997).

2) Literature Reports

a) Clozapine does not cause sustained increases in serum prolactin levels as the traditional neuroleptics do. One author theorized that due to both the resolution of impaired sexual functioning secondary to hyperprolactinemia and improved social interactions secondary to clozapine treatment, higher birth rates may occur with clozapine therapy. At the Calgary General Day Hospital clinic, 235 patients were treated primarily for schizophrenia with 12% taking clozapine. In this small group taking clozapine, 4 babies were born (to 3 patients), while the other 88% of the patients not taking clozapine produced only 5 children (to 4 patients). Further studies are needed to elicit the effects of clozapine on fertility (Dickson & Edwards, 1997).

3.3.3.I Lactic acidosis

1) Refractory lactic acidosis (blood pH 6.97, bicarbonate 8 mEq/liter, and lactate 92.3 milligrams/deciliter), with hyperglycemia and heart failure, agranulocytosis and candidiasis, has been reported following several weeks of clozapine therapy (Koren et al, 1997).

3.3.3.J Metabolic syndrome

See Drug Consult reference: ANTIPSYCHOTIC AGENTS - METABOLIC SYNDROME

3.3.3.K Selenium deficiency

1) Summary

a) Clozapine was associated with decreased plasma and red-cell selenium concentrations in one study. Selenium deficiency has been associated with cardiomyopathy and with myocarditis and these same adverse effects are also known to occur with clozapine treatment (Vaddadi et al, 2003).

2) Literature Reports

a) Plasma and red-cell selenium concentrations were significantly (p less than 0.01) lower in schizophrenic patients treated with clozapine (n=54) compared to patients with mood disorders (n=36), schizophrenic patients not treated with clozapine (n=41) and a healthy control group (n=56). The plasma and red-cell selenium concentrations (micromoles/liter) were 1.28 +/- 0.33, 1.47 +/- 0.57; 1.39 +/- 0.29, 1.70 +/- 0.40; 1.47 +/- 0.41, 1.70 +/- 0.48; and 1.49 +/- 0.30, 1.80 +/- 0.58 for the four groups respectively. Selenium deficiency has been associated with cardiomyopathy and with myocarditis and these same adverse effects are also known to occur with clozapine treatment. Although it could not be determined by this study whether clozapine causes selenium deficiency or if treatment-resistant schizophrenic patients (who are often treated with clozapine) are selenium deficient prior to treatment, the authors suggested that it may prove beneficial to provide selenium supplementation to schizophrenic patients receiving clozapine (Vaddadi et al, 2003).

3.3.3.L Sweating

1) Incidence: 4% to 6% (Prod Info Clozaril(R), 2002)

2) In clinical trials (n=842) with therapeutic use of clozapine increased sweating was reported in 4% to 6% of patients (Prod Info Clozaril(R), 2002).

3.3.3.M Weight gain

1) Summary

a) In clinical trials (n=842) weight gain was reported in 4% to 6% of patients with therapeutic use of clozapine. One percent of patients experienced an appetite increase (Prod Info Clozaril(R), 2000). In other studies the report of weight gain and increased appetite was as high as 50% to 75%(Briffa & Meehan, 1998; Cohen et al, 1990; Norris & Israelstam, 1975). Two proposed mechanisms of clozapine-induced weight gain include increased insulin secretion, either by a direct effect on the pancreatic beta cells or via induction of peripheral insulin resistance, and impaired growth hormone secretion (Melkersson et al, 1999).

2) Incidence: 4%

3) Literature Reports

a) The weight plateau achieved with clozapine apparently depends on genotype. Male monozygotic twins developed paranoid type schizophrenia at ages 17.4 years and 17.6 years. The first one was treated with risperidone and gained 17 kilograms (kg) over 11 months. The other was treated with

classic antipsychotics for 2 months and gained 2 kg. Because of insufficient clinical response, both were switched to clozapine (500 mg/day and 450 mg/day). Both gained weight. Both twins developed binge eating episodes (2 to 3 per week) after starting clozapine. At the time of this report, weight gains since the initiation of antipsychotic treatment had totaled 38 and 40 kg (Theisen et al, 2001).
b) Two proposed mechanisms of clozapine-induced weight gain include increased insulin secretion, either by a direct effect on the pancreatic beta cells or via induction of peripheral insulin resistance, and impaired growth hormone secretion. In a study of 28 patients (median age: 42) on classical antipsychotics and 13 patients (median age: 35) on clozapine for schizophrenia and related psychotic disorders, body mass index (BMI), fasting serum glucose, fasting serum insulin, and insulin-like growth factor binding protein-1 (IGFBP-1) did not differ statistically between groups. Age-correlated insulin-like growth factor-1 (IGF-1) was significantly lower in clozapine recipients, which investigators speculated may be due to decreased growth hormone secretion. A higher percentage of clozapine users (46% versus 21%, p=NS) had above-normal insulin levels, but only one subject had abnormal glucose levels. BMI was elevated in 54% and 46% of the classical and clozapine groups, respectively. Findings unique to clozapine users were lack of correlations between IGFBP-1 and insulin and between IGFBP-1 and BMI; a negative correlation between IGF-1 and IGFBP-1; and a positive correlation between serum drug concentration and insulin. These data require further confirmation (Melkersson et al, 1999).
c) In four case reports (males with schizophrenia or other psychotic disorders, aged 32 to 42), clozapine therapy (500 to 900 milligrams (mg)/day) was associated with increased serum triglyceride levels, which declined after clozapine discontinuation. Individual changes in triglyceride levels after substitution of risperidone for clozapine included: 229 to 104 mg/deciliter (dL); 140 to 60 mg/dL; 309 to 164 mg/dL; and 194 to 150 mg/dL. Total cholesterol levels showed similar reductions in two cases, but remained stable in two cases; all values were below 200 mg/dL. Two individuals stopped risperidone and restarted clozapine, with accompanying increases in triglyceride levels of 164 to 270 mg/dL and 150 to 262 mg/dL, respectively (Ghaeli & Dufresne, 1999).
d) Significant weight gain occurred in patients prescribed clozapine (Briffa & Meehan, 1998). In a group of 48 patients, a mean absolute weight gain of 3.6 kilograms (kg) occurred over the first 3 months of therapy. An average of 4.95 kg was gained by 36 patients while 12 patients lost an average of 0.4 kg. Weight increase was most notable in men. After 1 year, 36 patients were available for follow-up and they gained an average of 3.35 kg. An average of 7.48 kg was gained by 25 patients while 11 patients lost an average of 4.7 kg.
e) Nine of 13 patients receiving clozapine (10 for the treatment of behavior disorder and 3 for schizophrenia) had an enormous and persistent increase in appetite resulting in day-long compulsive eating. Four patients gained between 10 and 20 kg within a 2-month period. After discontinuation of clozapine in 2 patients, their weight gain was rapidly lost (Norris & Israelstam, 1975).
f) Significant weight gain occurs during both short- and long-term treatment with clozapine. A group of 82 patients were studied for a period of 90 months; the cumulative incidence of patients becoming 20% or more overweight was 54%. Monitoring and dietary counseling are necessary to minimize this long-term health risk (Umbricht et al, 1994). Six of 7 patients gained between 6 and 69 pounds with clozapine therapy (Cohen et al, 1990).

3.3.4 Gastrointestinal Effects

Abdominal discomfort

Bowel obstruction

Colitis, Necrotizing

Constipation

Diarrhea

Excessive salivation

Fecal impaction

Gastrointestinal hypomotility

Heartburn

Ischemic bowel disease

Nausea

Nausea and vomiting

Pancreatitis

Paralytic ileus

Parotitis

Perforation of intestine

Summary

Swelling of salivary gland

Vomiting

Xerostomia

3.3.4.A Abdominal discomfort

1) Incidence: 4% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Abdominal discomfort/heartburn occurred in 4% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

3.3.4.B Bowel obstruction

1) In postmarketing reports, intestinal obstruction/paralytic ileus has occurred in patients receiving clozapine with some cases resulting in death. Treat constipation with adequate hydration and ancillary medications (eg, bulk laxatives) and consider consulting with a gastroenterologist for serious cases (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

2) Intestinal obstruction necessitating hospitalization occurred in a 51-year-old male and a 35-year-old female with resistant schizophrenia receiving clozapine 275 milligrams (mg)/day for 2 months and 500 mg/day for 4 months, respectively. No other predisposing factors were identified. The patients recovered with conservative management and continued on clozapine therapy with adjunctive dietary measures and stool softeners (Tang & Ungvari, 1999).

3.3.4.C Colitis, Necrotizing

1) A 36-year-old male developed fatal necrotizing colitis 4 months after beginning clozapine (Shammi & Remington, 1997).

3.3.4.D Constipation

1) Incidence: 14% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Constipation occurred in 14% of patients treated with clozapine in clinical trials (n=842). Elderly patients may be particularly susceptible to the anticholinergic effects of clozapine, such as constipation. Intestinal peristalsis leading to fecal impaction, paralytic ileus, and intestinal obstruction has also been reported with some cases resulting in death. Treat constipation with adequate hydration and ancillary medications (eg, bulk laxatives) and consider consulting with a gastroenterologist for serious cases (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

3) Constipation occurs when the daily dose exceeds 150 milligrams. These adverse effects may disappear with continued administration of the same dose. However, if not, they are managed easily by dose reduction or temporary discontinuation of clozapine (Ayd, 1974a).

3.3.4.E Diarrhea

1) Incidence: 2% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Diarrhea occurred in 2% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

3) Diarrhea, associated with decreasing lymphocyte counts, was reported in 3 patients between 13 days and 9 months following initiation of clozapine therapy. Re-challenge in 2 cases did not cause further diarrhea. The mechanism for this is unclear (Harvey et al, 1992).

3.3.4.F Excessive salivation

1) Incidence: 31% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Salivation occurred in 31% of patients treated with clozapine in clinical trials (n=842). Salivation may be profuse, particularly during sleep, but may be diminished with a dosage reduction (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).
3) Ipratropium nasal spray given sublingually provided relief of sialorrhea in 8 patients receiving daily clozapine. A retrospective analysis of patients receiving daily clozapine (150 to 600 milligrams (mg)) for schizophrenia or bipolar disorder who complained about excessive drooling was conducted. Nine patients received an intranasal formulation of ipratropium (0.03% or 0.06%) to be used sublingually (2 sprays) up to 3 times daily, if needed, for excessive drooling. After several weeks of use, full response was reported by 2 patients, partial response (symptoms controlled for 2 to 8 hours) by 5 patients, and no response by 1 patient. One patient rated the spray not effective and discontinued drug after a few days. Sublingual ipratropium nasal spray may be useful for situations in which drooling would be socially undesirable (Freudenreich et al, 2004).
4) An overview of clozapine-induced hypersalivation explores possible mechanisms involved as well as management options. Potential contributing factors are clozapine's muscarinic M4 receptor stimulation, alpha-2 antagonism and/or interference with the normal swallowing reflex. Published data have not documented any increase in daytime salivary flow rate with clozapine; however, nighttime flow rates have not been studied. Management strategies include clozapine dosage reduction if clinically feasible, sleeping with a towel over the pillow to absorb excess saliva, chewing gum to stimulate swallowing, and as a last resort, an anticholinergic agent or alpha-2 agonist. Because supportive studies are lacking, treatment decisions must be individualized (Davydov & Botts, 2000).
5) In a 50-year-old schizophrenic woman, hypersalivation and sedation developed after several days on clozapine. By day 10, she developed aspiration pneumonia. This prompted the authors to warn that aspiration precautions may be necessary with hypersalivation due to clozapine (Hinkes et al, 1996).
6) Hypersalivation was reported in 16 of 19 patients receiving clozapine therapy. Doses ranged from 75 to 800 milligrams (mg)/day (Lapierre et al, 1980). Nocturnal hypersalivation occurred at a dosage range of 225 to 800 mg/day (Kirkegaard et al, 1982).

3.3.4.G Fecal impaction

1) In postmarketing reports, fecal impaction has occurred in patients receiving clozapine with some cases resulting in death. Treat constipation with adequate hydration and ancillary medications (eg, bulk laxatives) and consider consulting with a gastroenterologist for serious cases (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).
2) A 20-year-old otherwise healthy male receiving clozapine for schizophrenia had fecal impaction and experienced fatal bowel ischemia and infarction following complaints of constipation. During a 1-year period, the patient was titrated up to a clozapine dose of 900 milligrams (mg)/day; additionally, amisulpiride 400 mg twice daily had been added for persistent negative symptoms with good results after one month. He presented to his physician with severe abdominal pain following a 2-day history of constipation and was prescribed medication and returned home. The patient collapsed and died a few hours later before reaching a hospital; subsequently, a postmortem examination discovered the patient had impacted feces leading to bowel-wall ischemia and infarction (Townsend & Curtis, 2006).

3.3.4.H Gastrointestinal hypomotility

1) A review of pharmacovigilance data from the Australian Adverse Drug Reactions Advisory Committee (ADRAC) and New Zealand's Intensive Medicines Monitoring Program (IMMP) identified 74 cases of serious clozapine-induced gastrointestinal hypomotility (CIGH). A total of 102 cases of suspected life-threatening CIGH were compiled using data from ADRAC and IMMP. Cases of CIGH were further identified as serious in the database if they were recorded as: 1) serious or life-threatening constipation or constipation resulting in hospitalization, surgery, or a fatal outcome; 2) fecal impaction; 3) ileus; 4) bowel obstruction, ischemia, necrosis, or perforation; or 5) megacolon. Only cases identified by pharmacovigilance staff as having possible or probable association with clozapine were included from the ADRAC data while 2 authors identified and excluded cases with confounding pathology from the IMMP data. Additionally, multiple reports of the same or similar adverse events for 1 patient were treated as single cases to avoid duplication. There were 57 and 17 cases, respectively, from ADRAC and IMMP data that met the criteria for being cases of serious CIGH. Of these cases, the mortality rate was 27.5% and incidence was higher in males (66.7%) than in females (30.4%). Of the patients who developed serious CIGH, 20% developed it within the first month of treatment, 36.3% within the first 4 months, and 50% within the first year of treatment. The risk seemed to be greater at higher doses of clozapine (535 milligrams/day in fatal cases) (Palmer et al, 2008).

3.3.4.I Heartburn

1) Incidence: 4% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)
2) Abdominal discomfort/heartburn occurred in 4% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

3.3.4.J Ischemic bowel disease

1) A 20-year-old otherwise healthy male receiving clozapine for schizophrenia experienced fatal bowel ischemia following complaints of constipation. During a 1-year period, the patient was titrated up to a clozapine dose of 900 milligrams (mg)/day; additionally, amisulpiride 400 mg twice daily had been added for persistent negative symptoms with good results after one month. He presented to his physician with severe

abdominal pain following a 2-day history of constipation and was prescribed medication and returned home. The patient collapsed and died a few hours later before reaching a hospital; subsequently, a postmortem examination discovered the patient had impacted feces leading to bowel-wall ischemia and infarction (Townsend & Curtis, 2006).

3.3.4.K Nausea

1) Incidence: 5% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Nausea occurred in 5% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

3) Nausea occurs when the daily dose exceeds 150 milligrams. These adverse effects may disappear with continued administration of the same dose; however, if not, they are managed easily by dose reduction or temporary discontinuation of clozapine (Ayd, 1974a).

3.3.4.L Nausea and vomiting

1) Incidence: 3% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Nausea/vomiting occurred in 3% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

3) Nausea occurs when the daily dose exceeds 150 milligrams. These adverse effects may disappear with continued administration of the same dose; however, if not, they are managed easily by dose reduction or temporary discontinuation of clozapine (Ayd, 1974a).

3.3.4.M Pancreatitis

1) In postmarketing reports, pancreatitis has occurred in patients receiving clozapine (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

2) Pancreatitis followed by pericardial effusion occurred in a 17-year-old male patient who was receiving clozapine for the treatment of paranoid schizophrenia. Following 23 days of treatment, during which time the clozapine dose was titrated from 25 milligrams (mg) per day to 175 mg/day, the patient experienced mild epigastric pain and had elevated levels of pancreas amylase and lipase. A diagnosis of pancreatitis was made and the clozapine was discontinued. One day later, the clozapine was resumed at 100 mg/day and the epigastric pain disappeared within 3 days. Amylase and lipase levels returned to normal after 19 days. Four days after decreasing the dose, the patient experienced inspiratory chest pain, increasing pain in both shoulders, and had a heart rate of 120 beats per minute. A CT scan of the chest revealed a pericardial effusion. The clozapine was again discontinued and the patient recovered following cardiocentesis that removed 250 milliliters of slightly hemorrhagic fluid (Wehmeier et al, 2003).

3) In one study of reported cases (n=192) of antipsychotic-induced pancreatitis, 40% of the cases were associated with the use of clozapine at a mean daily dose of 306.7 milligrams. In most patients, time to onset of pancreatitis was within 6 months after initiation of treatment (Koller et al, 2003c).

3.3.4.N Paralytic ileus

1) Patients with paralytic ileus should not receive clozapine. In postmarketing reports, intestinal obstruction/paralytic ileus has occurred in patients receiving clozapine with some cases resulting in death. Treat constipation with adequate hydration and ancillary medications (eg, bulk laxatives) and consider consulting with a gastroenterologist for serious cases (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

2) Intestinal obstruction necessitating hospitalization occurred in a 51-year-old male and a 35-year-old female with resistant schizophrenia receiving clozapine 275 milligrams (mg)/day for 2 months and 500 mg/day for 4 months, respectively. No other predisposing factors were identified. The patients recovered with conservative management and continued on clozapine therapy with adjunctive dietary measures and stool softeners (Tang & Ungvari, 1999).

3.3.4.O Parotitis

1) A 49-year-old woman receiving clozapine 300 milligrams (mg) daily developed parotitis. She was first noted to have swelling on the right side of her face and pain in her right parotid gland. She received a 7-day course of penicillin and benztropine 2 mg. Her symptoms improved after 1 week (Southall & Fernando, 1999).

3.3.4.P Perforation of intestine

1) Colon perforation with peritonitis and sepsis occurred in a 49-year-old patient receiving clozapine 200 milligrams twice daily for 6 weeks. Clozapine was discontinued and after emergency hemicolectomy and colostomy, the patient was successfully treated with risperidone (Freudenreich & Goff, 2000).

3.3.4.Q Summary

1) Common gastrointestinal effects associated with clozapine therapy include constipation (14%) and nausea (5%). Elderly patients may be particularly susceptible to the anticholinergic effects of clozapine, such as constipation. Intestinal peristalsis leading to fecal impaction, paralytic ileus, and intestinal obstruction has also been reported with some cases resulting in death. Treat constipation with adequate hydration and ancillary medications (eg, bulk laxatives) and consider consulting with a gastroenterologist for serious cases (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

3.3.4.R Swelling of salivary gland

1) In postmarketing reports, salivary gland swelling has occurred in patients receiving clozapine (Prod Info FAZACLO(R) orally disintegrating tablets, 2007).

2) A 49-year-old woman receiving clozapine 300 milligrams (mg) daily developed parotitis. She was first noted to have swelling on the right side of her face and pain in her right parotid gland. She received a 7-day course of penicillin and benztropine 2 mg. Her symptoms improved after 1 week (Southall & Fernando, 1999).

3) Salivary gland swelling has been reported with clozapine. One case describes transient swelling of the left submandibular salivary gland in a patient on stable clozapine treatment for 13 months (Troia et al, 1996). Another case describes painless, bilateral swelling in the parotid region associated with hypersalivation after only 14 days of therapy (Patkar & Alexander, 1996).

3.3.4.S Vomiting

1) Incidence: 3% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Vomiting occurred in 3% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

3.3.4.T Xerostomia

1) Incidence: 6% (Prod Info FAZACLO(R) orally disintegrating tablets, 2007)

2) Dry mouth occurred in 6% of patients treated with clozapine in clinical trials (n=842) (Prod Info FAZACLO (R) orally disintegrating tablets, 2007).

3.3.5 Hematologic Effects

Agranulocytosis

Blood coagulation disorder

Disorder of hematopoietic structure

Drug-induced eosinophilia

Hematology finding

Neutropenia

Thromboembolic disorder

3.3.5.A Agranulocytosis

1) Summary

a) In pre-marketing evaluation, the cumulative incidence of agranulocytosis at 1 year was 1.3% (15 of 1743 patients). Agranulocytosis was defined as a neutrophil count of less than 500 cells/millimeters cubed. In the US there have been 585 cases (n=150,409) of agranulocytosis as of August 21, 1997; 19 of which were fatal. Few deaths have been reported since 1977 due to increased knowledge of clozapine-induced agranulocytosis and the importance of white blood cell monitoring (Prod Info Clozaril (R), 2002). One reference reports that the incidence of agranulocytosis following clozapine treatment is 10 to 20 times higher than that of phenothiazines (Oren et al, 1993).

b) Asymptomatic agranulocytosis developing in a patient several months after start of treatment with clozapine for treatment- resistant schizophrenia was initially attributed to clozapine treatment but later was found to be a result of a large B-cell lymphoma. Replacement of clozapine with chlorpromazine and quetiapine resulted in deterioration of the patient's mental state, resulting in hospitalization. During hospitalization, the lymphoma was discovered and was treated with chemotherapy. Clozapine was later reintroduced for better antipsychotic control and was continued with good effect, despite significant neutropenia secondary to the chemotherapy (Hundertmark & Campbell, 2001).

c) In data evaluating 11,555 patients, the majority of agranulocytosis occurred within the first three months of drug therapy; older patients and women appeared to be at an increased risk. Recent studies suggest people of Jewish and Asian origin may also be at higher risk (Meged et al, 1999; Munro et al, 1999). The hazard can be reduced by weekly monitoring of the white blood cell count (Alvir et al, 1993). Some cases of clozapine-induced agranulocytosis have been successfully treated with filgrastim or sargramostim (Gullion & Yeh, 1994). The mechanisms of clozapine-induced agranulocytosis have been reviewed (Pirmohamed & Park, 1997a)

2) Incidence: 1.3%

3) LITERATURE REPORTS

a) Two 18-year-old, female monozygotic twins developed schizophrenia within 2 weeks of one another and both developed agranulocytosis after 9 weeks of treatment with clozapine. Twin A responded poorly to initial treatment with haloperidol (prominent extrapyramidal symptoms) and was switched to sulpiride 400 milligrams (mg) per day and clozapine 6 mg/day. Her condition worsened and she was given 4 electroconvulsive (ECT) treatments. She was discharged, fully remitted, at 6 weeks after the start of clozapine treatment, with a maintenance dose of clozapine 150 mg/day. At discharge her leucocyte count was 13,700/milliliter (mL). At 10 weeks after start of clozapine treatment, her leukocyte count was 1400/mL. Clozapine was discontinued. Her leukocyte level normalized within 3 weeks, but psychotic symptoms recurred. Complete remission was obtained with risperidone 5 mg/day. Because of her sister's experience with haloperidol, twin B was treated immediately with clozapine, up to a dose of 300 mg/day. Because of insufficient response, she was given 8 ECT treatments. After 8 weeks of treatment, she was discharged, fully remitted. Her leukocyte count at discharge was 6100/mL. By 9 weeks after start of clozapine treatment, her leukocyte count was 1800/mL. Clozapine was discontinued, resulting in a recurrence of psychotic symptoms. Leukocytopenia persisted for 11 weeks. After control of her psychotic symptoms, her leukocyte level normalized. Her psychotic symptoms disappeared only after addition of oxazepam 15 mg/day to her regimen of risperidone 4 mg/day. This case report suggests that genetic factors play a role in the timing of onset of schizophrenia and also on the timing of agranulocytosis in response to clozapine treatment (Horacek et al, 2001).

b) In a study of 50 Jewish clozapine recipients, a 20-year-old female of Ashkenazi origin with the human leukocyte antigens (HLA) B38 and DR4 developed agranulocytosis with sepsis 12 weeks after initiation of clozapine (last dose: 300 milligrams (mg)/day). She recovered with antibiotic treatment and colony stimulating factor support. Two other females, a 20-year-old of Ashkenazi origin with HLA-B38 and a 33-year-old of non-Ashkenazi origin without suspected HLA haplotypes, experienced neutropenia. Overall, 38% of the study sample were of Ashkenazi origin, yet they represented two-thirds of those with resultant neutropenia/agranulocytosis. An additional 7 individuals manifested abnormalities in white blood cell count such as reduction that did not meet criteria for neutropenia (n=4); eosinophilia (n=2); and leukocytosis (n=1). Five of 7 (71%) in this group were of Ashkenazi origin. Because of the small numbers involved, none of the comparisons reached statistical significance. The authors note that the HLA susceptibility antigens are B38 and DR4 in Jews, and B7 and DR2 in non-Jews. Investigation is continuing as to whether a rare allele of these HLA haplotypes is responsible for agranulocytosis in the presence of clozapine and whether other non-major histocompatibility complex genes might be involved (Meged et al, 1999).

c) The cumulative incidence of clozapine-induced agranulocytosis was 0.73%, based on the Clozaril Patient Monitoring System (1990 to 1997, n=12,760) in the United Kingdom and Ireland. The peak onset was during weeks 6 to 18 of therapy. Only 2 of 93 cases were fatal. In this registry, the average and mean maximum clozapine doses were 388 and 462 milligrams/day, respectively. Cox proportional hazards regression analysis revealed a 53% increased risk with each 10-year increase in age at clozapine initiation (p=0.0001) and a 2.4 times higher risk among Asians compared to Caucasians (p=0.03). The authors categorized "Asian" and "Oriental" races separately without explanation. Maximum dose was inversely associated with risk (Munro et al, 1999).

d) Toxicity, inborn errors of metabolism, and/or immunological reactions may be involved in clozapine-induced agranulocytosis (Claas, 1989; Hasegawa et al, 1994). Other authors have suggested that genetic factors marked by major histocompatibility complex haplotypes may be associated with the susceptibility to agranulocytosis (Lieberman et al, 1990; Joseph et al, 1992). There is a 20% incidence in a Jewish group of patients strongly correlating with the presence of the haplotype HLA-B38, DR4, or DQW3. In addition, clozapine-induced agranulocytosis was reported in two non-Jewish patients, both of whom expressed HLA-B38 but did not express DR4 or DQW3 (Joseph et al, 1992).

e) A 37-year-old, Ashkenazic Jewish man developed fatal agranulocytosis and FEVER 11 weeks after starting clozapine therapy. At 10 weeks, the patient's white blood cell count fell to 3900 cells/cubic millimeter (mm(3)) with a neutrophil count of 1400 cells/mm(3) and lymphocyte count of 2000 cells/mm (3). The clozapine was discontinued. Four days later the patient was admitted with fever and severe agranulocytosis (neutrophil count 120 cells/mm(3), lymphocyte count 810 cell/mm(3)). Filgrastim, piperacillin and gentamicin were initiated. However, 6 hours later the patient collapsed and was found to have severe HYPERGLYCEMIA (blood glucose 1000 milligrams/dl) and LACTIC ACIDOSIS (pH 7.13; bicarbonate 10 mEq/liter, and lactate 79.3 milligrams/deciliter). Despite intensive treatment the patient developed intractable HYPOTENSION, ANURIA and CARDIAC ARREST. He died 36 hours after admission (Koren et al, 1997).

f) Clozapine-induced agranulocytosis was prolonged in 3 patients with the initiation of olanzapine therapy. The granulocyte recovery time was 21 days, as compared to an average 3 days in a group of patients not receiving olanzapine. The authors recommend avoiding olanzapine in this setting until hematologic indices have returned to normal (Flynn et al, 1997).

g) Five cases of clozapine-induced agranulocytosis were reported as being successfully treated with rG-CSF (filgrastim) (Gullion & Yeh, 1994). The patients were treated with at least 300 micrograms/day of filgrastim administered subcutaneously with the onset of agranulocytosis, increasing by 300 micrograms/day for the first 3 days to a total of 900 micrograms/day until resolution of agranulocytosis. Time from onset until resolution was a mean of 8.2 days, as compared to a historical control group of 15.7 days. One patient was successfully treated with sargramostim 3 micrograms/kilogram/day for 4

days (Oren et al, 1993).

h) Clozapine has been associated with a significant risk for granulocytopenia during clinical trials at therapeutic dosages and onset of symptoms occur between the 6th and 18th week of therapy(Bablenis et al, 1989); (Povlsen et al, 1985).

3.3.5.B Blood coagulation disorder

1) Summary

a) An increased aPPT of 34.2 sec (control 27 sec) was reported as a result of a positive lupus anticoagulant in a 39 year-old male after therapy with clozapine (225 milligrams/day), Klonopin, Cogentin, and Lopid. Normal laboratory tests included PT (14 sec), CBC, TT (21 sec), and a negative ANA titer (Kanjolia et al, 1997).

3.3.5.C Disorder of hematopoietic structure

1) Summary

a) Adverse effects that were temporally associated with clozapine and occurred in less than 1% of patients include ANEMIA and LEUKOCYTOSIS. Other adverse effects voluntarily reported by the manufacturer include ELEVATED HEMOGLOBIN, ELEVATED HEMATOCRIT, INCREASED ERYTHROCYTE SEDIMENTATION RATE, THROMBOCYTOPENIA, and SEPSIS; a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

2) LITERATURE REPORTS

a) Aplastic anemia developed in a 53-year-old man with Parkinson's disease following the administration of clozapine. The patient developed aplastic anemia after taking clozapine 50 milligrams daily for the treatment of dopamine-induced psychosis with hallucinations. The man developed a fever one week after beginning therapy. Blood tests exposed a severe form of drug-induced aplastic anemia. Clozapine was discontinued and the patient received treatment including blood transfusions, hematopoietic growth factors and antibiotics. The aplastic anemia resolved within 14 days and the patient's hallucinations and delusions were successfully treated with quetiapine (Ziegenbein et al, 2003).

b) N-DESMETHYLCLOZAPINE, the major metabolite of clozapine, is toxic. N-desmethylclozapine is further metabolized to an unstable compound that is toxic to hemopoietic precursors of both myeloid and erythroid lineages (Gerson et al, 1994).

3.3.5.D Drug-induced eosinophilia

1) Summary

a) In clinical studies, 1% of patients developed eosinophilia; rarely were cases substantial. If a differential count indicates a total eosinophil count above 4000 cell/cubic millimeter (mm(3)), interrupt therapy until the count falls below 3000 cells/mm(3) (Prod Info Clozaril(R), 2002). The onset of eosinophilia usually occurs after 3 to 5 weeks of treatment (Meged et al, 1999; Chatterton, 1997; Pirmohamed & Park, 1997a).

2) Incidence: 1%

3) LITERATURE REPORTS

a) A In a study of 50 Jewish clozapine recipients, two males aged 34 and 46 years developed eosinophilia 4 and 6 weeks after clozapine initiation, respectively. Their most recent clozapine doses were 150 and 300 milligrams/day, respectively. Their eosinophil counts peaked at 1365 and 984 per cubic millimeter, respectively (Meged et al, 1999).

b) In a study comparing the incidences of eosinophilia and neutropenia for patients on clozapine (n=41) versus haldol (n=29), no significant differences were found. During a 6 month period, patients were monitored weekly for blood dyscrasias. Eosinophilia was defined as an absolute eosinophil level in excess of 500 cells/cubic millimeter (mm(3)) and neutropenia was defined as an absolute neutrophil count below 2000 cells/mm(3). In the clozapine group, eosinophilia and neutropenia occurred in 32% and 7% of the patients, while the occurrence in the haloperidol group was 31% and 7%, respectively. Most patients developed eosinophilia in the first 6 weeks. No significant differences were found between men and women, ethnic groups, or age groups. Also, eosinophilia did not predict neutropenia (Ames et al, 1996). In a retrospective review, the rate of eosinophilia reported at an Australian hospital was 13% (Chatterton, 1997).

c) A 30-year-old woman receiving clozapine 200 milligrams/day developed eosinophilia with a peak of 1320/microliter on treatment day 26 (Lucht & Riestschel, 1998). Clozapine was discontinued and the eosinophil count decreased to 220/microliter on day 45. Also of note is that neutropenia developed with a low of 1800/microliter on day 32 and IgE increased to 254 IU/deciliter (reference value less than 120 IU/deciliter).

d) A 37-year-old man developed eosinophilia (700 cells/cubic millimeter) 2 weeks after beginning clozapine therapy (Amital et al, 1997). The eosinophil count remained stable for 7 weeks until he developed severe agranulocytosis, necessitating clozapine discontinuation. After 3 weeks the granulocyte count returned to normal. It has been theorized that eosinophilia predicts later agranulocytosis.

e) Eosinophilia developed in a 38-year-old schizophrenic patient following 5 weeks of clozapine therapy (eosinophil count of 1500 cells/cubic millimeter). Within 4 days of clozapine discontinuation, leukocyte and differential counts returned to normal and clozapine was restarted with no further abnormalities

(Tihonen & Paanila, 1992). Another case of eosinophilia has been reported when treated therapeutically with clozapine; anecdotal knowledge of several more cases exists (Stricker & Tielens, 1991).

3.3.5.E Hematology finding

1) N-desmethylclozapine, the major metabolite of clozapine, is toxic. N- desmethylclozapine is further metabolized to an unstable compound that is toxic to hemopoietic precursors of both myeloid and erythroid lineages. Therapeutic use of clozapine has been associated with neutropenia, agranulocytosis, neutrophilia, and rare eosinophilia. A few recent studies suggest patients of Jewish and Asian origin may be at higher risk for agranulocytosis. Adverse effects that were temporally associated with clozapine and occurred in patients are anemia and leukocytosis. Other effects voluntarily reported by the manufacturer include sepsis, thrombocytopenia, thrombocytosis, pulmonary embolism, deep vein thrombosis, elevated hemoglobin, elevated hematocrit, and increased erythrocyte sedimentation rate and a causal relationships that could not be determined.

2) Plasma and red-cell selenium concentrations were significantly (p less than 0.01) lower in schizophrenic patients treated with clozapine (n=54) compared to patients with mood disorders (n=36), schizophrenic patients not treated with clozapine (n=41) and a healthy control group (n=56). The plasma and red-cell selenium concentrations (micromoles/liter) were 1.28 +/- 0.33, 1.47 +/- 0.57; 1.39 +/- 0.29, 1.70 +/- 0.40; 1.47 +/- 0.41, 1.70 +/- 0.48; and 1.49 +/- 0.30, 1.80 +/- 0.58 for the four groups respectively. Selenium deficiency has been associated with cardiomyopathy and with myocarditis and these same adverse effects are also known to occur with clozapine treatment. Although it could not be determined by this study whether clozapine causes selenium deficiency or if treatment-resistant schizophrenic patients (who are often treated with clozapine) are selenium deficient prior to treatment, the authors suggested that it may prove beneficial to provide selenium supplementation to schizophrenic patients receiving clozapine (Vaddadi et al, 2003).

3.3.5.F Neutropenia

1) Summary

a) In clinical studies, neutropenia occurred in 2.7 to 22% of patients The peak onset was during weeks 6 to 18 of therapy. Cox proportional hazards regression analysis revealed a 17% decreased risk with each 10-year increase in age at clozapine initiation and a 77% greater risk in African-Caribbean subjects compared to Caucasians. The racial difference may be partially explained by significantly lower baseline white blood cell counts (an independent predictor of neutropenia) among African-Caribbeans. Maximum dose was inversely associated with risk (Prod Info Clozaril(R), 2002; Munro et al, 1999; Atkin et al, 1996; Hummer et al, 1997a).

2) Incidence: 3%

3) LITERATURE REPORTS

a) Although recommended by the manufacturer, the emergence of neutropenia in clozapine-treated patients has not required discontinuation of clozapine therapy in several cases. In a retrospective chart review, researchers assessed outcome over 600 days in patients (n=5) who continued clozapine therapy despite the development of neutropenia in the "red alert zone" (ie, white blood cell count below 3000 per cubic millimeter (mm(3)) or absolute neutrophil count (ANC) below 1500 per mm(3)). All five patients were maintained on clozapine after initial onset and recovery of neutropenia with no recurrence of neutropenia during the observation period. In three patients, the neutrophil counts remained at or just above the "amber zone" (ie, ANC 1500 to 2000 per mm(3)) throughout long-term follow-up while no hematological abnormalities were observed in the other two patients. Favorable response to clozapine treatment was observed in four of the five patients as assessed by Clinical Global Impression-Severity scores. The authors suggest the need for methods to differentiate between benign neutropenia and neutropenia progressing to agranulocytosis (Ahn et al, 2004).

b) TRANSIENT NEUTROPENIA developed in a 44-year-old Caucasian man after taking clozapine (200 to 400 milligrams (mg)/day) for the treatment of paranoid schizophrenia. Twenty-seven weeks after initiation of clozapine therapy, the patient's morning neutrophil count had declined to 1300/cubic millimeter (mm(3)), while the total white blood cell (WBC) count was within a normal range (4100/mm (3)). However, the blood sample taken the same afternoon at 2 p.m. showed that the neutrophil count had returned to normal (2200/mm(3)) and the total WBC count had risen to 5500/mm(3). Blood tests were continued twice a week and whenever the morning neutrophil counts fell between 1200 and 1900/mm(3) (WBC counts: 4100 to 4700/mm(3)), they were between 2200 and 2700/mm(3) in the afternoon (WBC counts: 5400 to 5800/mm(3)). Because the neutrophil counts were normal in the afternoon, the risk of the patient developing agranulocytosis was considered to be low and clozapine was continued at a dose of 200 mg daily. Decreased neutrophil counts were no longer observed after 30 weeks of clozapine therapy (Esposito et al, 2003).

c) After 20 months of clozapine treatment, the white blood cell (WBC) count declined over a four-month period and resulted in neutropenia in a 36-year-old chronic, paranoid schizophrenic man. During the prior 20 months of clozapine therapy (400 milligrams per day), the patient's WBC count was stable and ranged between 6000 and 10000 cubic millimeters (mm(3)). On the 21st and 22nd months of treatment, his WBC count decreased to an average of 4500 with an absolute neutrophil count (ANC) of 2300. By the fourth week of the 25th month of treatment, his WBC count continued its steady decline and was 2400 with an ANC of 1100. At that time the patient developed a high fever and the diagnosis of neutropenia was made and the clozapine was discontinued (Taman et al, 2001).

d) The cumulative incidence of clozapine-induced neutropenia was 2.7%, based on the Clozaril Patient

Monitoring System (1990 to 1997, n=12,760) in the United Kingdom and Ireland. The peak onset was during weeks 6 to 18 of therapy. In this registry, the average and mean maximum clozapine doses were 388 and 462 milligrams/day, respectively. Cox proportional hazards regression analysis revealed a 17% decreased risk with each 10-year increase in age at clozapine initiation (p=0.0003) and a 77% greater risk in African-Caribbean subjects compared to Caucasians (p=0.003). The age association is opposite that observed for agranulocytosis risk. The racial difference may be partially explained by significantly lower baseline white blood cell counts (an independent predictor of neutropenia) among African-Caribbeans. Maximum dose was inversely associated with risk (Munro et al, 1999).

e) Neutropenia has been reported in up to 22% of patients therapeutically treated with clozapine (Hummer et al, 1997a).

f) A 17-year-old boy with severe schizophrenic disorder was able to continue clozapine treatment (50 milligrams) despite decreased leukocytes (2480 cells/cubic millimeter (mm(3)), decreased neutrophil granulocytes (800 cells/mm(3)) and an acute febrile respiratory infection. He received G-CSF 300 micrograms with an increase in leukocytes and neutrophils 6 hours later (2680/mm(3) and 1250/mm(3), respectively), and normal body temperature the next morning. Over the next 2 days he received 2 more G-CSF injections. He continued clozapine for an additional 38 weeks until he experienced another decrease in granulocytes and clozapine was discontinued. One year later, the patient again required clozapine and after 20 weeks of therapy required G-CSF. After 2 doses of G-CSF 300 mcg, he was again maintained on clozapine for an additional 8 months (Sperner-Unterweger et al, 1998).

g) A 29-year-old male with schizophrenia was able to reinitiate clozapine therapy despite previous neutropenia after receiving pretreatment with lithium. Clozapine was previously discontinued after a decrease in granulocytes to 1400 cells/cubic millimeter. After failing other antipsychotics, lithium was initiated and increased to 0.8 to 1.1 millimoles/liter. Clozapine was introduced 2 weeks later at 12.5 milligrams (mg) and increased to 200 mg/day. Over the next 9 months white blood cell counts remained stable. The rational for lithium use was to increase granulopoiesis by enhancement of the production of granulocyte-macrophage colony-stimulating factor (Silverstone, 1998).

3.3.5.G Thromboembolic disorder

1) Summary

a) Six cases of PULMONARY EMBOLISM and 6 cases of VENOUS THROMBOSIS were reported during clozapine therapy. The adverse reaction was fatal in 5 cases with the affected patients being 3 women and 9 men aged 25-59 years. Complications that included VENOUS THROMBOEMBOLISM developed within the first 3 months of clozapine therapy in 8 of the patients (Hagg & Soderstrom, 2000). Adverse effects voluntarily reported by the manufacturer are THROMBOCYTOSIS and DEEP VEIN THROMBOSIS; a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

2) LITERATURE REPORTS

a) Between April 1989 and March 2000, 6 cases of pulmonary embolism and 6 cases of venous thrombosis were reported during clozapine therapy. The adverse reaction was fatal in 5 cases. The affected patients were 3 women and 9 men. Venous thromboembolism (VTE) complications developed within the first 3 months of clozapine therapy in 8 of the patients. The mean clozapine dose was 277 milligrams per day (Hagg & Soderstrom, 2000). After reviewing the available literature on case reports of VTE from the Swedish Adverse Reactions Advisory Committee, the authors suggest that VTE may not be clozapine associated after all and that other risk factors, such as reduced motor activity, should be taken into account. The authors concluded that an increased risk of VTE seems to be a general property of the antipsychotic drugs (Thomassen et al, 2000).

3.3.6 Hepatic Effects

Hepatotoxicity

Increased liver enzymes

Liver finding

3.3.6.A Hepatotoxicity

1) Summary

a) In clinical trials of clozapine, LIVER FUNCTION ABNORMALITIES occurred; in patients with clinically relevant elevations or with jaundice, clozapine should be discontinued. CHOLESTASIS, HEPATITIS, and JAUNDICE were voluntarily reported in postmarketing experience (Prod Info Clozaril (R), 2002). A 39-year-old male also developed fatal acute fulminant LIVER FAILURE with encephalopathy and coagulopathy after 8 weeks of clozapine therapy (Macfarlane et al, 1997).

3.3.6.B Increased liver enzymes

1) Summary

a) Clozapine, in therapeutic dosages, has been associated with a rise in liver enzymes in 37. 3% to

61% of patients (Hummer et al, 1997a; Gaertner et al, 2001). A case report also notes this adverse effect (Panagiotis, 1999).

2) LITERATURE REPORTS

a) In a prospective study, the incidence of alanine aminotransferase (ALT) elevation to more than twice the upper normal limit was statistically greater with clozapine (37%, n=167) than with haloperidol (17%, n=71). Among those receiving clozapine, the rates of elevations in aspartate aminotransferase (AST) and gamma-glutamyl transpeptidase (GGT) to more than twice the upper normal limit were 12% and 15%, respectively. No such increases in bilirubin or alkaline phosphatase occurred in clozapine-treated patients. These effects were transient in the majority of patients (disappearing by week 13) with no clinical manifestations reported (Hummer et al, 1997a).

b) A 30-year-old man developed abnormal liver enzymes and a grand mal seizure while receiving clozapine 400 milligrams (Panagiotis, 1999). Liver enzymes and electroencephalogram (EEG) were normal before therapy. After 4 weeks, he presented with a grand mal seizure and clozapine was reduced to 300 milligrams. Liver enzymes were evaluated 5 days after the seizure. The aspartate aminotransferase and gamma-glutamyl transferase were 3 times the upper limits of normal and the alanine aminotransferase was 5 times the upper limits of normal. Clozapine was discontinued.

3.3.6.C Liver finding

1) Liver function abnormalities have occurred with clozapine therapy that include elevated liver enzymes, liver failure, jaundice, hepatitis and cholestasis.

3.3.7 Immunologic Effects

Drug-induced lupus erythematosus, Systemic

Immune hypersensitivity reaction

Immunology finding

Systemic lupus erythematosus

3.3.7.A Drug-induced lupus erythematosus, Systemic

1) Summary

a) Two cases of lupus-like reactions have been reported with clozapine therapy (Kanjolia et al, 1997; Wickert et al, 1994).

2) LITERATURE REPORTS

a) A positive lupus anticoagulant, with resultant increased aPTT, was reported in an adult male taking clozapine (225 milligrams/day), Klonopin, Cogentin and Lopid. The etiologic relationship of clozapine to the lupus anticoagulant is probable (Kanjolia et al, 1997).

b) A case of systemic lupus erythematosus-like reaction was reported in a 39-year-old man taking 300 milligrams per day of clozapine for paranoid schizophrenia. The patient rapidly improved over 5 days following discontinuation of the clozapine. The symptom complex included: fever, fatigue, cough, chest pain, arthralgia, elevated activated partial thromboplastin time, and other hematological abnormalities (Wickert et al, 1994).

3.3.7.B Immune hypersensitivity reaction

1) Summary

a) Hypersensitivity reactions have been noted in a few case reports during clozapine therapy. Monitor plasma levels if a hypersensitivity reaction is suspected (Haack et al, 2003; Stanislav & Gonzalez-Blanco, 1999; Jaunkalns et al, 1992; Stoppe et al, 1992).

2) LITERATURE REPORTS

a) A hypersensitivity reaction to clozapine manifested as fever, bilateral pleural effusions and rapidly spreading papular rash in a 37-year-old woman 9 days after initiation and titration to 150 milligrams/day. Other etiologies were ruled out. Signs and symptoms began to resolve within a week of discontinuing clozapine (Stanislav & Gonzalez-Blanco, 1999).

b) A 33-year-old woman with chronic paranoid schizophrenia refractory to numerous neuroleptics started clozapine at 25 milligrams daily increments. On day 15, fever myalgia, arthralgia, and urticarial plaques on elbows and knees developed. Clozapine was stopped and symptoms abated. All tests including rechallenge with clozapine indicated that the extremely high titers of antimyeloperoxidase antibodies may have contributed to the pathogenesis of the syndrome. The relationship between idiosyncratic drug reactions, especially agranulocytosis, and myeloperoxidase system was described (Jaunkalns et al, 1992).

c) A 69-year-old woman suffering from chronic paranoid schizophrenia received clozapine for three weeks with no complications. For unknown reasons clozapine was discontinued. Two years later and 1

day after the first dose of clozapine, this patient developed an alarming, life-threatening allergic asthmatic reaction requiring intensive care treatment. When clozapine was restarted, the patient had a similar asthma-like attack. This reaction could be a delayed hypersensitivity or pseudoallergic reaction to the drug. This reaction is not due to its weak binding to D, and D2 dopamine receptors, or the blockage of S2 serotonergic, alpha, adrenergic, muscarinic, and H1 histamine receptors (Stoppe et al, 1992).

3.3.7.C Immunology finding

1) Malaise and hypersensitivity reactions occurred with clozapine therapy.

3.3.7.D Systemic lupus erythematosus

See Drug Consult reference: DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS

3.3.8 Musculoskeletal Effects

Musculoskeletal finding

Pain

Polyserositis

Rhabdomyolysis

Serum creatinine raised

3.3.8.A Musculoskeletal finding

1) Summary

a) In clinical trials (n=842), during clozapine therapy adverse effects temporally associated with clozapine and occurring at a frequency less than 1% included TWITCHING. A voluntary postmarketing report noted MYASTHENIC SYNDROME however a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

2) Muscle weakness, muscle spasms, muscle pain, back pain, neck pain, and leg pain occurred in patients with clozapine therapy. Adverse effects temporally associated with clozapine and occurring at a lower frequency include twitching and joint pain. Other less common effects include rhabdomyolysis, lupus-like findings, cpk elevations, and myasthenic syndrome.

3.3.8.B Pain

1) Summary

a) In clinical trials, MUSCLE WEAKNESS, MUSCLE SPASMS, MUSCLE PAIN, BACK PAIN, NECK PAIN, and LEG PAIN occurred in 1% of patients (n=842) during clozapine therapy. JOINT PAIN was temporally associated with clozapine and occurring at a frequency less than 1% (Prod Info Clozaril(R), 2002).

3.3.8.C Polyserositis

1) Summary

a) Polyserositis developed in a 74-year-old man after receiving clozapine (initial, 25 milligrams (mg) daily, then increased by 12.5 mg increments at weekly intervals) for the treatment of schizoaffective disorder. Initial symptoms, including dry cough, chills, and fever, developed twenty days after the initiation of therapy. He was treated for an assumed chest infection; however, respiratory symptoms worsened and the patient developed a PERICARDIAL EFFUSION and BILATERAL PLEURAL EFFUSION. Clozapine was withdrawn and systematic symptoms resolved within a week (Lim et al, 2003).

3.3.8.D Rhabdomyolysis

1) Summary

a) A 42-year-old man receiving clozapine and being treated for polydipsia developed rhabdomyolysis during the correction of the hyponatremia. After correction of his hyponatremia, his creatine kinase (CK) level was 8184 units/L and then 6186 units/L; however at 68 hours after admission, his CK peaked at 62,730 units/L. He had no muscle aches. To prevent acute renal insufficiency, high-volume alkaline diuresis was initiated. The CK concentration fell and returned to normal after 14 days. The authors feel that the rhabdomyolysis may have been enhanced by the use of clozapine (Wicki et al, 1998).

3.3.8.E Serum creatinine raised

1) Summary

a) Clozapine may be associated with increases in creatine kinase (CK), without features of neuroleptic malignant syndrome, and mild MYOPATHY. In 37 consecutive clozapine-treated outpatients, weekly CK levels were evaluated. Extreme CK elevations (greater than 20,000 International Units/Liter(IU/L)) without myoglobinuria occurred in 3 patients, and moderate CK elevation (between 725 and 20,000 IU/L) in 10 patients. Six patients in the moderately elevated CK group also had MUSCLE WEAKNESS. Five patients had mild myopathic dysfunction by electromyography. The CK elevations were not dependent upon clozapine dose (Scelsa et al, 1996).

3.3.9 Neurologic Effects

Dizziness

Dystonia

EEG finding

Headache

Movement disorder

Myoclonus

Neuroleptic malignant syndrome

Neurological finding

Paralysis

Seizure

Somnolence

Stuttering

3.3.9.A Dizziness

1) Summary

a) In clinical trials (n=842), dizziness and VERTIGO occurred in 19% of patients during therapeutic use of clozapine (Prod Info Clozaril(R), 2002).

2) Incidence: 19%

3.3.9.B Dystonia

1) Summary

a) During the first few days after initiating treatment with an antipsychotic medication, symptoms of dystonia may occur in susceptible individuals. Symptoms may include spasm of neck muscles, which may progress to tightening of the throat, swallowing difficulty, breathing difficulty, and/or protrusion of the tongue. These symptoms can occur at low doses but most often occur (and occur with a greater severity) with high potency and at higher doses of first generation antipsychotic medications. Males and younger age groups appear to be at greater risk for developing acute dystonia (Prod Info CLOZARIL(R) oral tablets, 2008).

b) Several case reports note dystonic reactions in patients during therapeutic use of clozapine (Mendhekar & Duggal, 2006)(Elliott et al, 2000)(Molho & Factor, 1999; Poersch et al, 1996; Kastrup et al, 1994). In the manufacturer's clinical trials (n=842), a few cases of tardive dyskinesia have also been reported in patients receiving clozapine; however, a causal relationship could not be established(Prod Info Clozaril(R), 2002). Atypical antipsychotics such as clozapine are associated with a lower risk of extrapyramidal symptoms (EPS) than conventional antipsychotics because of higher (ie, more balanced) serotonin-to-dopamine blockade ratios. This may also partially explain the decreased incidence of tardive dyskinesia with atypical agents, as one proposed mechanism of tardive dyskinesia involves "supersensitivity" to chronic, unopposed dopamine blockade (Glazer, 2000; Reynolds, 2000).

2) A case of clozapine induced tardive dyskinesia occurred in a 47-year-old woman with a history of with schizophrenia and hypothyroidism. Significant past medical history include extrapyramidal side effects from haloperidol. The patient's concurrent medications included levothyroxine (100 mg/day) and clozapine (150

mg/day). She presented with dyskinetic movements of the tongue and horizontal grinding movements of the lower jaw 7-months after starting clozapine. She was initially and unsuccessfully treated by discontinuing her levothyroxine for 8 weeks; her dyskinetic movements persisted and her thyroid stimulating hormone level increased. Diagnostic testing, which included computed tomography scan and electroencephalogram, were unremarkable. She was restarted on levothyroxine and also given a sequential trial of propranolol (80 mg/day) and tetrabenazine (125 mg/day) with improvement only in her thyroid profile. She subsequently was diagnosed with tardive dyskinesia and an attempt to reduce her clozapine dose to 125 mg/day failed. The dose reduction worsened her psychotic symptoms requiring an even higher dose of clozapine (200 mg/day) to manage her schizophrenia. Neither reduction nor increase of her clozapine dose improved the dyskinetic movements, which she continued to exhibit (Mendhekar & Duggal, 2006).

3) An acute dystonic reaction involving the tongue and neck developed in a 44-year-old male inpatient the day after a 50-milligram (mg) clozapine dosage increase to 450 mg/day. Despite a 20-year history of schizophrenia, extrapyramidal symptoms and tardive dyskinesia had not been previously documented. However, a pseudoparkinsonian tremor and orofacial movements consistent with tardive dyskinesia were noted on admission. His outpatient medication regimen had included clozapine and haloperidol. At the time of the dystonic reaction, the only concomitant medications were vitamin E and aspirin. The dystonia abated following a dose of intramuscular diphenhydramine (Elliott et al, 2000).

4) Tardive dystonia characterized by left rotational torticollis with intermittent spasms was attributed to clozapine 825 milligrams/day in a 37-year-old male with a 21-year history of schizophrenia. The dystonia first appeared 2 years after initiation of clozapine monotherapy and continued to worsen despite daily trihexyphenidyl. Other concomitant medications included metformin and glyburide. The torticollis continued unabated 4 years later, as the patient was intolerant to increased dosages of trihexyphenidyl (Molho & Factor, 1999).

5) 58-year-old patient treated for psychosis with clozapine 600 milligrams and benperidol 30 milligrams daily experienced episodes of ASTERIXIS, tachycardia and sweating, exacerbated by hypoglycemia (blood sugar 65 to 75 milligrams/deciliter). The symptoms disappeared upon reduction in an oral hypoglycemic agent that the patient was taking concurrently (Poersch et al, 1996).

6) A case of acute DYSTONIA manifested as retrocollic torsion and dystonic cramps of the tongue and mouth was reported after six weeks of therapy with clozapine at a dose of 400 milligrams/day. The dystonia was successfully treated with biperiden and the clozapine tapered to 250 milligrams/day. Biperiden was then discontinued without further incidences of dystonia (Kastrup et al, 1994).

3.3.9.C EEG finding

1) Summary

a) EEG changes have been noted in patients with clozapine use. There is some disagreement on whether these changes are dose-related occurrences or normal baselines within the patient population being treated with clozapine (Silvestri et al, 1998; Welch et al, 1994; Tihonen et al, 1991; Spatz et al, 1978).

2) LITERATURE REPORTS

a) One author states that most patients receiving clozapine treatment have abnormal EEGs. However, they believed that abnormal EEGs should not contraindicate increase of the clozapine dose beyond 600 milligrams/day if no signs of clinical adverse effects are observed (Tihonen et al, 1991). However, another author advocates lowering the clozapine dose by 25 to 50 milligrams per day and adjusting the dose weekly until the EEG returns to baseline (Welch et al, 1994).

b) In a group of 35 patients, 26 (74%) were found to have evidence of EEG abnormalities (slowing, dysrhythmia, or paroxysmal discharges) during clozapine treatment (Welch et al, 1994). EEGs were measured as a means of detecting clinical toxicity and reducing the incidence of seizures.

c) Eight out of 12 psychiatric patients receiving clozapine were found to have interictal epileptiform abnormalities on EEG. Six of the 8 had seizures while receiving clozapine. The abnormalities were focal or multifocal with a predominance of left temporal foci (Silvestri et al, 1998).

d) Changes in the EEG pattern similar to those caused by other neuroleptics has been seen in patients receiving clozapine. Monthly EEGs were evaluated in 34 schizophrenic patients treated with clozapine 100 to 700 milligrams daily. After 2 to 6 months of treatment, the EEG in 6 patients showed dysrhythmias and other changes similar to those caused by other neuroleptics. In 2 months after discontinuation of clozapine, the EEG had reverted to the pretreatment pattern (Gross & Langner, 1966). Similar results have been reported by other authors (Spatz et al, 1978).

3.3.9.D Headache

1) Summary

a) In clinical trials (n=842) 7% of patients experienced headache with clozapine therapy (Prod Info Clozaril(R), 2002).

2) Incidence: 7%

3.3.9.E Movement disorder

1) Summary

a) In clinical trials (n=842) 6% of patients experienced TREMOR. The following adverse effects were also reported in 1% to 4% of patients: HYPOKINESIA, AKINESIA, RIGIDITY, AKATHISIA, HYPERKINESIA, WEAKNESS, and ATAXIA. Adverse effects that were temporally associated with

clozapine and occurred in less than 1% of patients include TICS, POOR COORDINATION, INVOLUNTARY MOVEMENTS, DYSARTHRIA, HISTRIONIC MOVEMENTS, SHAKINESS, PARKINSONISM, and NUMBNESS (Prod Info Clozaril(R), 2002). One case of asterixis has been reported (Poersch et al, 1996).

3.3.9.F Myoclonus

1) Summary

a) Myoclonic jerking and EPILEPTIFORM MOVEMENTS have developed in patients taking therapeutic doses of clozapine (Prod Info Clozaril(R), 2002); (Antelo et al, 1994). A case report noted that 40-year-old man developed OROLARYNGEAL MYOCLONUS after 1 month of clozapine therapy. The myoclonus resolved with a reduction in clozapine dose (Knoll, 1997).

3.3.9.G Neuroleptic malignant syndrome

1) Summary

a) The estimated overall incidence of neuroleptic malignant syndrome (NMS) is 1% in patients receiving neuroleptics. Although the incidence is thought to be less with clozapine than with other neuroleptics, there are reports in the literature describing this syndrome following therapy with clozapine, some in conjunction with other neuroleptics or lithium. The syndrome generally occurs within the first two weeks of treatment and is associated with elevated creatine phosphokinase (CPK) and white blood cell count (WBC); symptoms usually persist 5 to 10 days after medications are discontinued. Without prompt treatment, patients may experience crippling effects of muscle destruction, renal impairment, encephalopathy, and even death (Prod Info Clozaril(R), 2002); (Kontaxkis et al, 2001)(Karagianis et al, 1999; Dalkilic & Grosch, 1997; Campellone et al, 1995; Viner & Escobar, 1994; Keshavan et al, 1994; DasGupta & Young, 1991); (Miller et al, 1991)(Anderson & Powers, 1991); (Muller et al, 1988).

b) Clozapine-induced neuroleptic malignant syndrome (NMS) developed in a 52-year-old man with a concomitant underlying brain injury. The patient was admitted to the hospital for exacerbation of psychotic and affective symptoms, including self-injurious behavior, after having been treated effectively for bipolar disorder for the previous ten years with clozapine at a daily dose of 400 milligrams (mg). Clozapine was increased to 500 mg daily on the first day of hospitalization. On day 4, altered mental status, moderate rigidity, urinary retention, and fever were observed; and laboratory findings revealed leucocytosis, elevated levels of creatine phosphokinase (CPK), alanine aminotransferase (ALT), and aspartate aminotransferase (AST). Clozapine was discontinued after magnetic resonance imaging showed a subacute bilateral frontal hematoma. The CPK peaked on day 5 at 18,000 international units/liter and then started to decrease, returning to normal on day 9 along with resolution of fever, rigidity, and altered mental status. The author attributes the development of NMS in this patient to concurrent clozapine administration and an underlying brain injury, which may have been caused by the patient's self-injurious behavior (Duggal, 2004).

2) LITERATURE REPORTS

a) Two patients presented with neuroleptic malignant syndrome associated with clozapine which was not similar to the presentation with classical neuroleptic agents. One man presented after 16 days of clozapine therapy with a temperature of 38.4 degrees Celsius (C) and increased heart rate. There was no rigidity noted. Five days later his white blood cell (WBC) count peaked at 15,000/mm(3) and his creatine kinase at 1501 units(U)/liter(L). Marked neck rigidity was noted. Medications were discontinued and he recovered; however, intubation was required. In the other case, a woman treated with clozapine for 2 years developed diaphoresis, pallor and vomiting. Her temperature was 37.7 C. Two weeks later, she was found to be disoriented. Finally, 1 week later she was admitted and found to have a mild neck stiffness. Her temperature peaked at 38.3 C. Her WBC count was 10,600/mm(3). Her creatine kinase peaked at 189 units/L (normal 20 to 184). Clozapine was discontinued and she improved after 1 week (Karagianis et al, 1999).

b) In a review of clozapine and cases of presumed neuroleptic malignant syndrome, approximately 9 of the 19 cases were designated as having high probability of actually being neuroleptic malignant syndrome. Alternative diagnoses in low probability cases included benzodiazepine withdrawal, infection, drug-drug interaction, or serotonin syndrome (Hasan & Buckley, 1998).

c) The Australian Adverse Drug Reactions Advisory Committee has received 11 reports of Neuroleptic Malignant Syndrome associated with clozapine therapy (1 case questionable). The patients were all male (median age 40 years) and onset occurred primarily in the first two weeks after initiating treatment but ranged from 6 days to 9 months. Clozapine doses ranged from 75 to 600 milligrams (mg) daily (median 400 mg). Clinical symptomology included fever, confusion, disorientation, profuse sweating, tachycardia, and delirium. Laboratory tests revealed leukocytosis in 7 cases and elevated creatinine kinase levels in 10 cases (230 to 12,800 units/liter); all but 1 patient recovered (Anon, 1997a).

d) A patient with a history of neuroleptic malignant syndrome (NMS) following neuroleptic therapy also developed NMS after initiation of clozapine. After 4 days of clozapine treatment (12.5 milligrams daily), the patient experienced marked changes in mental status, weakness, and dizziness; creatine phosphokinase (CPK) was significantly elevated. Following discontinuation of the drug, the patient completely recovered after several days (Illing & Ancill, 1996).

e) A 71-year-old man with chronic paranoid schizophrenia presented with fever, rigidity, and altered mental status. Medications were therapeutic doses of clozapine and 1500 milligrams of valproic acid

used for prophylaxis for clozapine-induced seizures. His creatine phosphokinase level was 2536 U/liter, his urine contained myoglobin, and he had evidence of acute renal insufficiency. Despite discontinuation of clozapine, intravenous hydration, bromocriptine, diazepam, dantrolene, etc, the patient developed pulmonary and renal infection, multiorgan failure, gastrointestinal hemorrhage and subsequently died (Campellone et al, 1995).

3.3.9.H Neurological finding

1) Summary

a) In clinical trials (n=842), the following adverse effects were reported in 1% to 4% of patients were CONFUSION, FATIGUE, LETHARGY, and SLURRED SPEECH. Adverse effects that were temporally associated with clozapine and occurred in less than 1% of patients include LOSS OF SPEECH, AMENTIA, STUTTERING, DYSARTHRIA, NYSTAGMUS, AMNESIA/MEMORY LOSS and PARESTHESIA. (Prod Info Clozaril(R), 2002).

2) Drowsiness and sedation are very common dose-dependent adverse effects with therapeutic use of clozapine and are likely to subside with continued therapy or dose reduction. Dizziness and vertigo also commonly occur. Tremor, headache and seizures occur with some frequency. The following adverse effects that were less frequently reported and include hypokinesia, akinesia, agitation, rigidity, akathisia, confusion, fatigue, hyperkinesia, weakness, lethargy, ataxia, delirium, EEG changes, asterixis, paresthesia, slurred speech, and epileptiform movements/myoclonic jerks. Adverse effects that were temporally associated with clozapine therapy include loss of speech, tics, poor coordination, involuntary movements, stuttering, dysarthria, histrionic movements, shakiness, parkinsonism and numbness. Several cases of dystonic reactions have been reported but a causal relationship could not be established.

3.3.9.I Paralysis

1) A Chinese male schizophrenia patient developed hyperglycemia, hyperlipemia, and PERIODIC PARALYSIS while taking clozapine. The episodes of paralysis often lasted 30 to 40 minutes and then spontaneously stopped. Symptoms resolved when clozapine was withdrawn and recurred when clozapine treatment was reestablished. Symptoms appeared at clozapine doses as low as 37.5 milligrams (mg) per day. Other drugs were not as effective as clozapine for treating his mental state. His mental state was finally stabilized with a combination of clozapine 25 mg/day and haldol 20 mg/day, without elevations of blood glucose or lipids (Wu et al, 2000).

3.3.9.J Seizure

1) Summary

a) In the manufacturer's clinical trials (n=842) one or more seizures occurred in 5% (61 of 1743) of patients. During earlier clinical trials, the reported prevalence of seizures was also 5% of patients treated with 600 to 900 milligrams daily. Therapeutic use of clozapine has been reported to lower the seizure threshold, especially in epileptic patients and patients with organic brain disease. Seizures appear to be dose-related. Patients with a history of seizures or predisposing factors should be closely monitored during clozapine therapy. These patients should not be engaged in any activities where the sudden loss of consciousness could cause serious risk to themselves or others. STATUS EPILEPTICUS was reported, however a causal relationship with clozapine could not be determined. (Prod Info Clozaril(R), 2002; Supprian et al, 1999; Panagiotis, 1999; Devinsky & Pacia, 1994; Haller & Binder, 1990a).

2) Incidence: 5%

3) LITERATURE REPORTS

a) In one case, a 30-year-old man developed a grand mal seizure and liver toxicity after 3 weeks of clozapine therapy which had been increased to 400 milligrams per day (Panagiotis, 1999).

b) A 49-year-old female on maintenance clozapine therapy for refractory schizophrenia experienced a generalized epileptic seizure after a self-imposed dose increase to 750 milligrams (mg)/day. Myoclonic jerks continued for 2 hours, necessitating intravenous phenytoin. Electroencephalographic abnormalities (initial diffuse slowing progressing to triphasic sharp waves) had previously coincided with dosage increases from 450 to 650 mg/day. Preceding the seizure was new-onset stuttering at 700 mg/day, with dose-related fluctuations in severity. After the seizure, the patient was stabilized on valproate 900 mg/day and clozapine 600 mg/day, with no further stuttering or seizures during 6 months of follow-up. The authors speculated that clozapine-induced stuttering might be an indicator of epileptic brain activity (Supprian et al, 1999).

c) Seizures occur in approximately 1% of patients treated with antipsychotic drugs, but the reported prevalence of seizures is higher with clozapine and appears to be dose-dependent: 1% with less than 300 milligrams/day, 3% with 300 to 599 milligrams/day, and 5% with 600 to 900 milligrams/day. Clinical management of the seizures including the use of anticonvulsants or the discontinuation of clozapine has been outlined (Haller & Binder, 1990a). Another author reported similar results (Devinsky et al, 1991).

d) Some data do not clearly confirm the dose-dependent effect (Devinsky & Pacia, 1994). A 28-year-old woman with schizophrenia experienced a grand mal seizure while receiving clozapine at a low dose of 200 milligrams (Ravasia & Dickson, 1998). This occurred after 6 months of clozapine that included a 5-month initial taper. Her clozapine level was, however, 3290 nmol/liter (suggested range: 153 to 1836 nmol/liter).

See Drug Consult reference: PREVENTION OF CLOZAPINE-INDUCED SEIZURES

3.3.9.K Somnolence

1) Summary

a) In the manufacturer's clinical trials with clozapine therapy, drowsiness and SEDATION were reported in 39% of patients (n=842) and was reported likely to subside with continued therapy or dose reduction (Prod Info Clozaril(R), 2002). Earlier studies have also noted that drowsiness was a common dose-dependent adverse effect of clozapine (Bablenis et al, 1989; Haller & Binder, 1990a; Kirkegaard et al, 1982; Ayd, 1974a; Battegay et al, 1977).

2) Incidence: 39%

3.3.9.L Stuttering

1) Summary

a) Stuttering was noted to occur with clozapine use.

2) LITERATURE REPORTS

a) A 28-year-old, paranoid schizophrenic, man began stuttering when his clozapine dose reached 300 milligrams (mg) per day. An earlier EEG taken when he was receiving 150 mg/day showed bilateral frontotemporal slowing (left more than right), a photic convulsive response, and generalized nonparoxysmal sharp and slow waves. As he had a good response to clozapine his dose was increased to 300 mg/day and he began to stutter. At 425 mg/day he had a generalized tonic-clonic seizure. His clozapine dose was reduced to 200 mg/day and valproate 800 mg/day was added. There was no recurrence of stuttering when his clozapine dose was again increased to 300 mg/day. The authors speculate that stuttering accompanied by left-sided slowing or other EEG abnormalities may be a forerunner to seizures (Duggal et al, 2002).

3.3.10 Ophthalmic Effects

3.3.10.A Eye / vision finding

1) Summary

a) In clinical manufacturer trials, VISUAL DISTURBANCES occurred in 5% of patients (n=842) during clozapine therapy. MYDRIASIS, EYELID DISORDER, and BLOODSHOT EYES occurred in less than 1% of patients; a causal relationship with clozapine could not be determined (Prod Info Clozaril(R), 2002). ACCOMMODATION DIFFICULTIES may also be noted (Reynolds, 2000). No pathological pigmentation in the refractive media or retina were observed in 11 patients treated with clozapine for 6 months to 2 years (Gross & Langner, 1970).

2) Visual disturbances have occurred in patients during clozapine therapy that include mydriasis, eyelid disorder, accommodation difficulties and bloodshot eyes.

3.3.11 Otic Effects

Disorder of ear

Ear and auditory finding

3.3.11.A Disorder of ear

1) Summary

a) Ear disorder was temporally associated with clozapine therapy and occurred at a frequency less than 1% (Prod Info Clozaril(R), 2002).

3.3.11.B Ear and auditory finding

1) Ear disorder was temporally associated with clozapine therapy.

3.3.12 Psychiatric Effects

Delirium

Obsessive-compulsive disorder

Psychiatric sign or symptom

3.3.12.A Delirium

1) Summary

a) Delirium may occur, secondary to antimuscarinic side-effects, following therapeutic dosages (Reynolds, 2000; Burke et al, 1998); (Wilkins-Ho & Hollarder, 1997). An incidence of 8% was reported

in a case series of 391 treatments in 315 inpatients (Gaetner et al, 1989). Some authors recommended a low starting dose and gradual titration in retreatment with clozapine (Szymanski et al, 1991b)

2) LITERATURE REPORTS

a) Two cases of NEUROLEPTIC-SENSITIVITY were reported with clozapine therapy in patients with Lewy body dementia. Both received low doses of clozapine (6.25 or 12.5 milligrams) and experienced increased confusion, hallucinations, and behavioral symptoms. These symptoms persisted despite discontinuation of clozapine. Both families noted that the patients never returned to their pre-clozapine level of mental function (Burke et al, 1998).

b) A 48-year-old woman with a past history of alcohol dependency developed delirium after 3 days of clozapine therapy. Clozapine was discontinued and a slower upward titration resulted in no recurrence of her schizoaffective symptoms or her delirium (Wilkins-Ho & Hollander, 1997).

c) A 22-year-old man with chronic schizophrenia experienced acute symptoms of an ANTICHOLINERGIC SYNDROME (delirium, DECREASED GASTROINTESTINAL MOTILITY, TACHYCARDIA, and urinary hesitancy), antiadrenergic symptoms (orthostatic hypotension), and drug-induced HYPERBILIRUBINEMIA and HYPERAMYLASEMIA, after reintroduction of clozapine at a moderate and previously well-tolerated dosage. The authors recommended a low starting dose and gradual titration in retreatment with clozapine (Szymanski et al, 1991b).

3.3.12.B Obsessive-compulsive disorder

1) Summary

a) Adverse effects that have been reported during clozapine therapy are unmasked obsessive compulsive disorder, PSYCHOTIC EXACERBATIONS and CATAPLEXY (Prod Info Clozaril(R), 2002; Biondi et al, 1999; de Haan et al, 1999; Suppes & Rush, 1996; Baker et al, 1992).

2) LITERATURE REPORTS

a) In a retrospective cohort study of recent-onset schizophrenia or other psychotic disorders (n=121, mean age 21 years, 79% male), significantly more clozapine recipients (7 of 34, 21%) reported emergent or worsened obsessions compared to recipients of other antipsychotics (1 of 76, 1.3%, p less than 0.01). Clozapine-associated obsessions were new-onset in 5 of 7 (71%) cases. Discontinuation of clozapine produced complete remission of obsessive symptoms in one case. Three were successfully managed with clozapine dosage reduction plus adjunctive selective serotonin reuptake inhibitor (SSRI) therapy. Obsessions were refractory to SSRI therapy in the remaining patients (de Haan et al, 1999).

b) A 27-year-old man experienced obsessive-compulsive symptoms while receiving clozapine 150 milligrams/day for his schizophrenia (Biondi et al, 1999). Symptoms emerged after 5 weeks of clozapine. He had no previous history of obsessive-compulsive disorder. His score on the Yale-Brown Obsessive Compulsive Scale was 30. This decreased to 10 after clomipramine 110 milligrams/day was added.

c) Clozapine has produced or unmasked obsessive compulsive symptoms in 6 patients. In a review of 49 patients treated with clozapine for at least 3 months, five patients experienced de novo obsessive compulsive symptoms or a worsening of previous obsessive compulsive symptoms with improvement of psychosis (Baker et al, 1992). A similar case has been reported (Suppes & Rush, 1996).

3.3.12.C Psychiatric sign or symptom

1) Summary

a) In clinical trials (n=842), the following adverse effects were reported in 1% to 4% of patients; DISTURBED SLEEP/NIGHTMARES, RESTLESSNESS, AGITATION, PANIC, INSOMNIA, DEPRESSION, and ANXIETY. Adverse effects that were temporally associated with clozapine and occurred in less than 1% of patients include AMENTIA, DELUSIONS/HALLUCINATIONS, AMNESIA/MEMORY LOSS, PARANOIA, and IRRITABILITY. (Prod Info Clozaril(R), 2002; Bressan et al, 2000).

2) The following adverse effects that were less frequently reported in include disturbed sleep/nightmares, depression, restlessness, insomnia, and anxiety disorders. Adverse effects that were temporally associated with clozapine therapy include amentia, delusions/hallucinations, amnesia/memory loss, paranoia and irritability. Other adverse effects that have been reported are unmasked obsessive compulsive disorder, psychotic exacerbation and cataplexy.

3) LITERATURE REPORTS

a) A 34-year-old woman treated with clozapine 400 milligrams (mg) daily, developed daily PANIC and agoraphobic symptoms after 20 weeks that confined her to the house. Even with a reduction of clozapine to 250 mg daily, the patient only showed modest improvement. Clozapine was discontinued and changed to olanzapine without further recurrence of anxiety symptoms (Bressan et al, 2000).

3.3.13 Renal Effects

Interstitial nephritis

Nocturnal enuresis

Urinary incontinence

Urinary retention

Urogenital finding

3.3.13.A Interstitial nephritis

1) Summary

a) Voluntary postmarketing reports from the manufacturer include the adverse effect of acute interstitial nephritis during clozapine therapy, however a causal relationship could not be determined (Prod Info Clozaril(R), 2002). There have also been a few case reports of interstitial nephritis (Fraser and Jibani, 2000)(Elias et al, 1999).

2) LITERATURE REPORTS

a) In one report, a 49-year-old man developed ACUTE RENAL FAILURE due to interstitial nephritis during treatment with clozapine. He received no other medication except diazepam as needed. On clozapine day 42, blood draw showed marked renal impairment. He was dehydrated and pyrexial on day 45 with no abnormality on physical exam or chest x-ray. Blood and urine cultures were negative, clozapine was stopped, and he was started on intravenous cefotaxime. Despite hydration, dopamine, and furosemide infusions his plasma urea and creatinine continued to rise. On day 47 he started peritoneal dialysis. A percutaneous renal biopsy on day 50 showed a florid interstitial nephritis. He was treated with intravenous methylprednisolone 1 gram on each of days 51 to 53 then switched to oral prednisolone. He was switched to hemodialysis on day 52 and by day 61, his biochemistry improved and was taken off dialysis. Discontinuation of the drug often leads to resolution in those with mild to moderate renal failure but unless the offending agent is discontinued, the renal failure may be irreversible. Also included were details of 7 additional cases of acute renal failure associated with clozapine therapy reported to the Committee On Safety Of Medicines in the UK (Fraser and Jibani, 2000).

b) Investigators reported a case of acute interstitial nephritis, diagnosed by renal biopsy in a 38-year-old female, which they attributed to a hypersensitivity reaction to clozapine. Eleven days after initiation of clozapine 125 milligrams twice daily, the patient developed anuric renal failure necessitating hemodialysis and the discontinuation of all medications. Other possible etiologies were ruled out. The patient began improving after 1 week with renal function values normalizing by day 15 (Elias et al, 1999).

3.3.13.B Nocturnal enuresis

1) Summary

a) Bladder urgency and/or enuresis occurred in a series of 10 patients during treatment with clozapine (Frankenburg et al, 1996). In another study it occurred in 11 of 25 patients (Lin et al, 1999). The incidence of nocturnal enuresis was at least 0.23% to as high as 41% of patients treated with clozapine (Lin et al, 1999; Steingard, 1994). URINARY URGENCY and URINARY FREQUENCY, occurred in 1% of patients (n=842) with therapeutic use of clozapine (Prod Info Clozaril(R), 2002).

2) LITERATURE REPORTS

a) The incidence of NOCTURNAL ENURESIS was 41% in a sample of 61 Chinese inpatients with chronic schizophrenia treated with clozapine for at least 3 months. Daytime urinary incontinence accompanied nocturnal enuresis in 11 of 25 cases (Lin et al, 1999).

b) Bladder urgency and/or enuresis occurred in a series of 10 patients during treatment with clozapine. Eight of the patients experienced these symptoms during medication initiation, and two of the patients had preexistent enuresis that worsened with clozapine therapy. Oxybutynin (5 to 15 milligrams/day) was effective in relieving the symptoms of enuresis and urgency in five patients; intranasal desmopressin was effective in another four. The authors also report a cumulative incidence of enuresis in two previous studies of 28% and suggest that all clozapine-treated patients be questioned about changes in bladder habits (Frankenburg et al, 1996).

c) Nocturnal enuresis has been reported to occur in at least 0.23% of patients treated with clozapine. Desmopressin acetate administered intranasally at a dose of one puff (10 micrograms) in each nostril at bedtime was reported as successfully treating this side effect in one case report (Steingard, 1994).

3.3.13.C Urinary incontinence

1) Summary

a) In clinical manufacturer trials, incontinence has occurred in 1% of patients (n=842) with therapeutic use of clozapine (Prod Info Clozaril(R), 2002). Two other studies reported incontinence in patients ranging from 29% to 44% (Lin et al, 1999; Fuller et al, 1996).

2) LITERATURE REPORTS

a) In a retrospective review of 61 Chinese inpatients with chronic schizophrenia treated with clozapine for at least 3 months, the incidence of urinary incontinence (UI) was 44%. Investigators compared age, gender, clozapine dose and duration, length of hospitalization, duration of illness and age at onset of

illness and found no significant difference between those who did and did not experience UI. The same characteristics were also statistically equivalent between subjects with persistent versus self-limiting UI. Of the 27 patients with UI, 15 (56%) had persistent and 12 (44%) had self-limiting UI; 25 (93%) had nocturnal enuresis with (n=11) or without (n=14) daytime symptoms; 2 (7%) had daytime UI only. Concomitant medications were not associated with UI in this sample (Lin et al, 1999).

b) In one report, urinary incontinence developed in 17 of 57 inpatients after initiation of clozapine therapy. Patients who developed incontinence were significantly more likely to be receiving a typical antipsychotic agent in addition to clozapine, receiving a higher dose of the agent, and to be female. Sixteen of the incontinent patients were treated with ephedrine (25 to 150 milligrams/day) with 12 patients having a complete response to treatment (Fuller et al, 1996).

3.3.13.D Urinary retention

1) Summary

a) Urinary retention occurred in 1% of patients (n=842) during clozapine therapy. Elderly patients may be particularly susceptible to the anticholinergic effects of clozapine, such as urinary retention (Prod Info Clozaril(R), 2002).

3.3.13.E Urogenital finding

1) Summary

a) In clinical trials, ABNORMAL EJACULATION occurred in 1% of patients (n=842) with clozapine therapy. Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include DYSMENORRHEA, IMPOTENCE, DECREASE LIBIDO, INCREASED LIBIDO, BREAST PAIN, VAGINAL ITCHING, and POLYDIPSIA. Voluntary postmarketing reports also noted PRIAPISM, however a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

2) In clinical trials, incontinence, urinary urgency/urinary frequency, urinary retention, and abnormal ejaculation have occurred in patients with clozapine therapy. Elderly patients may be particularly susceptible to the anticholinergic effects of Clozaril (clozapine), such as urinary retention Adverse effects temporally associated with clozapine and occurring less frequently include dysmenorrhea, impotence, decrease libido, increased libido, breast pain, vaginal itching, and polydipsia. Reports also include acute interstitial nephritis and priapism but a causal relationship could not be determined.

3.3.15 Respiratory Effects

Lung finding

Pleural effusion

Pulmonary embolism

Respiratory finding

3.3.15.A Lung finding

1) Summary

a) Clozapine has induced orthostatic hypotension severe enough to cause collapse and respiratory arrest. This adverse effect usually occurs following the initial titration or during rapid escalation of the dose. In clinical trials, DYSPNEA, NASAL CONGESTION, and THROAT DISCOMFORT occurred in 1% of patients (n=842). Adverse effects temporally associated with clozapine and occurring at a frequency less than 1% include COUGHING, PNEUMONIA, RHINORRHEA, HYPERVENTILATION, WHEEZING, BRONCHITIS, LARYNGITIS, and SNEEZING. Voluntary postmarketing reports include ASPIRATION and PLEURAL EFFUSIONS; a causal relationship could not be determined (Prod Info Clozaril(R), 2002).

3.3.15.B Pleural effusion

1) Summary

a) Two cases of pulmonary effusion were reported with clozapine therapy (Stanislav & Gonzalez-Blanco, 1999; Chatterjee & Safferman, 1997).

2) LITERATURE REPORTS

a) Bilateral pleural effusion, accompanied by a fever and papular rash, appeared in a 37-year-old female 9 days after clozapine initiation and titration to 150 milligrams/day. Diagnostic findings were consistent with a drug hypersensitivity reaction, as no infectious or cardiopulmonary etiology was identified. The remainder of her medication regimen had been stable with no recent dose changes. Within a week of clozapine discontinuation, signs and symptoms resolved (Stanislav & Gonzalez-Blanco, 1999).

b) A 37-year-old male developed right arm cellulitis after 5 days of clozapine therapy and a left-sided

pleural effusion after 12 days. Eosinophilia was also present (white blood cell count of 17,100 cells/cubic millimeter, 23.6% eosinophils). Clozapine was discontinued and he improved with antibiotics. The patient was re-challenged with clozapine. After 8 days, he again experienced right arm swelling and chest x-ray showed reemergence of left-sided pleural effusion (Chatterjee & Safferman, 1997).

3.3.15.C Pulmonary embolism

1) Summary

a) (Hagg et al, 2000f) identified 12 cases of thromboembolism associated with clozapine treatment (mean dose of 277 milligrams per day). Six cases of venous thrombosis and 6 cases of pulmonary embolism were reported; five patients died. No confounding illness was found in any of the patients that would have contributed to thromboembolic disease. One other case of pulmonary embolism was noted and the patient recovered (Maynes, 2000).

2) Incidence: rare

3) LITERATURE REPORTS

a) A case of bilateral pulmonary embolism was reported in a 30-year-old man, five months after starting clozapine. He had a sudden onset of shortness of breath and dizziness while walking. He then collapsed on the street and taken to the emergency room. Upon examination he was found to be diaphoretic and tachycardic, with a pulse of 115 beats per minute. Further investigation included a ventilation-perfusion scan, and he was diagnosed with a bilateral pulmonary embolism. The patient was anticoagulated with heparin then warfarin and he made a gradual recovery (Maynes, 2000).

3.3.15.D Respiratory finding

1) Pulmonary effusion and embolisms have occurred with therapeutic clozapine use. Clozapine has induced orthostatic hypotension severe enough to cause collapse and respiratory arrest. This adverse effect usually occurs following the initial titration or during rapid escalation of the dose. Dyspnea and nasal congestion occurred in patients. Adverse effects temporally associated with clozapine and occurring at a low frequency include coughing, pneumonia, rhinorrhea, hyperventilation, wheezing, bronchitis, laryngitis, aspiration and sneezing.

3.3.16 Other

Summary

Dead - sudden death

Death

Extrapyramidal disease

Fever

Malaise

Seizure

Withdrawal sign or symptom

3.3.16.A Summary

1) OTHER EFFECTS

a) Withdrawal and sudden death has been associated with clozapine therapy.

3.3.16.B Dead - sudden death

1) Summary

a) In a retrospective review of inpatient mental health records (1991 to 1997, n=5479) and national death registry data, investigators discovered a higher incidence of sudden death among clozapine users compared to nonusers. Of 561 clozapine recipients, there were 6 sudden deaths (1.07%), 2 suicides (0.35%), and 2 disease-related deaths (0.35%). The 6 sudden deaths occurred in 4 current and 2 former (2 weeks and 5 years posttreatment) users of clozapine, respectively. Of 4918 not exposed to clozapine, there were 14 sudden deaths (0.28%), 5 suicides (0.1%) and 86 disease-related deaths (1.75%). Sudden deaths were significantly more frequent in the clozapine group (p less than 0.01), while disease-related deaths were significantly more common in the non-clozapine group (p less than 0.05). The average age at sudden death was lower in clozapine users (41 versus 51 years, p less than 0.04). However, the validity of attributing a sudden death to clozapine 5 years after its discontinuation is

doubtful. These data should be interpreted with caution because of the small numbers of sudden deaths and lack of autopsies (Modai et al, 2000).

3.3.16.C Death

1) Results of a population-based, retrospective cohort study demonstrated that the use of conventional antipsychotics was associated with an even greater risk for death than atypical antipsychotics when administered to elderly patients (aged 66 years and older) with dementia. Atypical versus no antipsychotic use and conventional versus atypical antipsychotic use pair-wise comparisons were made. A total of 27,259 matched pairs were identified and the dementia cohort was stratified based on place of residence (community versus long-term care facilities). In order to adjust for difference in baseline health status, propensity score matching was used. The primary outcome of the study was all-cause mortality. The risk for death was evaluated at 30, 60, 120, and 180 days after the antipsychotic medications were initially dispensed. There was a statistically significant increase in the risk for death at 30 days associated with new use of atypical antipsychotic medications compared with nonuse in both the community-dwelling cohort (adjusted hazard ratio (HR), 1.31 (95% confidence interval (CI), 1.02 to 1.70); absolute risk difference, 0.2 percentage point) and long-term care cohort (adjusted HR, 1.55 (95% CI, 1.15 to 2.07); absolute risk difference, 1.2 percentage points). For both cohorts, the risk associated with atypical antipsychotics appeared to persist to 180 days. The risk for death associated with conventional antipsychotics was even greater than the risk identified with atypical antipsychotics. At 30 days, the adjusted HR for the community-dwelling cohort was 1.55 (95% CI, 1.19 to 2.02) and 1.26 (95% CI, 1.04 to 1.53) for the long-term care cohort (adjusted risk difference for both was 1.1 percentage points). The risk appeared to persist to 180 days for both groups. Some important limitations to the study include unknown or unmeasured confounders may influence the results and cause of death could not be examined (Gill et al, 2007).

2) Results of a population-based, retrospective cohort study demonstrated comparable to possibly greater risk of death associated with the use of conventional antipsychotic medications in the elderly (aged 65 years and older) compared with atypical antipsychotic medications. The analysis excluded patients with cancer and included only new users of antipsychotic medications. The primary study outcome was 180-day all-cause mortality. A set of potential confounders was measured based on healthcare utilization data within 6 months before the initiation of antipsychotic medications. Of the 37,241 elderly patients identified, 12,882 and 24,359 received conventional and atypical antipsychotic medications, respectively. The risk of death in the conventional drug group within the first 180 days was 14.1% compared with 9.6% in the atypical drug group (unadjusted mortality ratio, 1.47; 95% confidence interval (CI), 1.39 to 1.56). In the multi-variable analysis which controlled for potential confounders, the adjusted mortality ratio for the risk of death within 180 days for conventional versus atypical drug therapy was 1.32 (95% CI, 1.23 to 1.42). When the most frequently prescribed conventional antipsychotic drugs were compared with risperidone, the mortality ratio associated with haloperidol was 2.14 (95% CI, 1.86 to 2.45) and loxapine was 1.29 (95% CI, 1.19 to 1.40), while there was no difference associated with olanzapine. The increased mortality risk for conventional versus atypical drug therapy was greatest when doses higher (above median) doses were used (mortality ratio 1.67; 95% CI, 1.5 to 1.86) and also during the first 40 days of therapy (mortality ratio 1.6; 95% CI, 1.42 to 1.8). Confirmatory analyses consisting of multi-variable Cox regression, propensity score, and instrumental variable estimation confirmed the results of the study (Schneeweiss et al, 2007).

3) The results of a retrospective cohort study indicate that conventional antipsychotic agents are at least as likely as atypical antipsychotic agents to increase the risk of death among elderly patients 65 years of age or older. The study included 9,142 new users of conventional agents (mean age, 83.2 years) and 13,748 new users of atypical agents (mean age, 83.5 years). A higher adjusted relative risk of death was associated with the use of conventional antipsychotics as compared with atypical antipsychotics at all timepoints studied after beginning therapy (within 180 days: relative risk) RR, 1.37; 95% confidence interval (CI), 1.27 to 1.49; less than 40 days: RR, 1.56; 95% CI, 1.37 to 1.78; 40 to 79 days: RR, 1.37; 95% CI, 1.19 to 1.59; 80 to 180 days: RR, 1.27; 95% CI, 1.14 to 1.41). In addition, the adjusted risks of death observed in patients with dementia (RR, 1.29; 95% CI, 1.15 to 1.45), without dementia (RR, 1.45; 95% CI, 1.30 to 1.63), in a nursing home (RR, 1.26; 95% CI, 1.08 to 1.47), or not in a nursing home (RR, 1.42; 95% CI, 1.29 to 1.56) were also higher with the use of conventional antipsychotic therapy as compared with atypical antipsychotic use. This risk appeared to be dose-related and was greater with the use of higher dose (ie, greater than the median) conventional antipsychotics (RR, 1.73; 95% CI, 1.57 to 1.90). Additional studies which specifically investigate the optimum care of elderly patients requiring antipsychotic therapy are needed so that appropriate guidance regarding therapeutic intervention can be provided (Wang et al, 2005).

3.3.16.D Extrapyramidal disease

See Drug Consult reference: NEUROLEPTIC-INDUCED EXTRAPYRAMIDAL REACTIONS

3.3.16.E Fever

1) Summary

a) Fever was associated in 4% to 6% of patients (sometimes along with flu-like symptoms) following therapeutic dosages of clozapine. It (100.4 degrees Farenheit (38 degrees Centigrade)) is usually transient with a peak occurring within the first 3 weeks of therapy. The fever is generally benign and self-limiting. Temperature elevation appeared to be independent of dose (Prod Info Clozaril(R), 2002); (Blum, 1990).

2) Incidence: 5%

3.3.16.F Malaise

1) Summary

a) Malaise was temporally associated with clozapine therapy and occurred at a frequency less than 1% (Prod Info Clozaril(R), 2002).

3.3.16.G Seizure

See Drug Consult reference: PREVENTION OF CLOZAPINE-INDUCED SEIZURES

3.3.16.H Withdrawal sign or symptom

1) Summary

a) Several different kinds of withdrawal symptoms including cholinergic rebound, dystonias, dyskinesias and worsening psychotic symptoms have occurred with clozapine therapy (Tollefson et al, 1999; Delassus-Guenault et al, 1999; Stanilla et al, 1997)

2) LITERATURE REPORTS

a) In a double-blind, placebo-controlled study of 106 patients undergoing elective discontinuation of clozapine, the immediate substitution of olanzapine 10 milligrams (mg)/day attenuated some withdrawal symptoms. Clozapine doses were gradually tapered to 300 mg/day or less prior to abrupt discontinuation, followed by randomization to either placebo or olanzapine for a 3- to 5-day study period. During this time, 24.5% and 7.5% of placebo- and olanzapine-treated patients, respectively, experienced a worsening of at least one psychotic sign or symptom (p=0.02). This was reflected by significant between-group differences in the Positive and Negative Syndrome Scale total score (p=0.04) and general psychopathology subscale (p=0.03) as well as the Montgomery-Asberg Depression Rating Scale total score (p less than 0.001). However, the primary efficacy variable, the Clinical Global Impression Scale-Severity, was statistically similar in both groups. All subjects then entered a 9-week open-label olanzapine period, with equivalent outcomes. Investigators stress the importance of a gradual taper of clozapine with possible overlap and/or substitution with olanzapine to minimize the risk of withdrawal symptoms. Olanzapine may be preferred over risperidone or typical antipsychotics because its receptor affinities are similar to those of clozapine (Tollefson et al, 1999).

b) In two case reports, rapid clozapine tapering from high doses resulted in severe cholinergic rebound symptoms despite substitution with olanzapine. Maintenance clozapine doses of 700 to 800 milligrams (mg)/day were tapered over only 4 to 7 days, discontinued and replaced by olanzapine 5 to 10 mg/day. Withdrawal symptoms included severe anxiety, agitation, aggression, nausea, vomiting, diaphoresis, confusion and disorientation, necessitating medical hospitalization in one case. The authors recommend a 2- to 3-week taper period for clozapine with concomitant anticholinergic therapy (Delassus-Guenault et al, 1999).

c) Severe dystonias and dyskinesias were experienced by 4 patients withdrawn from clozapine therapy (Ahmed et al, 1998). Patients were 18 to 60 years old and had a history of extrapyramidal symptoms while receiving high potency and older neuroleptics. In 3 patients clozapine was discontinued abruptly. Cholinergic rebound was experienced by 2 subjects. Severe limb-axial and neck dystonias, and dyskinesias were experienced by 3 patients for 5 to 14 days. The dystonias were so severe in 2 patients that they were unable to ambulate. Significant improvement was seen after 2 restarted clozapine, 1 started risperidone, and 1 started olanzapine.

d) Three cases of acute delirium and psychosis occurred upon withdrawal of clozapine. The patients involved were male, ages 38, 46, and 63, whose schizophrenia had been controlled on 250 to 600 milligrams/day for 12 to 18 months. In two patients, clozapine was abruptly stopped, while the other was weaned off clozapine over 2 weeks. Withdrawal symptoms (hallucinations, diaphoresis, agitation, disorientation, choreoathetoid movements) appeared within 24 to 48 hours of the last clozapine dose and resolved upon reinstitution of clozapine. When a prolonged taper of clozapine is not possible, the authors recommend the temporary use of thioridazine when transitioning to another antipsychotic agent to counteract cholinergic hyperactivity (Stanilla et al, 1997).

e) A withdrawal syndrome occurred in 9 of 13 patients after sudden discontinuation of long-term clozapine therapy at doses ranging from 50 to 200 milligrams/day. After sudden discontinuation, patients experienced a severe relapse requiring hospitalization within 24 to 48 hours. Five patients reported vomiting, sleeplessness, depression, stupor, fatigue, and dizziness. Withdrawal akathisia was reported by 4 patients. These symptoms regressed when the patient was given clozapine or disappeared gradually when patients began to receive other neuroleptics (Zapletalek et al, 1980).

f) Difficulty in switching patients from other neuroleptics to clozapine has been reported. In 7 patients, unspecific restlessness, psychotic symptoms, and extrapyramidal symptoms which required hospitalization were seen for an average of 4 weeks after withdrawal of neuroleptics and starting clozapine (Mauthe et al, 1980).

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category B (Prod Info CLOZARIL(R) oral tablets, 2008) (All Trimesters)

a) Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal-reproduction studies have shown adverse effect (other than a decrease in

fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).

2) Australian Drug Evaluation Committee's (ADEC) Category: C(Australian Drug Evaluation Committee, 1999)

a) Drugs which, owing to their pharmacological effects, have caused or may be suspected of causing harmful effects on the human fetus or neonate without causing malformations. These effects may be reversible. Accompanying texts should be consulted for further details.

See Drug Consult reference: PREGNANCY RISK CATEGORIES

3) Crosses Placenta: Unknown

4) Clinical Management

a) Limited human data from case reports indicate no complications during pregnancy or delivery and no adverse effects on the infant when clozapine is administered during pregnancy. Animal studies have also not demonstrated adverse effects due to clozapine use during gestation in rats and rabbits. Therefore, in consideration of maintaining the lowest effective dose of any drug during pregnancy and because animal studies are not always predictive of human response, clozapine should be used during pregnancy only if clearly needed (Prod Info CLOZARIL(R) oral tablets, 2008).

5) Literature Reports

a) Two case reports described uncomplicated pregnancies and vaginal term deliveries resulting in healthy infants when clozapine 200 mg/day was used during the pregnancies of 2 women with schizophrenia. In both cases, breast feeding was not recommended. In the first case, the patient was taking clozapine 400 mg/day. One year later, the patient wanted to conceive. Subsequently, clozapine was tapered off to the point of psychotic symptoms to determine the lowest effective dose. Prior to pregnancy, her BMI was 23.6 and serum folate level was 8.2 nanograms/mL. No psychotic symptoms occurred during gestation. The newborn's height of 52 cm and weight of 2900 g were normal . APGAR scores were 9 and 10 in minute 1 and 5, respectively. WBC count was normal with no neonatal history of seizures. In a subsequent pregnancy 1.5 years later, the patient was still taking clozapine 200 mg/day. Routine follow-up during pregnancy revealed no gestational diabetes, orthostatic hypotension, agranulocytosis, or psychotic symptoms. The second child was 50 cm and 3000 g with APGAR scores of 10 in minutes 1 and 5. In the second case, a woman had been experiencing auditory hallucinations for which she was initiated on clozapine 400 mg/day while tapering off of other drugs that were not working. She improved significantly and wanted a second child. Her BMI was 24.1. Birth control or clozapine dose reduction in the event of pregnancy was recommended. The patient presented to an outpatient clinic reporting that she had delivered healthy twins who were 51 and 49 cm and 3100 and 2940 g with APGAR scores in minute 1 and 5 of 9 and 10, respectively, for one twin and 10 for the other. WBC count was not monitored during pregnancy. No seizures or agranulocytosis were recorded (Duran et al, 2008).

b) A case report described an uncomplicated pregnancy and delivery resulting in a healthy infant who exhibited normal development, except for speech, when clozapine was used during pregnancy in a 30-year-old woman with schizophrenia. The mother had been maintained on clozapine 100 mg/day for 6 months when she became pregnant. Laboratory tests for blood glucose, hemoglobin, and WBC count were within normal limits. The 100-mg daily clozapine dose was maintained throughout her pregnancy. Weight gain was normal and no psychotic exacerbations occurred during gestation. A term delivery (9 months and 2 days) resulted in a healthy baby girl with a normal weight of 2.95 kg and no perinatal complications. The patient was maintained on the same clozapine dose while breast-feeding her infant until 1 year of age The infant achieved normal developmental milestones, with the exception of speech. At the age of 1 year, she began using consonants and began using combined syllables at the age of 18 months. She spoke only 6 to 8 words at 2 years of age and would speak only 12 to 15 words until 3 years of age. She was also stuttering. At 4 years of age, she developed speaking skills with small sentences of 2 or 3 words and she could repeat small sentences. She was able to speak fluently by the end of 5 years. Local pathology was ruled out and audiometric assessment was within normal limits. The mother-child relationship was not impaired and there was no evidence of familial phonological disorder or a bilingual environment (Mendhekar, 2007).

c) Cases of clozapine use during pregnancy (150 to 625 mg/day) have not resulted in fetal abnormalities (Dickson & Hogg, 1998; Stoner et al, 1997). A case report described a 30-year-old female who was treated with clozapine throughout her pregnancy. The patient delivered a female infant at 39 weeks gestation with abnormal findings including a cephalhematoma, hyperpigmentation folds, and a coccygeal dimple, all of which were resolving within 2 days of delivery. At 8 days old, the infant was reported to have a seizure and developed gastroenteritis, both of which resolved. At 2 years of age, the child was reported to be healthy with no physical problems (Stoner et al, 1997). Another case report described a 32-year-old female who was treated with clozapine throughout her pregnancy. She delivered a female at 40 weeks gestational age with no reported abnormalities except a low-grade fever which resolved prior to hospital discharge (Stoner et al, 1997).

d) A case report described an infant born to a mother treated with clozapine 100 mg per day until the last nine weeks of pregnancy at which time the dose was decreased to 50 mg/day. The infant girl weighed 3600 g at birth and had Apgar scores of 5 at one minute and 8 at five minutes. The infant had normal l psychomotor development up to 6 months of age. Maternal clozapine plasma levels were measured monthly during pregnancy, the day of delivery, one day after delivery when the mother began lactating, and one week after delivery. While taking 100 mg/day, the mother's clozapine plasma levels were 38 to 55 nanograms (ng)/mL; at 50 mg/day, the level was 15.4 ng/mL. When the infant was delivered, the maternal, amniotic, and fetal plasma levels were 14.1 ng/mL, 11.6 ng/mL, 27 ng/mL, respectively. The accumulation of drug in the fetal plasma can be explained by the higher concentration of albumin in fetal blood which binds

clozapine, an acidic, lipophilic drug, and by ion trapping in the fetal compartment which results in a pH gradient in the fetus (Barnas et al, 1994).

e) There are no adequate and well-controlled studies in pregnant women. In animal studies, there was no evidence of impaired fertility or harm to the fetus when rat and rabbits were exposed to disease approximately 2 to 4 times the human dose (Prod Info CLOZARIL(R) oral tablets, 2008).

B) Breastfeeding

1) American Academy of Pediatrics Rating: Drugs for which the effect on nursing infants is unknown but may be of concern. (Anon, 2001)

2) Thomson Lactation Rating: Infant risk cannot be ruled out.

a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk when used during breastfeeding. Weigh the potential benefits of drug treatment against potential risks before prescribing this drug during breastfeeding.

3) Clinical Management

a) Human data showing the effects, if any, of clozapine on the nursing infant are limited. A case report demonstrated a milk/plasma ratio of greater than 2.5 in a woman taking clozapine 100 mg/day. The high milk/plasma ratio was attributed to the high lipid solubility and lipophilic properties of clozapine (Barnas et al, 1994a). Another case report described a problem with speech development in an infant who had been breast-fed for 1 year while her mother was maintained on a daily 100-mg dose of clozapine. However, it is not possible to determine whether the speech difficulty is a result of postnatal exposure to clozapine (Mendhekar, 2007). Animal studies have indicated that clozapine may be excreted in breast milk. Therefore, breast-feeding should be avoided during clozapine treatment (Prod Info CLOZARIL(R) oral tablets, 2008).

4) Literature Reports

a) A case report described an uncomplicated pregnancy and delivery resulting in a healthy infant who exhibited normal development, except for speech, when clozapine was used during pregnancy and lactation in a 30-year-old woman with schizophrenia. The mother had been maintained on clozapine 100 mg/day for 6 months when she became pregnant. Laboratory tests for blood glucose, hemoglobin, and WBC count were within normal limits. The 100-mg daily clozapine dose was maintained throughout her pregnancy. Weight gain was normal and no psychotic exacerbations occurred during gestation. A term delivery (9 months and 2 days) resulted in a healthy baby girl with a normal weight of 2.95 kg and no perinatal complications. The patient was maintained on the same clozapine dose while breast-feeding her infant until 1 year of age The infant achieved normal developmental milestones, with the exception of speech. At the age of 1 year, she began using consonants. At 18 months, she began using combined syllables. She spoke only 6 to 8 words at 2 years of age and would speak only 12 to 15 words until 3 years of age. She was also stuttering. At 4 years of age, she developed speaking skills with small sentences of 2 or 3 words and she could repeat small sentences. She was able to speak fluently by the end of 5 years. Local pathology was ruled out and audiometric assessment was within normal limits. The mother-child relationship was not impaired and there was no evidence of familial phonological disorder or a bilingual environment (Mendhekar, 2007).

b) A case report described a healthy infant born to a mother treated with clozapine 100 mg/day until the last 9 weeks of pregnancy at which time, the dose was decreased to 50 mg/day. The infant girl weighed 3600 g at birth and had Apgar scores of 5 at one minute and 8 at five minutes. She had normal psychomotor development up to 6 months of age. Maternal clozapine plasma levels were measured monthly during pregnancy, the day of delivery, one day after delivery when the mother began lactating, and one week after delivery. While taking 100 mg/day, the mother's clozapine plasma level was 38 to 55 nanograms (ng)/mL; at 50 mg/day, her level was 15.4 ng/mL. When the infant was delivered, the maternal, amniotic, and fetal plasma levels were 14.1 ng/mL, 11.6 ng/mL, 27 ng/mL, respectively. The day after delivery, the concentration of clozapine in the maternal plasma was 14.7 ng/mL and the first portion of the breast milk contained 63.5 ng/mL. At one week postdelivery, the mother was taking clozapine 100 mg/day; the breast milk concentration of drug measured 115.6 ng/mL, and plasma level measured 41.4 ng/mL. The authors postulated that clozapine accumulates in the breast milk because of the high lipid concentration of breast milk (Barnas et al, 1994a).

5) Drug Levels in Breastmilk

a) Parent Drug

1) Milk to Maternal Plasma Ratio

a) 2.8 to 4.3 (Barnas et al, 1994a)

3.5 Drug Interactions

Drug-Drug Combinations

Drug-Food Combinations

3.5.1 Drug-Drug Combinations

Aprindine

Belladonna

Belladonna Alkaloids

Benztropine

Buspirone

Carbamazepine

Cimetidine

Ciprofloxacin

Citalopram

Dehydroepiandrosterone

Droperidol

Encainide

Erythromycin

Flecainide

Fluoxetine

Fluvoxamine

Fosphenytoin

Guarana

Lithium

Lorazepam

Lorcainide

Mate

Nefazodone

Nicotine

Norfloxacin

Paroxetine

Perphenazine

Phenobarbital

Phenylalanine

Phenytoin

Propafenone

Quinidine

Rifampin

Risperidone

Ritonavir

Sertraline

St John's Wort

Thioridazine

Tramadol

Venlafaxine

Zotepine

3.5.1.A Aprindine

1) Interaction Effect: increased plasma concentrations of clozapine and or class I antiarrhythmic agents
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as class I antiarrhythmics, should be approached with caution (Prod Info Clozaril(R), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as class I antiarrhythmic agents, may require lower doses than usually prescribed for either clozapine or the class I antiarrhythmic.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.B Belladonna

1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)
2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with clozapine. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the clinical severity of the interaction with clozapine is unknown. Caution is advised.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.
7) Probable Mechanism: additive anticholinergic effect

3.5.1.C Belladonna Alkaloids

1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)
2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with clozapine. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the

clinical severity of the interaction with clozapine is unknown. Caution is advised.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.
7) Probable Mechanism: additive anticholinergic effect

3.5.1.D Benztropine
1) Interaction Effect: excessive anticholinergic effects (sedation, constipation, dry mouth)
2) Summary: The use of antipsychotics and anticholinergics may increase the incidence of ileus, hyperpyrexia, or neurologic deficits. In addition, the concurrent use of these drugs may decrease the gastrointestinal absorption of selected antipsychotics. Anticholinergic drugs that pass into the central nervous system may antagonize antipsychotic effects (Linnoila et al, 1980; Mann & Boger, 1978).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Use this combination only when clearly indicated. Monitor for excessive anticholinergic effects. Dosage adjustments may be required.
7) Probable Mechanism: additive anticholinergic effects

3.5.1.E Buspirone
1) Interaction Effect: an increased risk of gastrointestinal bleeding and hyperglycemia
2) Summary: A 33-year old male who was taking clozapine for more than a year without adverse effects, but developed gastrointestinal bleeding and severe hyperglycemia when buspirone therapy was also instituted, has been reported (Good, 1997). Since clozapine can cause gastric ulcer and hyperglycemia by itself, it is possible that buspirone augmented the serum level of clozapine, either by enzyme inhibition or by displacing clozapine from its binding sites.
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Caution should be observed when clozapine and buspirone are coadministered. Monitor blood glucose levels and watch for signs and symptoms of bleeding, especially from the gastrointestinal tract.
7) Probable Mechanism: unknown
8) Literature Reports
a) A 33-year old institutionalized paranoid schizophrenic male was placed on clozapine 600 mg daily for hallucinations and serious assaultiveness. A series of other medications failed to control his feelings of anxiety, so buspirone therapy was initiated at a dose of 5 mg three times daily. His clozapine serum level was 390 ng/mL (range 100-700 ng/mL) prior to buspirone therapy. One month after buspirone was started, the dose was increased to 20 mg daily, and the patient began to complain of nausea and epigastric pain. After an episode of coffee-grounds emesis, he was transferred to the intensive care unit, where he was found to have severe acidosis. His blood glucose level was over 1300 mg/dL, and hematocrit had dropped to 31 mL/dL. Both the clozapine and buspirone were discontinued. An upper gastrointestinal series did not reveal a source of the bleeding, and the patient required insulin therapy until his blood glucose level eventually returned to normal. Clozapine was reinitiated because of his assaultiveness, and he had no recurrence of adverse effects (Good, 1997).

3.5.1.F Carbamazepine
1) Interaction Effect: an increased risk of bone marrow suppression, asterixis, or decreased serum clozapine levels
2) Summary: Clozapine and carbamazepine both have the potential to cause bone marrow suppression, including agranulocytosis (Prod Info Clozaril(R), 2002n). Asterixis (flapping tremor) has also been reported in patients undergoing concurrent therapy with carbamazepine and clozapine (Rittmannsberger, 1996a). In addition, a therapeutic drug monitoring study revealed significantly lower clozapine concentrations when carbamazepine was added to therapy (Jerling et al, 1994c). The mechanism may be due to carbamazepine induction of clozapine metabolism through cytochrome P450 3A4. Controlled studies are needed to further evaluate the pharmacokinetic and clinical effects of combining these agents.
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Avoid concurrent use; an alternative anticonvulsant agent should be considered. If coadministration of these agents is necessary, monitor patients for decreased response to clozapine and agranulocytosis. Lower doses of either clozapine or carbamazepine may be required.

7) Probable Mechanism: additive bone marrow-suppressive effects and neurotoxicity; induction of clozapine metabolism

8) Literature Reports

a) One agranulocytosis fatality has been reported in association with the use of a multi-drug regimen which included clozapine, carbamazepine, clonazepam, benztropine, and lithium (Gerson & Lieberman JA Friedenberg, 1991). This case exhibited pancytopenia which is not characteristic of clozapine-induced agranulocytosis.

b) Over a three-year period, some drug combinations caused a greater risk of asterixis (flapping tremor) in patients on a regimen of multiple psychopharmacologic agents (Rittmannsberger, 1996). With regard to the agents carbamazepine, clozapine, and lithium, incidence of asterixis was greatest in those patients that were on at least two of these three agents. Out of ten patients developing asterixis, five patients received carbamazepine and clozapine as part of multi-drug therapy, and in two cases carbamazepine and clozapine were the sole psychopharmacologic agents. In all cases serum levels of all the drugs were within normal therapeutic ranges, suggesting an additive effect of combination therapy rather than the effect of a single agent.

c) Therapeutic drug monitoring data showed a 50% lower clozapine concentration/dose (C/D) ratio when concurrent carbamazepine was taken compared to clozapine alone. The clozapine C/D ratio was inversely correlated with the dose of carbamazepine. An additional analysis of eight patients confirmed that upon addition of carbamazepine to the drug regimen, clozapine concentrations decreased significantly. The mean C/D ratio during monotherapy was 1.21 and during cotherapy with carbamazepine fell to 0.30. The change in clozapine metabolism was suggested to be due to carbamazepine induction of cytochrome P450 3A4 (Jerling et al, 1994b).

3.5.1.G Cimetidine

1) Interaction Effect: an increased risk of clozapine side effects (dizziness, vomiting, hypotension, bone marrow suppression)

2) Summary: Concomitant administration of drugs known to inhibit the activity of cytochrome P450 isozymes may increase the plasma levels of clozapine, potentially resulting in adverse effects (Prod Info Clozaril(R), 2002a). In a case report the concomitant use of clozapine and cimetidine resulted in elevated serum levels of clozapine and subsequent side effects (Szymanski et al, 1991a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: With concurrent use, monitor patients for clozapine toxicity. Consider selecting another H2 antagonist (eg, ranitidine or famotidine) that has less potential to alter drug metabolism or switching to another anti-ulcer medication such as sucralfate.

7) Probable Mechanism: cimetidine inhibits cytochrome P450-mediated clozapine metabolism

8) Literature Reports

a) An elevation in the serum level of clozapine and subsequent side effects developed following the administration of cimetidine in a patient receiving clozapine 900 mg/day. The patient did not experience any side effects with the concomitant administration of cimetidine 800 mg/day. However, within 3 days following an increase to cimetidine 1200 mg/day, marked diaphoresis, dizziness, vomiting, severe orthostatic hypotension, and generalized weakness developed. Cimetidine was discontinued and the clozapine dose was reduced to 200 mg/day; symptoms gradually resolved over 5 days. Clozapine was reinitiated over 1 week to 900 mg/day. The patient continued to experience epigastric distress; therefore, ranitidine 150 mg twice daily was instituted and no interaction has been identified over a 3-month follow-up (Szymanski et al, 1991).

3.5.1.H Ciprofloxacin

1) Interaction Effect: increased clozapine serum concentrations and increased risk of side effects (sedation, incoordination, slurred speech, seizures, hematologic abnormalities)

2) Summary: Concomitant administration of drugs known to inhibit the activity of cytochrome P450 isozymes, such as ciprofloxacin, may increase the plasma levels of clozapine, potentially resulting in adverse effects (Brouwers et al, 2009; Prod Info CLOZARIL(R) tablets, 2005a).

3) Severity: moderate

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Monitor patients for signs and symptoms of clozapine intoxication (sedation, incoordination, slurred speech, seizures, hematologic abnormalities). Doses of clozapine may need to be reduced when ciprofloxacin is added to therapy.

7) Probable Mechanism: inhibition of cytochrome P450 3A4 by ciprofloxacin resulting in delayed clozapine metabolism

8) Literature Reports

a) Coadministration of ciprofloxacin and clozapine led to elevated clozapine plasma level in a 46-year-old male presented with urosepsis. History included smoking, caffeine use, and treatment at a psychiatric facility with citalopram, lorazepam, valproic acid, and clozapine. He was treated with a 5-day course of IV ciprofloxacin 400 mg twice daily and amoxicillin while on maintenance therapy of clozapine 900 mg daily for paranoid schizophrenia, and was discharged after 4 days in good condition. He

returned 3 days later with suspected rhabdomyolysis, but did not report any pain. Lab results indicated creatine phosphokinase (CPK) levels of 195,000 units per liter, lactic dehydrogenase (LDH) of 6687 units per liter, aspartate aminotransferase (AST) 845 units per liter, alanine aminotransferase (ALT) of 93 units per liter, and a urine test positive for myoglobin. Clozapine treatment was stopped and high-volume alkaline diuresis started. Three days after the end of ciprofloxacin treatment and one day after stopping clozapine, the patient's clozapine plasma concentration was 890 nanograms/mL, higher than the recommended therapeutic concentration of 350 to 600 ng/mL. Five days after stopping clozapine, the clozapine plasma concentration was undetectable. LDH, AST, and ALT concentrations returned to normal by day 18, and CPK levels returned to normal by day 28. The patient did not show signs of worsening psychotic symptoms after the cessation of clozapine; however, clozapine was restarted 2 weeks after discharge. The Drug Interaction Probability Scale (DIPS) score was 5, indicating a probable reaction between the clozapine and the ciprofloxacin (Brouwers et al, 2009).

b) Coadministration of ciprofloxacin and clozapine led to elevated clozapine plasma level in a 58-year-old male presented with delirium and suspected urinary tract infection or pneumonia. History included smoking, caffeine use, and treatment at a psychiatric facility with valproic acid, hydrochlorothiazide, clonazepam, and clozapine 300 mg per day. Lab results before the addition of ciprofloxacin indicated normal aspartate aminotransferase (AST; 10 units/L) and alanine aminotransferase (ALT; 13 units/L) levels, and his clozapine plasma concentration was 850 nanograms/mL. He was treated with IV ciprofloxacin 200 mg twice daily. AST and ALT levels slightly increased (46 and 74 units/liter, respectively), and ciprofloxacin was stopped after 2 days due to the suspected drug-drug interaction between ciprofloxacin and clozapine. Three days after the start of ciprofloxacin treatment, the patient's clozapine plasma concentration was 1720 ng/mL although he did not show signs of rhabdomyolysis or other clozapine-induced adverse effects. He was discharged after 5 days. The Drug Interaction Probability Scale (DIPS) score was 6, indicating a probable reaction between the clozapine and the ciprofloxacin (Brouwers et al, 2009).

3.5.1.I Citalopram

1) Interaction Effect: an increased risk of clozapine toxicity (sedation, seizures, hypotension)

2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as antidepressants, should be approached with caution (Prod Info Clozaril(R), 2002f). Five hospitalized patients who had been receiving a constant dose of clozapine for at least two weeks were started on citalopram 20 mg daily. Plasma clozapine levels were closely monitored for 14 days after the start of citalopram. Out of the five participants, one patient experienced an increase in their clozapine level from 0.70 mg/L to 1.16 mg/L. Plasma clozapine levels did not change in one patient, but the other three patients experienced a slight decline. Overall, clozapine mean serum levels were 1.13 mg/L prior to citalopram, 1.07 mg/L following one week of coadministration, and 0.93 mg/L following two weeks of concurrent administration. The ratio of clozapine to norclozapine remained much the same during the study. These results suggest that citalopram use is safe in patients receiving clozapine, although further studies are needed to verify this hypothesis (Taylor et al, 1998).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor the therapeutic efficacy of clozapine and for any evidence of toxicity, particularly when the daily clozapine dose exceeds 300 mg or 3.5 mg/kg. Lower clozapine dosage may be required in some clinical situations.

7) Probable Mechanism: inhibition by citalopram of N-dealkylation and N-oxidation of clozapine via the cytochrome P450 2D6 enzymatic pathway

8) Literature Reports

a) In a case report, Borba and Henderson describe a 39-year-old white male with a 20-year history of DSM-IV schizoaffective disorder, depressive type, who was referred for a trial of clozapine after failing various antipsychotic and antidepressant medications. Prior to switching to clozapine 400 mg/day, the patient's medications included lithium 900 mg/day, risperidone 3 mg/day, and bupropion 300 mg/day. Improvement in positive and negative symptoms occurred with clozapine. Citalopram dosage was 20 mg/day for two weeks then 40 mg/day. The patient experienced worsening sedation, new onset fatigue, enuresis, hypersalivation and mild confusion. The citalopram dose was reduced to 20 mg/day which resulted in complete resolution of symptoms within two weeks. The patient has continued with the combination of clozapine 400 mg/day and citalopram 20 mg/day with good results. The authors conclude that this case report suggests higher serum concentrations of clozapine may result when given with citalopram 40 mg/day. Inhibition of metabolism of clozapine occurs with citalopram 40 mg/day, resulting in higher serum concentrations compared with citalopram 20 mg/day. It has been documented that other selective serotonin reuptake inhibitors (SSRIs) elevate serum clozapine levels by inhibiting CYP1A2 and CYP3A3/4. Presumably, inhibition of CYP1A2 or CYP3A3/4 enzymes with citalopram may be dose related (Borba & Henderson, 2000).

3.5.1.J Dehydroepiandrosterone

1) Interaction Effect: reduced effectiveness of clozapine

2) Summary: Dehydroepiandrosterone (DHEA) levels within the normal range of 100 to 400 microgram/deciliter (mcg/dL) are conducive to optimal treatment of patients with psychosis (Howard, 1992a).

In case reports, patients have been resistant to antipsychotics when DHEA levels were elevated (Howard, 1992a). Patients being treated with clozapine should avoid DHEA supplementation.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of dehydroepiandrosterone (DHEA) and clozapine. If DHEA is elevated, treatment with dexamethasone 1 mg orally per day may be used to normalize DHEA levels.
7) Probable Mechanism: elevated dehydroepiandrosterone (DHEA) blood levels may reduce responsiveness to clozapine
8) Literature Reports
a) A 24-year-old female diagnosed with schizophrenia was resistant to daily doses of haloperidol 20 milligrams (mg), fluphenazine 40 mg, lithium carbonate 1200 mg, and lithium carbonate 900 mg plus thioridazine 300 mg. The patient appeared Cushinoid with moon face, acne, facial hair, abdominal hair, and a 40 pound weight gain in the previous 8 months. Dehydroepiandrosterone (DHEA) measured as part of an endocrine panel was 725 micrograms/deciliter (mcg/dL) (normal: 100 to 400 mcg/dL). Dexamethasone 1 mg orally at bedtime resulted in substantial improvement within one week. The patient appeared calmer, more alert with improved psychotic symptoms and ability to concentrate. At two weeks, a repeated DHEA level was within normal range (328 mcg/dL). The author concluded that elevated DHEA levels were associated with severe psychosis resistant to conventional antipsychotic therapy (Howard, 1992).
b) A 13-year-old male decompensated with a subsequent two-year period of emotional problems accompanied by heavy use of LSD, hashish, barbiturates, and alcohol. His mental status included bizarre, disorganized, delusional thinking, auditory and visual hallucinations, paranoia, lack of attention to personal hygiene, agitation, and combativeness. He was diagnosed with chronic paranoid schizophrenia; schizophrenia, chronic undifferentiated type, and schizoaffective disorder, excited type. He was resistant to daily doses of trifluoperazine 40 mg, chlorpromazine 400 mg, and imipramine 100 mg. He was also resistant to combination therapy with chlorpromazine 400 mg with thiothixene 80 mg, thioridazine 1000 mg, perphenazine 48 mg with lithium carbonate 1200 mg, clonazepam 4 mg, and carbamazepine 1200 mg daily. Baseline DHEA level exceeded 900 mcg/dL. A seven-day suppression test with dexamethasone 1 mg orally at bedtime resulted in a normal DHEA level of 200 mcg/dL. By day 5, psychosis improved and the patient was well-oriented, conversational, and was making good eye contact. Once dexamethasone was discontinued, rapid decompensation and florid psychosis ensued despite "substantial amounts of psychotropic medications." DHEA increased to 536 mcg/dL. The author concluded that elevated DHEA levels were associated with florid psychosis resistant to conventional antipsychotic therapy (Howard, 1992).

3.5.1.K Droperidol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Any drug known to have the potential to prolong the QT interval should not be used together with droperidol. Possible pharmacodynamic interactions can occur between droperidol and potentially arrhythmogenic agents such as neuroleptics that prolong the QT interval (Prod Info Inapsine(R), 2001).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of droperidol and agents that prolong the QT interval, such as neuroleptics, is contraindicated.
7) Probable Mechanism: additive cardiac effects

3.5.1.L Encainide
1) Interaction Effect: increased plasma concentrations of clozapine and or class I antiarrhythmic agents
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as class I antiarrhythmics, should be approached with caution (Prod Info Clozaril(R), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as class I antiarrhythmic agents, may require lower doses than usually prescribed for either clozapine or the class I antiarrhythmic.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.M Erythromycin
1) Interaction Effect: increased clozapine serum concentrations and risk of side effects (sedation, incoordination, slurred speech, seizures, hematologic abnormalities)
2) Summary: Coadministered erythromycin may inhibit clozapine metabolism, resulting in increased clozapine serum concentrations and clozapine toxicity (Prod Info Clozaril(R), 2002g; Cohen et al, 1996a; Funderburg et al, 1994a). Elevated levels of clozapine have been associated with somnolence, disorientation, dizziness, nausea, seizures, and leukocytosis. It is not known if similar effects will occur when

other macrolide antibiotics are given concomitantly with clozapine.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor patients for signs and symptoms of clozapine intoxication (sedation, incoordination, slurred speech, seizures, hematologic abnormalities). Doses of clozapine may need to be reduced when erythromycin is added to therapy. Alternatively, consider using azithromycin, which is less likely to interfere with clozapine metabolism, or a non-macrolide antibiotic.
7) Probable Mechanism: inhibition by erythromycin of hepatic cytochrome P450 3A4 metabolism of clozapine
8) Literature Reports
a) A 32-year-old male was being treated with clozapine 800 mg daily for schizophrenia. A week after beginning erythromycin 250 mg four times a day for pharyngitis, he experienced a tonic-clonic seizure followed by a period of postictal confusion. Shortly after the seizure, his clozapine serum concentration was 1300 mcg/mL. Both erythromycin and clozapine were discontinued. Two days later, low-dose clozapine therapy was initiated and gradually increased to the former dose. With a daily clozapine dose of 800 mg, his serum concentration was 700 mcg/mL (Funderburg et al, 1994).
b) A 34-year-old male with schizophrenia was stabilized for three months on a regimen of clozapine 600 mg daily, thiothixene 10 mg three times daily, divalproex sodium 1000 mg three times daily, and propranolol 20 mg three times daily. Three days before admission, he had started erythromycin 333 mg three times a day for a lower respiratory infection. The day after beginning erythromycin, the patient experienced increased somnolence, incoordination, and difficulty walking. Two days later, he had slurred speech, increasing disorientation, and incontinence of urine and stool. On admission, his white blood cell count was 31 X 10(9)/L and his clozapine serum concentration was 1150 mcg/L. Clozapine and erythromycin were discontinued, and intravenous acyclovir, ampicillin, and ceftriaxone were administered for suspected CNS infection. Four days later, treatment with clozapine was resumed, with the dose gradually increased to 600 mg daily. His clozapine serum concentration was 385 mcg/mL and his leukocyte count was normal. The authors postulated that the mechanism of this interaction was inhibition by erythromycin of P450 isoenzymes (including CYP2D6 and CYP3A) responsible for clozapine metabolism (Cohen et al, 1996).
c) Erythromycin was not found to inhibit the metabolism of a single dose of clozapine in twelve healthy male volunteers. Each participant received a single dose of clozapine 12.5 mg alone or in combination with erythromycin 1500 mg daily in a randomized, crossover manner. No significant differences were observed in the clozapine area under the concentration-time curve (AUC), half-life, maximum concentration (Cmax), time to Cmax (tmax), or apparent oral clearance. The authors suggest that cytochrome P450 3A4 (CYP3A4) only plays a minor role in clozapine metabolism (Hagg et al, 1999). However, erythromycin steady-state was not reached in this study, and doses of clozapine used are typically much higher than the starting dose of 12.5 mg.

3.5.1.N Flecainide
1) Interaction Effect: increased plasma concentrations of clozapine and or class I antiarrhythmic agents
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as class I antiarrhythmics, should be approached with caution (Prod Info Clozaril(R), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as class I antiarrhythmic agents, may require lower doses than usually prescribed for either clozapine or the class I antiarrhythmic.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.O Fluoxetine
1) Interaction Effect: an increased risk of clozapine toxicity (sedation, seizures, hypotension)
2) Summary: With concurrent administration of fluoxetine, increased serum clozapine concentrations have been reported (Prod Info Clozaril(R), 2002m; Centorrino et al, 1994a; Centorrino et al, 1996e; Spina et al, 1998a). Certain adverse effects associated with clozapine are dose-dependent, including sedation (Ayd, 1974) and seizures (Haller & Binder, 1990), and might be expected to occur with concurrent use of these medications.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor the therapeutic efficacy of clozapine and for any evidence of toxicity, particularly when the daily clozapine dose exceeds 300 mg or 3.5 mg/kg. Lower clozapine dosage may be required in some clinical situations.
7) Probable Mechanism: inhibition by fluoxetine of N-dealkylation and N-oxidation of clozapine via the cytochrome P450 2D6 enzymatic pathway
8) Literature Reports
a) Subjects receiving concurrent clozapine and fluoxetine had 76% higher serum clozapine

concentrations and 61% higher metabolite concentrations on average compared with controls receiving only clozapine. The mean ratio of total drug level (clozapine plus metabolites) to dose was 60% higher and the mean ratio of concentrations to dose was 75% higher in patients receiving clozapine and fluoxetine compared with concentrations in patients receiving clozapine alone (Centorrino et al, 1994).
b) A study evaluated the serum concentrations of clozapine and norclozapine, the major metabolite, when given in combination with the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, paroxetine, and sertraline. Eighty outpatients receiving clozapine all had been diagnosed with schizophrenia or major affective disorder, and 40 of these patients were receiving an SSRI in combination with clozapine. Of these 40 patients, 14 were receiving fluoxetine, 10 were receiving sertraline, and 16 were receiving paroxetine therapy. Among the patients on SSRI therapy, serum concentrations of clozapine and norclozapine were 41.1% and 44.8% higher, respectively, than in matched patients who were not receiving an SSRI. The ratio of clozapine plus norclozapine concentration to dose was also 37.7% higher in patients receiving SSRIs, indicating clozapine impaired clearance. The differences between the three SSRIs were minor, and the study groups were too limited for an accurate statistical comparison between the individual SSRIs (Centorrino et al, 1996d).
c) A 44-year-old male receiving fluoxetine and clozapine was found dead in his yard. The dates of the prescriptions and the number of tablets which remained indicated that he had been taking his medications as prescribed. Autopsy results showed a high therapeutic fluoxetine concentration (0.7 mcg/mL) and also a high therapeutic norfluoxetine concentration (0.6 mcg/mL). Fluoxetine found in his gastric contents also indicated that the medication was being taken as directed. The clozapine blood concentration was in the lethal concentration range (4.9 mcg/mL), but the clozapine in the gastric contents suggested that the clozapine was being taken as prescribed and that the patient had not consumed a large overdose amount prior to his death. Other pathological findings included pulmonary edema, visceral vascular congestion, paralytic ileus, gastroenteritis, and eosinophilia, which are all consistent with clozapine toxicity. The combined central nervous system, respiratory, and cardiovascular depression caused by these two drugs was sufficient to result in the death of this patient, and his death was ruled to be a clozapine overdose due to a fatal drug interaction (Ferslew et al, 1998).
d) Ten institutionalized schizophrenic patients stabilized on clozapine therapy for at least one month participated in a prospective study to evaluate the effect of fluoxetine on clozapine pharmacokinetics. Fluoxetine 20 mg once daily was administered for eight consecutive weeks. Mean plasma clozapine concentrations increased from 348 ng/mL to 550 ng/mL (58%) at week 8. Plasma levels of norclozapine were also increased by 36% (from 280 ng/mL to 381 ng/mL). Clozapine N-oxide levels rose from 89 ng/mL at baseline to 128 ng/mL, representing a 38% increase. However, these increases in clozapine and metabolite plasma concentrations were not associated with significant changes in efficacy or safety (Spina et al, 1998).

3.5.1.P Fluvoxamine

1) Interaction Effect: increased serum clozapine concentrations
2) Summary: Coadministration of clozapine with fluvoxamine has been reported to result in increased clozapine levels and worsening of psychotic symptoms (Prod Info Clozaril(R), 2002c; Chong et al, 1997a; Jerling et al, 1994a). Extrapyramidal symptoms have also been reported with this drug combination (Kuo et al, 1998a). Fluvoxamine, a potent inhibitor of CYP1A2, may decrease metabolism of clozapine, resulting in increased serum concentrations (Chong et al, 1997a; Wetzel et al, 1998a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Clinicians should be aware of a potential interaction between clozapine and fluvoxamine. If these drugs are given concurrently, monitor patients for increased serum clozapine concentrations, worsening of psychosis, and the development of extrapyramidal symptoms. Downward dosage adjustments of clozapine may be necessary.
7) Probable Mechanism: inhibition of cytochrome P450 1A2-mediated clozapine metabolism
8) Literature Reports
a) Therapeutic drug monitoring data showed higher clozapine concentration/dose ratios in three of four patients when concurrent fluvoxamine was used compared with clozapine alone. In two of these patients, clozapine concentrations were 5 to 10 times higher when fluvoxamine was coadministered. One patient experienced adverse effects, including sedation and urinary incontinence. Inhibition of the CYP1A2 enzyme by fluvoxamine was thought to be the mechanism in this drug interaction (Jerling et al, 1994).
b) One study presented two case reports in which addition of a selective serotonin reuptake inhibitor (SSRI) to clozapine therapy resulted in exacerbation of psychotic symptoms. The first patient, a 26-year old woman with schizophrenia, had been taking clozapine 175 mg per day. Other medications included propranolol for tachycardia and trihexyphenidyl for hypersalivation. After marked improvement in psychotic symptoms but continued compulsive behavior, sertraline 50 mg per day was added. Within four weeks, the patient's obsessive-compulsive symptoms and psychotic symptoms worsened. Plasma clozapine concentrations increased from 325 ng/mL before sertraline therapy to 695 ng/mL after sertraline therapy. Patient 2, a 24-year old woman with schizophrenia, was placed on a regimen of clozapine 500 mg per day which was later increased to 600 mg per day. After fluvoxamine 50 mg per day was started as adjunctive treatment, the patient's clozapine level rose from 1146 ng/mL before

fluvoxamine treatment to 2750 ng/mL after 28 days of fluvoxamine treatment. During this time the patient's compulsive symptoms remained unchanged, but psychotic symptoms worsened. The authors postulated that the worsening of psychotic symptoms could be due to SSRI inhibition of clozapine metabolism by cytochrome P450 isozymes, or an imbalance of the serotonergic and dopaminergic blockade caused by coadministration the two drugs (Chong et al, 1997).
c) Fluvoxamine significantly increased serum levels of clozapine in 16 patients with schizophrenia. Clozapine 2.5 to 3 mg/kg/day was given for 14 days, then fluvoxamine 50 mg daily was added for 14 days. Serum concentrations of clozapine and two metabolites were measured on days 1, 7, and 14. The increase in clozapine serum concentration was approximately 3-fold when given with fluvoxamine compared to clozapine alone (Wetzel et al, 1998).
d) Two patients experienced the onset of extrapyramidal symptoms (EPS) when fluvoxamine was added to an existing regimen that included clozapine. The first patient, a 46-year-old male, was stabilized on clozapine 400 mg daily for more than a year when fluvoxamine 25 mg daily was started. No signs of EPS were present before fluvoxamine therapy, and the clozapine plasma level was 686.2 ng/mL. Four days after fluvoxamine was initiated, the patient experienced rigidity and an Extrapyramidal Symptom Rating Scale (ESRS) score of 6. Three weeks later, the ESRS had increased to 8 and the clozapine level was 817.9 ng/mL. Fluvoxamine was discontinued, and the ESRS score and clozapine level decreased to 1 and 686.8 ng/mL, respectively, three weeks later. The second patient, a 46-year-old female, was maintained on clozapine 600 mg daily for more than two years with a plasma level of 1292.5 ng/mL and no signs of EPS. Fluvoxamine was started at 25 mg daily and six days later she developed moderate akathisia and tremors (ESRS of 7). Three weeks and six weeks into combination therapy, her clozapine plasma levels were 1438.2 ng/mL and 1548.9 ng/mL, respectively. The ESRS increased to 9, but the patient preferred the combination therapy due to the efficacy in alleviating psychotic symptoms (Kuo et al, 1998).

3.5.1.Q Fosphenytoin

1) Interaction Effect: decreased clozapine plasma levels associated with marked worsening of psychosis
2) Summary: Fosphenytoin is a prodrug of phenytoin and the same interactions that occur with phenytoin are expected to occur with fosphenytoin (Prod Info Cerebyx(R), 1999). Two case reports (Miller, 1991a) demonstrate that the addition of phenytoin to clozapine therapy can reduce steady-state plasma concentrations of clozapine by 65% to 85%, resulting in increased psychotic symptoms. Subsequent increases in clozapine dosage may be necessary.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: When adding fosphenytoin therapy to patients stabilized on clozapine, monitor patient closely for worsening of psychotic symptoms. If needed, increase the clozapine dose cautiously on basis of psychotic symptoms.
7) Probable Mechanism: increased metabolism of clozapine due to induction of cytochrome P-450 enzymes by fosphenytoin
8) Literature Reports
a) Two 29-year-old schizophrenic patients were stabilized on clozapine therapy. Their clozapine plasma concentrations decreased and psychotic symptoms markedly worsened after the addition of phenytoin for seizure activity. Phenytoin reduced clozapine plasma concentrations by 65% to 85% and necessitated an increase in clozapine dosage. The author's possible explanations for the decrease in clozapine plasma concentrations were a) induction of cytochrome P-450 enzymes by phenytoin, causing increased clozapine metabolism, b) decreased clozapine absorption due to phenytoin, and/or c) decreased protein binding of clozapine making more free drug available for metabolism. If the deterioration in clinical status was not related to the decrease in clozapine plasma levels, Miller's possible explanations were rebound psychosis after abruptly decreasing clozapine at the time of seizure activity, spontaneous fluctuation in illness, postictal exacerbation of preexisting psychosis, or postictal psychosis. The author recommends that clinicians closely monitor clozapine patients for worsening of psychotic symptoms when phenytoin is added to therapy (Miller, 1991).

3.5.1.R Guarana

1) Interaction Effect: increased clozapine levels, (leukopenia, agranulocytosis, and seizures) or increased guarana levels, (headache, insomnia, restlessness, diuresis, tachycardia)
2) Summary: The primary ingredient of guarana is caffeine. Caffeine inhibits CYP1A2, a major metabolic pathway for clozapine, thereby decreasing clozapine metabolism with resultant increased clozapine levels (Hagg et al, 2000c; Carrillo et al, 1998c). Patients who consume caffeine, especially acutely, may be at increased risk for clozapine toxicity. A case report has described an acute psychotic exacerbation in a patient taking clozapine who ingested caffeine acutely (Vainer & Chouinard, 1994c). Patients taking clozapine should take caffeine-containing products with caution to maintain a consistent intake.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Ideally, patients should avoid caffeine-containing products such as guarana as well as coffee, tea, and cola during clozapine treatment. Patients who are unwilling to discontinue caffeine intake

should be instructed to maintain consistent intake, and advised of the consequences of abrupt discontinuation (i.e., decreased clozapine levels and decreased effectiveness). Conversely, if a patient has been stabilized on clozapine and initiates a significant intake of caffeine, clozapine metabolism will likely be decreased, resulting in increased clozapine blood levels. Such patients will then be at increased risk for clozapine toxicity that may manifest as leukopenia, agranulocytosis, and seizures.

7) Probable Mechanism: caffeine component of guarana may inhibit metabolism of clozapine or clozapine may also inhibit the metabolism of caffeine

8) Literature Reports

a) In 12 healthy, nonsmoking subjects, caffeine intake increased clozapine area under the curve (AUC) following a single dose of clozapine in a randomized, crossover trial. Subjects refrained from other medication use during and 2 weeks prior to the study. Clozapine was administered as a 12.5 milligram (mg) dose. Dietary caffeine intake was allowed during the caffeine phase but not during the clozapine control phase, and was registered and estimated. Total caffeine intake during the caffeine phase ranged from 500-700 mg on day 1, and 400-1000 mg on day 2 (mean 550 mg/day). In one subject, clozapine AUC was doubled with concomitant caffeine intake, indicating individual variation. Overall, clozapine AUC was increased 19% as a result of caffeine intake (p equal to 0.05), with a range from -14% to +97%. Clozapine clearance was decreased 14% as a result of caffeine intake (p equal to 0.05), with a range from -49% to +7% (Hagg et al, 2000b).

b) In a study of 7 hospitalized patients (six men and one woman) averaging 31.0 +/- 5.5 years (range: 25-41 years) with a DSM-IV diagnosis of schizophrenia, clozapine levels decreased when caffeine was removed from the diet. All patients received monotherapy with clozapine at 271 +/- 102 milligrams/day (mg/day). Clozapine, norclozapine, and clozapine-N-oxide were assayed in plasma by high-performance liquid chromatography. Assays were conducted at three time points: with concomitant intake of caffeine, 5 days after caffeine withdrawal, and 2 weeks after rechallenge with habitual caffeine intake (mean caffeine intake: 296.4 +/- 354.8 mg; range: 150-1100 mg daily). Clozapine levels decreased from 486 nanograms/milliliter (ng/mL) during initial concomitant intake to 306 ng/mL (-47%) (p less than 0.02) 5 days after a caffeine-free diet. Clozapine-N-oxide levels decreased from 66 to 49 ng/mL (-31%) (p less than 0.03). All parameters returned to initial values after 2 weeks of resumption of caffeine intake (Carrillo et al, 1998b).

c) In a study of 14 healthy volunteers, clozapine metabolism was found to co-vary with CYP1A2 activity as determined by concomitant caffeine metabolism. Subjects were administered caffeine 150 mg as an oral tablet with clozapine 10 mg orally. N1- and N7-demethylation indices of caffeine correlated with clozapine clearance (r (s) equal to 0.89 and 0.85; p equal to 0.0013 and 0.0023, respectively). The authors conclude that 70% of the variance of clozapine clearance was accounted for by caffeine N3-demethylation reflecting CYP1A2 activity. There was no correlation between the area under the curve (AUC) for clozapine and the caffeine indices of xanthine oxidase (r(s) equal to -0.32) or N-acetyl transferase (rs equal to -0.33) activity (Bertilsson et al, 1994a).

d) Supraventricular tachycardia (SVT) was reported in a 66-year-old woman administered clozapine and caffeine while receiving electroconvulsive therapy (ECT). The patient suffered from severe, recurrent, affect psychosis necessitating ECT. During her first course of ECT, the duration of seizures decreased, requiring caffeine sodium benzoate 1000 mg (titrated from an initial dose of 125 mg). Although arrhythmias are a known side effect of ECT, none occurred, including none during augmentation with caffeine. Despite an initial response, the patient relapsed and was started on clozapine, titrated to a dosage of 300 mg daily. After one week, ECT was re-instituted with caffeine sodium benzoate titrated to 500 mg by the ninth treatment. The patient developed SVT with a heart rate of 180 beats/minute. The patient responded to verapamil 5 mg intravenously, converting to sinus tachycardia at 102 beats/minute and recovered uneventfully. Interestingly, 1000 mg intravenous caffeine augmentation was tolerated during the first course of therapy but 500 mg was not tolerated during the course of therapy accompanied by clozapine administration. This is suggestive of a caffeine-clozapine interaction (Beale et al, 1994a).

e) A 39-year-old man with paranoid schizophrenia with long-standing refractoriness to neuroleptics was treated with clozapine titrated up to 150 mg daily within 6 months of initiation. Clozapine was taken with two cups of coffee and the patient experienced a short-lasting acute psychotic exacerbation characterized by marked anxiety, agitation, insomnia, weakness, headaches, generalized stiffness, and intense paranoid ideation. These acute reactions were completely prevented when water replaced coffee. The acute episodes resumed when he took 200 mg/day clozapine with a caffeinated cola (40-50mg caffeine in each 12-ounce bottle). When taken with a decaffeinated cola beverage, the patient had no acute psychotic episodes (Vainer & Chouinard, 1994b).

3.5.1.S Lithium

1) Interaction Effect: weakness, dyskinesias, increased extrapyramidal symptoms, encephalopathy, and brain damage

2) Summary: An encephalopathic syndrome followed by irreversible brain damage has occurred in a few patients treated with lithium plus a dopamine-2 antagonist, particularly haloperidol. A causal relationship between these events and the concomitant administration of a dopamine-2 antagonist and lithium has not been established (Prod Info LITHOBID(R) slow-release oral tablets, 2005). Coadministration of lithium and a number of antipsychotic drugs has caused a wide variety of encephalopathic symptoms, brain damage, extrapyramidal symptoms, and dyskinesias in isolated case reports. In most cases, these effects have

occurred with therapeutic lithium levels (Amdisen, 1982; Prakash, 1982; Addonizio et al, 1988a). However, many series and trials have reported using such combinations with no severe adverse consequences (Goldney & Spence, 1986). The mechanism is not fully understood, but chronic lithium treatment decreases neostriatal dopaminergic activity, probably through a direct action on the G protein and the capacity of the G proteins, once activated, to stimulate adenyl cyclase (Carli et al, 1994). Hyperglycemic reactions have also occurred during combined phenothiazine and lithium use (Zall et al, 1968).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor patients closely for any signs of toxicity or extrapyramidal symptoms, especially if high doses of dopamine-2 antagonists, particularly haloperidol, and lithium are used. Serum lithium levels should be monitored periodically. Some clinicians advocate maintaining levels in the low therapeutic range.

7) Probable Mechanism: unknown

8) Literature Reports

a) Concomitant haloperidol and lithium therapy has resulted in symptoms of encephalopathy, confusion, extrapyramidal symptoms, and fever in several patients with mania (Cohen & Cohen, 1974; Loudon & Waring, 1976; Thomas, 1979). Irreversible neurological injuries have been reported (Sandyk & Hurwitz, 1983; Keitner & Rahman, 1984).

b) Seizures, encephalopathy, delirium, and abnormal EEG occurred in four patients during combined lithium and thioridazine therapy (Spring, 1979). Serum lithium levels were below 1 mEq/L at the time of the toxic reaction in all cases. All patients had previously tolerated lithium in combination with another phenothiazine. Three of these patients developed symptoms within eight days of initiating combination therapy.

c) The addition of lithium to neuroleptic therapy exacerbated extrapyramidal symptoms (EPS) in a small study (Addonizio et al, 1988). The patients had received at least five days of treatment with either oral thiothixene, haloperidol, or fluphenazine in mean doses of 607.5 chlorpromazine equivalents prior to initiation of the lithium and were experiencing drug-induced extrapyramidal symptoms. Oral lithium was added when clinically indicated in sufficient doses to achieve a therapeutic serum concentration. The maximum levels attained were 0.65 to 1.27 mEq/L. The EPS ratings increased in all ten patients following the addition of lithium. However, only three patients developed marked symptoms and no patient developed lithium toxicity. Significantly increased symptoms included gait, shoulder shaking, elbow rigidity, and tremor.

d) Ten patients treated with clozapine and lithium were studied (Blake et al, 1992). Of the ten patients, four experienced significant neurologic effects, including jerking of limbs, facial spasms and tics, tremor of hands and arms, tongue twitching, and stumbling gait. One of these also experienced delirium. These effects reversed when lithium was discontinued or given at a lower dose. On rechallenge, one of two patients suffered recurrence of symptoms. By keeping serum lithium no greater than 0.5 mEq/L, clozapine could be safely coadministered.

e) Chlorpromazine serum levels can be significantly reduced in the presence of lithium treatment. If used concurrently, abrupt cessation of lithium may result in rebound elevation of chlorpromazine levels, resulting in chlorpromazine toxicity. In patients on a lithium-chlorpromazine combination, abrupt withdrawal of the lithium may precipitate chlorpromazine cardiotoxicity. In this report, such toxicity was manifested as sudden ventricular fibrillation associated with prolongation of the QTc interval. Hypotension and EPS are also possible in this situation (Stevenson et al, 1989).

f) However, other data do not support that such adverse events are frequent or indeed causally related to combination therapy. Combination of dopamine antagonist antipsychotic drugs and lithium have been used successfully in many patients with manic-depressive illness. It has been proposed that the interaction may only become significant with very high doses of one or both drugs or with failure to discontinue dosing in the presence of toxic symptoms (Miller & Menninger, 1987).

g) A 69-year-old patient with oxygen-dependent chronic obstructive pulmonary disorder and a 25-year history of bipolar disorder was started on risperidone 3 mg for the treatment of new-onset auditory and visual hallucinations. She had also been maintained on a regimen of lithium (450 mg daily) for more than 10 years. In addition, she was given amantadine (100 mg twice daily) for tremor. Three weeks after the start of risperidone, the patient experienced a decline in mental status in addition to dizziness, worsening tremors, nausea and vomiting, polyuria, depression, and visual and auditory hallucinations. She was then admitted to the hospital for delirium. Her lithium serum level was 1.36 mEq/L at the time of the admission. All medications were discontinued. Although her lithium level decreased to 0.41 mEq/L, she continued to experience profound delirium, tremors, lethargy, and hallucinations for almost one week. After she started to respond to commands, she was restarted on lithium (300 mg at bedtime) because of the onset of mild hypomania. Five days later, she was discharged with a regimen of lithium and low-dose lorazepam for treatment of insomnia. It is suggested that delirium could have been caused by the concurrent use of lithium and risperidone. Other factors could also have caused delirium, such as the patient's serum lithium level and the underlying pulmonary pathology. In addition, amantadine, which facilitates the release of presynaptic dopamine and has a mild anticholinergic effect, may have contributed (Chen & Cardasis, 1996).

3.5.1.T Lorazepam

1) Interaction Effect: CNS depression
2) Summary: Two cases have been reported in which concomitant use of clozapine and lorazepam resulted in marked sedation, excessive salivation, and ataxia (Cobb et al, 1991). The manufacturer advises caution when giving clozapine with a benzodiazepine (Prod Info Clozaril(R), 1997).
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Monitor for signs of intoxication (eg, marked sedation, dizziness, ataxia, weakness, decreased cognition or motor performance, excessive salivation). If symptoms are present, reduce lorazepam dose.
7) Probable Mechanism: additive

3.5.1.U Lorcainide

1) Interaction Effect: increased plasma concentrations of clozapine and or class I antiarrhythmic agents
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as class I antiarrhythmics, should be approached with caution (Prod Info Clozaril(R), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as class I antiarrhythmic agents, may require lower doses than usually prescribed for either clozapine or the class I antiarrhythmic.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.V Mate

1) Interaction Effect: inhibition of clozapine metabolism (increasing the risk for leukopenia, agranulocytosis, and seizures) or inhibition of mate metabolism (headache, insomnia, restlessness, diuresis, tachycardia)
2) Summary: One of the primary ingredients of mate is caffeine. Caffeine inhibits CYP1A2, a major metabolic pathway for clozapine, thereby decreasing clozapine metabolism with resultant increased clozapine levels (Hagg et al, 2000a; Carrillo et al, 1998a). Patients who consume caffeine, especially acutely, may be at increased risk for clozapine toxicity. A case report has described an acute psychotic exacerbation in a patient taking clozapine who ingested caffeine acutely (Vainer & Chouinard, 1994a). Patients taking clozapine should take caffeine-containing products with caution to maintain a consistent intake.
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Ideally, patients should avoid caffeine-containing products such as mate as well as coffee, tea, and cola during clozapine treatment. Patients who are unwilling to discontinue caffeine intake should be instructed to maintain consistent intake, advising them of the consequences of abrupt discontinuation (i.e., decreased clozapine levels and decreased effectiveness). Conversely, if a patient has been stabilized on clozapine and initiates a significant intake of caffeine, clozapine metabolism will likely be decreased, resulting in increased clozapine blood levels. Such patients will then be at increased risk for clozapine toxicity that may manifest as leukopenia, agranulocytosis, and seizures.
7) Probable Mechanism: caffeine inhibits CYP1A2 activity and can increase clozapine levels; caffeine was also found to inhibit clozapine clearance
8) Literature Reports

a) In 12 healthy, nonsmoking subjects, caffeine intake increased clozapine area under the curve (AUC) following a single dose of clozapine in a randomized, crossover trial. Subjects refrained from other medication use during and 2 weeks prior to the study. Clozapine was administered as a 12.5 milligram (mg) dose. Dietary caffeine intake was allowed during the caffeine phase but not during the clozapine control phase, and was registered and estimated. Total caffeine intake during the caffeine phase ranged from 500-700 mg on day 1, and 400-1000 mg on day 2 (mean 550 mg/day). In one subject, clozapine AUC was doubled with concomitant caffeine intake, indicating individual variation. Overall, clozapine AUC was increased 19% as a result of caffeine intake (p equal to 0.05), with a range from -14% to +97%. Clozapine clearance was decreased 14% as a result of caffeine intake (p equal to 0.05), with a range from -49% to +7% (Hagg et al, 2000).

b) In a study of 7 hospitalized patients (six men and one woman) averaging 31.0 +/- 5.5 years (range: 25-41 years) with a DSM-IV diagnosis of schizophrenia, clozapine levels decreased when caffeine was removed from the diet. All patients received monotherapy with clozapine at 271 +/- 102 milligrams/day (mg/day). Clozapine, norclozapine, and clozapine-N-oxide were assayed in plasma by high-performance liquid chromatography. Assays were conducted at three time points: with concomitant intake of caffeine, 5 days after caffeine withdrawal, and 2 weeks after rechallenge with habitual caffeine intake (mean caffeine intake: 296.4 +/- 354.8 mg; range: 150-1100 mg daily). Clozapine levels decreased from 486 nanograms/milliliter (ng/mL) during initial concomitant intake to 306 ng/mL (-47%) (p less than 0.02) 5 days after a caffeine-free diet. In a similar fashion, clozapine-N-oxide levels decreased from 66 to 49 ng/mL (-31%) (p less than 0.03). All parameters returned to initial values after 2 weeks of resumption of caffeine intake (Carrillo et al, 1998).

c) In a study of 14 healthy volunteers, clozapine metabolism was found to co-vary with CYP1A2 activity as determined by concomitant caffeine metabolism. Subjects were administered caffeine 150 mg as an oral tablet with clozapine 10 mg orally. N1- and N7-demethylation indices of caffeine correlated with clozapine clearance (rs equal to 0.89 and 0.85; p equal to 0.0013 and 0.0023, respectively). The authors conclude that 70% of the variance of clozapine clearance was accounted for by caffeine N3-demethylation reflecting CYP1A2 activity. There was no correlation between the area under the curve (AUC) for clozapine and the caffeine indices of xanthine oxidase (rs equal to -0.32) or N-acetyl transferase (rs equal to -0.33) activity (Bertilsson et al, 1994).
d) Supraventricular tachycardia (SVT) was reported in a 66-year-old woman administered clozapine and caffeine while receiving electroconvulsive therapy (ECT). The patient suffered from severe, recurrent, affect psychosis necessitating ECT. During her first course of ECT, the duration of seizures decreased, requiring caffeine sodium benzoate 1000 mg (titrated from an initial dose of 125 mg). Although arrhythmias are a known side effect of ECT, none occurred, including none during augmentation with caffeine. Despite an initial response, the patient relapsed and was started on clozapine, titrated to a dosage of 300 mg daily. After one week, ECT was re-instituted with caffeine sodium benzoate titrated to 500 mg by the ninth treatment. The patient developed SVT with a heart rate of 180 beats/minute. The patient responded to verapamil 5 mg intravenously, converting to sinus tachycardia at 102 beats/minute and recovered uneventfully. Interestingly, 1000 mg intravenous caffeine augmentation was tolerated during the first course of therapy but 500 mg was not tolerated during the course of therapy accompanied by clozapine administration. This is suggestive of a caffeine-clozapine interaction (Beale et al, 1994).
e) A 39-year-old man with paranoid schizophrenia with long-standing refractoriness to neuroleptics was treated with clozapine titrated up to 150 mg daily within 6 months of initiation. Clozapine was taken with two cups of coffee and the patient experienced a short-lasting acute psychotic exacerbation characterized by marked anxiety, agitation, insomnia, weakness, headaches, generalized stiffness, and intense paranoid ideation. These acute reactions were completely prevented when water replaced coffee. The acute episodes resumed when he took 200 mg/day clozapine with a caffeinated cola (40-50mg caffeine in each 12-ounce bottle). When taken with a decaffeinated cola beverage, the patient had no acute psychotic episodes (Vainer & Chouinard, 1994).
f) Caffeine-induced reinforcement of dopaminergic enhancement may predispose some patients to exacerbations of psychosis. Caffeine elimination does not appear to improve or worsen schizophrenia. Chronic use of caffeine may lead to tolerance of adverse effects (Hughes et al, 1998).

3.5.1.W Nefazodone

1) Interaction Effect: increased clozapine plasma concentrations and clozapine toxicity (sedation, seizures, hypotension)
2) Summary: A study reported clozapine concentrations increased by an average of 19 mcg/L (4% of baseline) and norclozapine concentrations increased by 46 mcg/L (16% of baseline) (Taylor et al, 1999a). Concomitant administration of nefazodone resulted in decreased clearance resulting in elevated plasma concentrations of clozapine and norclozapine in a 40-year-old male. Seven days after initiation of treatment with nefazodone, the patient was increasingly anxious, increasingly dizzy and had mild hypotension. Nefazodone dose reduction resolved the patient's hypotension and other symptoms. Nefazodone may cause a modest, dose-dependent reduction in the clearance of both clozapine and norclozapine, with resultant increases in serum concentrations. The author suggests that this effect may be due to nefazodone inhibition of the cytochrome P450 3A4 isoenzyme. Caution is suggested when prescribing nefazodone concomitantly with clozapine (Khan & Preskorn, 2001a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor the therapeutic efficacy of clozapine and for any evidence of toxicity, particularly when the daily clozapine dose exceeds 300 mg or 3.5 mg/kg. Lower clozapine dosage may be required in some clinical situations.
7) Probable Mechanism: inhibition of cytochrome P450-mediated clozapine metabolism by nefazodone
8) Literature Reports
a) Concomitant administration of nefazodone may result in decreased clearance resulting in elevated plasma concentrations of clozapine and norclozapine. A 40-year-old male with a history of schizophrenia was successfully treated with clozapine and risperidone for several years. After experiencing persistent negative symptoms, nefazodone was initiated at 200 mg/day for seven days and then increased to 300 mg/day. Seven days later, the patient reported increased anxiety and dizziness. Physical exam revealed mild hypotension. An increase in plasma concentrations and decrease in clearance of both clozapine and norclozapine was documented. Nefazodone dose was reduced to 200 mg/day and, within one week, the patient's symptoms and hypotension resolved. Nefazodone may cause a modest, dose-dependent reduction in the clearance of both clozapine and norclozapine, with resultant increases in serum concentrations. The author suggests that this effect may be due to nefazodone inhibition of the cytochrome P450 3A4 isoenzyme. Caution is suggested when prescribing nefazodone concomitantly with clozapine (Khan & Preskorn, 2001).
b) Six patients receiving a stable dose of clozapine for at least two weeks were selected to begin nefazodone therapy at 100 mg twice daily for one week and then 200 mg daily for two more weeks. The

overall changes in clozapine pharmacokinetics were minimal when nefazodone was coadministered. Clozapine concentrations increased by an average of 19 mcg/L (4% of baseline) and norclozapine concentrations increased by 46 mcg/L (16% of baseline). Cytochrome P450 3A4 (CYP3A4) has been postulated to play a significant role in the metabolism of clozapine. Nefazodone is an inhibitor of CYP3A4. Because this study failed to show a significant interaction between these two drugs, CYP3A4 may play only an insignificant role in the metabolism of clozapine, or alternative routes of metabolism may be activated when CYP3A4 is inhibited (Taylor et al, 1999).

3.5.1.X Nicotine

1) Interaction Effect: decreased plasma clozapine levels
2) Summary: Concomitant administration of agents known to induce cytochrome P450 enzymes such as nicotine, may decrease the plasma levels of clozapine. This may result in a decrease in effectiveness of a previously effective clozapine dose (Prod Info Clozaril(R), 2002b).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Observe patients for signs and symptoms of decreased clozapine efficacy when nicotine is added to clozapine.
7) Probable Mechanism: induction of cytochrome P450-mediated clozapine metabolism by nicotine

3.5.1.Y Norfloxacin

1) Interaction Effect: increased clozapine serum concentrations
2) Summary: In vitro studies have shown that quinolones, including norfloxacin, are CYP1A2 inhibitors. Concomitant use with clozapine, a CYP1A2 substrate, may result in increased clozapine serum levels when given in usual doses. Caution is advised if these agents are used together. Monitor patients closely for signs and symptoms of clozapine intoxication (Prod Info NOROXIN(R) oral tablets, 2006).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of clozapine and norfloxacin may result in increased clozapine serum levels when given in usual doses. Use caution if these agents are used together and monitor patients closely (Prod Info NOROXIN(R) oral tablets, 2006). Signs and symptoms of clozapine intoxication may include sedation, incoordination, slurred speech, seizures, hematologic abnormalities.
7) Probable Mechanism: inhibition of CYP1A2-mediated clozapine metabolism

3.5.1.Z Paroxetine

1) Interaction Effect: an increased risk of clozapine toxicity (sedation, seizures, hypotension)
2) Summary: Increased serum concentrations of clozapine and its metabolites have been observed when it is given with serotonin reuptake inhibitors; however, other published reports describe paroxetine having no effect on serum concentrations of clozapine or its metabolites (Prod Info Clozaril(R), 2002l; Centorrino et al, 1996c; Wetzel et al, 1998c).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for signs of clozapine toxicity or serum concentrations when paroxetine is given concomitantly.
7) Probable Mechanism: decreased clozapine metabolism
8) Literature Reports

a) Paroxetine had no significant effect on serum levels of clozapine in 14 patients with schizophrenia. Clozapine 2.5 to 3 mg/kg/day was given for 14 days, then paroxetine 20 mg daily was added for 14 days. Serum concentrations of clozapine and two metabolites were measured on days 1, 7, and 14. Over the course of this study there was no significant difference in serum concentrations of clozapine or its metabolites (Wetzel et al, 1998b).

b) Serum concentrations of clozapine and norclozapine, the major metabolite, were evaluated when given in combination with the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, paroxetine, and sertraline. Eighty outpatients receiving clozapine all had been diagnosed with schizophrenia or major affective disorder, and 40 of these patients were receiving an SSRI in combination with clozapine. Of these 40 patients, 14 were receiving fluoxetine, 10 were receiving sertraline, and 16 were receiving paroxetine therapy. Among the patients on SSRI therapy, serum concentrations of clozapine and norclozapine were 41.1% and 44.8% higher, respectively, than in matched patients who were not receiving an SSRI. The ratio of clozapine plus norclozapine concentration to dose was also 37.7% higher in patients receiving SSRIs, indicating clozapine impaired clearance. The differences between the three SSRIs were minor, and the study groups were too limited for an accurate statistical comparison between the individual SSRIs (Centorrino et al, 1996b).

3.5.1.AA Perphenazine

1) Interaction Effect: increased plasma concentrations of clozapine and or the phenothiazine
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6,

such as phenothiazines, should be approached with caution (Prod Info Clozaril(R), 2002h).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as phenothiazines, may require lower doses than usually prescribed for either clozapine or the phenothiazine.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.AB Phenobarbital
1) Interaction Effect: decreased clozapine plasma levels associated with marked worsening of psychosis
2) Summary: Clozapine levels have been reported to be markedly elevated when phenobarbital therapy was discontinued (Lane et al, 1998a). Two case reports (Miller, 1991b) demonstrate that the addition of phenytoin, another enzyme inducer, to clozapine therapy can reduce steady-state plasma concentrations of clozapine by 65% to 85%, resulting in increased psychotic symptoms. Phenobarbital is capable of inducing multiple cytochrome P450 enzyme systems, including CYP1A2 and CYP3A4. Because clozapine is metabolized primarily by CYP1A2, a significant interaction with phenobarbital is possible (Lane et al, 1998a). A study conducted with 22 schizophrenic patients revealed 35% lower clozapine concentrations when given concurrently with phenobarbital, versus clozapine administration alone. In addition, the clozapine N-oxide metabolite concentrations were 64% higher, supporting the theory that phenobarbital induces clozapine metabolism (Facciola et al, 1998a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: When adding phenobarbital therapy to patients stabilized on clozapine, monitor patient closely for worsening of psychotic symptoms. If needed, increase the clozapine dose cautiously on the basis of psychotic symptoms. Conversely, when discontinuing phenobarbital, levels of clozapine may increase significantly.
7) Probable Mechanism: increased metabolism of clozapine due to induction of cytochrome P450 enzymes by phenobarbital
8) Literature Reports
a) A 26-year-old male schizophrenic patient was stabilized on clozapine 300 mg twice daily when he experienced a seizure. Phenobarbital 60 mg daily was initiated, and the clozapine dose was decreased to 400 mg daily over a period of two months because of the patient's stable mental status. One month after the clozapine dose was at 400 mg daily, the plasma levels for clozapine and its major metabolites, desmethylclozapine and clozapine-N-oxide were 346 ng/mL, 241 ng/mL, and 65 ng/mL, respectively. Phenobarbital therapy was tapered off over one month. Two and four weeks after the discontinuation of phenobarbital, the clozapine, desmethylclozapine, and clozapine-N-oxide levels were 608 ng/mL and 602 ng/mL, 253 ng/mL and 280 ng/mL, and 87 ng/mL and 96 ng/mL, respectively. The increase in the plasma levels of clozapine and its metabolites may be due to the fact that phenobarbital is an inducer of cytochrome P450 1A2 enzymes, and discontinuing phenobarbital slowed the metabolism of clozapine (Lane et al, 1998).
b) Steady-state plasma concentrations of clozapine and its two major metabolites were compared in 22 schizophrenic patients. Patients were distributed into two groups, either receiving clozapine monotherapy, or clozapine plus phenobarbital. The two groups were matched for age, sex, body weight, and daily dosage of clozapine. The group receiving combined therapy demonstrated mean plasma concentrations of clozapine which were 35% lower than the monotherapy group. In addition, the mean clozapine N-oxide metabolite concentrations were 64% higher in the combined therapy group. The authors concluded that these findings support the theory that phenobarbital induces metabolism of clozapine, and recommended careful monitoring of clozapine plasma concentrations when combined with phenobarbital (Facciola et al, 1998).

3.5.1.AC Phenylalanine
1) Interaction Effect: increased incidence of tardive dyskinesia
2) Summary: Taking phenylalanine concomitantly with certain neuroleptic drugs may exacerbate tardive dyskinesia (Gardos et al, 1992a). Abnormal phenylalanine metabolism in certain patients may lead to phenylalanine accumulation in the brain and in turn, reduced brain availability of other large neutral amino acids. This may interfere with the synthesis of catecholamines (Gardos et al, 1992a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if phenylalanine is administered with a neuroleptic agent. Monitor the patient closely for signs of tardive dyskinesia.
7) Probable Mechanism: reduced brain availability of other large neutral amino acids and interference with catecholamine synthesis
8) Literature Reports
a) Phenylalanine tended to increase the incidence of tardive dyskinesia in patients taking neuroleptics in an open study. Three groups of patients were studied: (1) patients with unipolar depression with

tardive dyskinesia (n=11), (2) patients with no tardive dyskinesia with current or past exposure to greater than or equal to 100 milligrams (mg) of a chlorpromazine equivalent for at least 3 months (n=10), and (3) patients with no tardive dyskinesia not previously exposed to a neuroleptic drug (n=10). Neuroleptic agents were taken during the study by 6 patients in group 1, and 5 patients in group 2. Patients received powdered phenylalanine 100 mg/kilogram dissolved in orange juice after an overnight fast. Blood samples were obtained just prior to phenylalanine administration and 2 hours after administration. Three patients in group 1 (with tardive dyskinesia) had the highest postloading phenylalanine plasma levels, this group as a whole had higher (though nonsignificant) mean phenylalanine levels than the other groups. Tardive dyskinesia score (measured using the Abnormal Involuntary Movements Scale (AIMS)) nonsignificantly increased in group 1. Postloading phenylalanine level and postloading AIMS scores were significantly positively correlated in group 1 (rs=0.347, p less than 0.05; Spearman correlation coefficient 0.543, p less than 0.05). Postloading phenylalanine level and baseline AIMS scores demonstrated a trend toward correlation (rs=0.246, p=0.092; Spearman correlation coefficient 0.679, p less than 0.05). In all patients, phenylalanine loading increased plasma phenylalanine levels approximately eight-fold, and plasma tyrosine increased 2.5 times as a result of conversion of phenylalanine to tyrosine. Plasma levels of competing large neutral amino acids such as tryptophan decreased slightly (Gardos et al, 1992).

3.5.1.AD Phenytoin

1) Interaction Effect: decreased clozapine plasma levels associated with marked worsening of psychosis
2) Summary: Concomitant administration of drugs known to induce cytochrome P450 enzymes may decrease the clozapine plasma levels, resulting in a decrease in effectiveness of a previously effective clozapine dose (Prod Info Clozaril(R), 2002e). Two case reports (Miller, 1991d) demonstrate that the addition of phenytoin to clozapine therapy can reduce steady-state plasma concentrations of clozapine by 65% to 85%, resulting in increased psychotic symptoms. Subsequent increases in clozapine dosage may be necessary.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: When adding phenytoin therapy to patients stabilized on clozapine, monitor patient closely for worsening of psychotic symptoms. If needed, increase the clozapine dose cautiously on basis of psychotic symptoms. Conversely, when phenytoin is discontinued, levels of clozapine may significantly increase.
7) Probable Mechanism: increased metabolism of clozapine due to induction of cytochrome P-450 enzymes by phenytoin
8) Literature Reports

a) Two 29-year-old schizophrenic patients were stabilized on clozapine therapy. Their clozapine plasma concentrations decreased and psychotic symptoms markedly worsened after the addition of phenytoin for seizure activity. Phenytoin reduced clozapine plasma concentrations by 65% to 85% and necessitated an increase in clozapine dosage. The author's possible explanations for the decrease in clozapine plasma concentrations were a) induction of cytochrome P-450 enzymes by phenytoin, causing increased clozapine metabolism, b) decreased clozapine absorption due to phenytoin, and/or c) decreased protein binding of clozapine making more free drug available for metabolism. If the deterioration in clinical status was not related to the decrease in clozapine plasma levels, Miller's possible explanations were rebound psychosis after abruptly decreasing clozapine at the time of seizure activity, spontaneous fluctuation in illness, postictal exacerbation of preexisting psychosis, or postictal psychosis. The author recommends that clinicians closely monitor clozapine patients for worsening of psychotic symptoms when phenytoin is added to therapy (Miller, 1991c).

3.5.1.AE Propafenone

1) Interaction Effect: increased plasma concentrations of clozapine and or class I antiarrhythmic agents
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as class I antiarrhythmics, should be approached with caution (Prod Info Clozaril(R), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as class I antiarrhythmic agents, may require lower doses than usually prescribed for either clozapine or the class I antiarrhythmic.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.AF Quinidine

1) Interaction Effect: increased plasma concentrations of clozapine
2) Summary: Coadministration of clozapine and quinidine should be approached with caution. Quinidine inhibits cytochrome P450 2D6, the isozyme that also metabolizes clozapine (Prod Info Clozaril(R), 2002k).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable

6) Clinical Management: Concomitant use of clozapine with drugs that inhibit cytochrome P450 2D6, such as quinidine, should be approached with caution.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of clozapine by quinidine.

3.5.1.AG Rifampin
1) Interaction Effect: subtherapeutic concentrations of clozapine and decreased clozapine efficacy
2) Summary: Concomitant administration of drugs known to induce cytochrome P450 enzymes may decrease the clozapine plasma levels, resulting in a decrease in effectiveness of a previously effective clozapine dose (Prod Info CLOZARIL(R) oral tablets, 2005). Case reports have shown subtherapeutic clozapine concentrations, with decreased clozapine efficacy during concomitant administration with rifampin (Joos et al, 1998; Peritogiannis et al, 2007).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Use caution when prescribing rifampin to patients who take clozapine as there have been reports of decreased clozapine levels and efficacy with concomitant use (Joos et al, 1998; Peritogiannis et al, 2007). Monitor clozapine levels when rifampin therapy is added, changed, or discontinued.
7) Probable Mechanism: induction of CYP450-mediated clozapine metabolism by rifampin
8) Literature Reports
a) A 33-year-old male schizophrenic patient was controlled on clozapine therapy for a few years when a chest X-ray revealed an opacity in the right lower quadrant. Rifampin, isoniazid, and pyrazinamide therapy was instituted for suspected tuberculosis. Within three and a half weeks, the patient became restless and sleepless, and clozapine serum concentrations were found to have significantly decreased to a subtherapeutic range. The dose of clozapine was increased from 400 mg daily to 600 mg daily without clinical improvement of the patient's psychosis. Rifampin therapy was substituted with ciprofloxacin when the opportunistic infection was found to be mycobacterium xenopi, and within three days the clozapine serum concentration increased back to a therapeutic level (Joos et al, 1998).
b) A case report described loss of clozapine efficacy following concomitant rifampin administration in a 30-year-old male schizophrenic. The patient had been initiated on clozapine for paranoid schizophrenia. Following problems with clozapine's adverse events (sedation, hypersalivation) at therapeutically successful doses, he had been controlled on clozapine therapy for 3 months at 300 mg daily when he was diagnosed with pulmonary tuberculosis. The patient was started on rifampin monotherapy at 600 mg daily. Two weeks later, the patient no longer complained of sedation and hypersalivation, but his psychotic symptoms worsened. At the end of the month, his psychopathology was as severe as when clozapine was first initiated. The dose of clozapine was increased to 550 mg daily with only mild improvement. However, the patient complained of no adverse events and was compliant with therapy. Following discontinuation of rifampin after 6 months of therapy, sedation and hypersalivation reappeared within 1 week. The dose of clozapine was not decreased to below 500 mg daily due to the marked improvement in the patient's psychotic symptoms. Induction of the CYP450-mediated clozapine metabolism was postulated as a probable mechanism. However, clozapine plasma levels were not available for confirmation due to laboratory difficulties (Peritogiannis et al, 2007).

3.5.1.AH Risperidone
1) Interaction Effect: decreased risperidone clearance
2) Summary: The manufacturer reports that clozapine may decrease risperidone clearance with chronic combined use (Prod Info Risperdal(R) Consta(TM), 2003).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor patients for increased adverse effects of risperidone when these drugs are given concurrently.
7) Probable Mechanism: unknown

3.5.1.AI Ritonavir
1) Interaction Effect: increased clozapine plasma concentrations and clozapine toxicity (sedation, seizures, hypotension)
2) Summary: When coadministering ritonavir with clozapine, a cytochrome P450 3A4 substrate, substantial increases in concentrations of clozapine may occur, possibly requiring a dosage reduction of clozapine (less than 50%) (Prod Info Norvir(R), 2000).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor the therapeutic efficacy of clozapine and for any evidence of toxicity, particularly when the daily clozapine dose exceeds 300 mg or 3.5 mg/kg. Lower clozapine dosage may be required in some clinical situations.
7) Probable Mechanism: inhibition of cytochrome P450 3A4-mediated clozapine metabolism by ritonavir

3.5.1.AJ Sertraline

1) Interaction Effect: an increased risk of clozapine toxicity (sedation, seizures, hypotension)

2) Summary: Coadministration of clozapine with sertraline has been reported to result in increased clozapine concentrations and worsening of psychotic symptoms (Prod Info Clozaril(R), 2002d; Chong et al, 1997c; Centorrino et al, 1996a). Clozapine is metabolized by the cytochrome P450 2D6 isoenzyme (CYP2D6). Sertraline is considered a moderate to weak inhibitor of this isoenzyme, in addition to being metabolized by CYP2D6 itself (Prod Info Zoloft(R), 1999; DeVane, 1994). Cytochrome P450 3A4 may also be involved with clozapine metabolism, and sertraline also inhibits CYP3A4 (Chong & Remington, 1998).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor the therapeutic efficacy of clozapine and for any evidence of toxicity, particularly when the daily clozapine dose exceeds 300 mg or 3.5 mg/kg. Lower clozapine dosage may be required in some clinical situations.

7) Probable Mechanism: decreased clozapine metabolism

8) Literature Reports

a) Two case reports revealed the exacerbation of psychotic symptoms with the addition of a selective serotonin reuptake inhibitor (SSRI) to clozapine. The first patient, a 26-year old woman with schizophrenia, had been taking clozapine 175 mg per day. Other medications included propranolol for tachycardia and trihexyphenidyl for hypersalivation. After marked improvement in psychotic symptoms but continued compulsive behavior, sertraline 50 mg per day was added. Within four weeks, the patient's obsessive-compulsive symptoms and psychotic symptoms worsened. Plasma clozapine concentrations increased from 325 ng/mL before sertraline therapy to 695 ng/mL after sertraline therapy. Patient 2, a 24-year old woman with schizophrenia, was placed on a regimen of clozapine 500 mg per day which was later increased to 600 mg per day. After fluvoxamine 50 mg per day was started as adjunctive treatment, the patient's clozapine level rose from 1146 ng/mL before fluvoxamine treatment to 2750 ng/mL after 28 days of fluvoxamine treatment. During this time the patient's compulsive symptoms remained unchanged, but psychotic symptoms worsened. The authors postulated that the worsening of psychotic symptoms could be due to SSRI inhibition of clozapine metabolism by cytochrome P450 isozymes, or an imbalance of the serotonergic and dopaminergic blockade caused by coadministration of the two drugs (Chong et al, 1997b).

b) A study evaluated the serum concentrations of clozapine and norclozapine, the major metabolite, when given in combination with the selective serotonin reuptake inhibitors (SSRI) fluoxetine, paroxetine, and sertraline. Eighty outpatients receiving clozapine all had been diagnosed with schizophrenia or major affective disorder, and 40 of these patients were receiving an SSRI in combination with clozapine. Of these 40 patients, 14 were receiving fluoxetine, 10 were receiving sertraline, and 16 were receiving paroxetine therapy. Among the patients on SSRI therapy, serum concentrations of clozapine and norclozapine were 41.1% and 44.8% higher, respectively, than in matched patients who were not receiving an SSRI. The ratio of clozapine plus norclozapine concentration to dose was also 37.7% higher in patients receiving SSRIs, indicating clozapine impaired clearance. The differences between the three SSRIs were minor, and the study groups were too limited for an accurate statistical comparison between the individual SSRIs (Centorrino et al, 1996).

3.5.1.AK St John's Wort

1) Interaction Effect: reduced clozapine efficacy

2) Summary: This interaction is based on in vitro information that St. John's Wort induced CYP1A2 enzymes, and a case report of a patient experiencing reduced blood theophylline concentrations and loss of efficacy (Nebel et al, 1999). Since clozapine is metabolized by CYP1A2 enzymes, like theophylline, clozapine may be similarly affected. If St. John's Wort and clozapine are taken together, their dosages should be consistently administered, recognizing that increased dosages of clozapine may be required. Discontinuation of St. John's Wort should be done carefully as side effects of clozapine may increase and dose reduction may be required.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Avoid concomitant use of clozapine with St. John's Wort. If patients elect to remain on St. John's Wort, they should maintain consistent dosing. Clozapine dosage may need to be increased. Patients should not discontinue St. John's Wort without first consulting their clinician as downward adjustments in clozapine dose may be necessary as well as monitoring for increased side effects of clozapine (e.g. decreased white blood cell count, increased salivation, orthostatic hypotension, tachycardia, sedation, seizures).

7) Probable Mechanism: induction of cytochrome P450 1A2 enzymes by St. John's Wort

3.5.1.AL Thioridazine

1) Interaction Effect: increased plasma concentrations of clozapine and or the phenothiazine

2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as phenothiazines, should be approached with caution (Prod Info Clozaril(R), 2002h).

3) Severity: moderate

4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concomitant use of clozapine with other drugs metabolized by cytochrome P450 2D6, such as phenothiazines, may require lower doses than usually prescribed for either clozapine or the phenothiazine.
7) Probable Mechanism: competitive substrate inhibition

3.5.1.AM Tramadol
1) Interaction Effect: an increased risk of seizures
2) Summary: Seizures have been reported in patients using tramadol. The manufacturer of tramadol states that combining neuroleptic medications with tramadol may enhance the risk of seizures (Prod Info Ultram(R), 1998).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution should be used if tramadol is to be administered to patients receiving neuroleptic therapy. If possible, avoid this combination, especially in patients with underlying conditions that might predispose to seizures.
7) Probable Mechanism: unknown

3.5.1.AN Venlafaxine
1) Interaction Effect: increased serum concentrations of clozapine and venlafaxine
2) Summary: Coadministration of clozapine with other drugs that are metabolized by cytochrome P450 2D6, such as antidepressants, should be approached with caution (Prod Info Clozaril(R), 2002i). The hepatic P450IID6 isoenzyme is apparently involved with clozapine metabolism. Venlafaxine is a weak inhibitor of this isoenzyme, in addition to being metabolized by cytochrome P450IID6 itself (Prod Info Effexor(R) XR, 1999; Ellingrod & Perry, 1994). With clozapine-venlafaxine coadministration, both agents may competitively inhibit the other's metabolism resulting in enhanced serum concentrations of both. Controlled studies are needed to validate these expectations and to document the clinical impact.
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor patients receiving concurrent clozapine and venlafaxine for signs of clozapine toxicity (dizziness, sedation, vomiting, hypotension, hematologic abnormalities) and venlafaxine toxicity (somnolence). Doses of either or both medications may need to be reduced.
7) Probable Mechanism: decreased clozapine and venlafaxine metabolism

3.5.1.AO Zotepine
1) Interaction Effect: increased risk of seizures
2) Summary: Zotepine used concurrently with neuroleptics may increase the risk of seizures (Prod Info Nipolept(R), 1994; Hori et al, 1992).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitoring for seizures is particularly important in those patients who: (1) are taking large doses of zotepine; (2) have a history of seizure disorders; (3) are of young age; or (4) have a past history of brain injury.
7) Probable Mechanism: unknown

3.5.2 Drug-Food Combinations

3.5.2.A Caffeine
1) Interaction Effect: an increased risk of clozapine toxicity (sedation, seizures, hypotension)
2) Summary: Caffeine may significantly inhibit the metabolism of clozapine when ingested in quantities ranging from 400 mg to 1000 mg daily. Caffeine is metabolized by cytochrome P450 1A2 (CYP1A2) enzymes, which are also responsible for the metabolism of clozapine. Because of dose-dependent caffeine pharmacokinetics, clozapine clearance is reduced when caffeine is ingested in moderate to high quantities (Prod Info Clozaril(R), 2002o; Hagg et al, 2000e).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Patients receiving clozapine therapy should be advised to avoid changes in habitual caffeine intake. Variations in caffeine ingestion should be considered when clozapine concentrations fluctuate.
7) Probable Mechanism: inhibition of cytochrome P450 1A2-mediated clozapine metabolism
8) Literature Reports
a) Twelve healthy nonsmoking male volunteers took part in an investigation to determine whether caffeine affects the pharmacokinetics of clozapine. In both phases of the randomized cross-over study,

single doses of clozapine 12.5 mg were administered after an overnight fast. During the caffeine phase, subjects received caffeine 100 mg as an oral tablet in addition to dietary caffeine intake. The mean caffeine ingestion was 550 mg daily. The clozapine area under the concentration-time curve (AUC) increased by 19% while the oral clearance decreased by 14% during the caffeine phase. However, in one subject, the AUC was nearly doubled, indicating that certain individuals may be more predisposed to this interaction than others (Hagg et al, 2000d).

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters

A) Therapeutic

1) Physical Findings

a) Decrease in signs and symptoms of psychoses

b) One small study (n=15) suggests that weight gain is a predictor of long-term (21 months) clozapine efficacy in treatment-resistant schizophrenic patients. Further studies are needed (Jalenques et al, 1996).

2) SERUM LEVEL

a) A decrease of 40% or more in the plasma level of clozapine from baseline values (baseline value determined when patient was free from positive symptoms for at least 4 months) for an extended period may be a predictor of relapse of schizophrenic psychosis. Eight of 12 patients who exhibited such "at-risk" plasma clozapine levels for more than 8.6 months during the study period (12% of the study interval) had relapses, while 2 of 11 patients who exhibited "at-risk" plasma levels for less than 8.6 months relapsed. Relapse rates were the same for the 2 groups for the first 2 years but after that increased rapidly in the group with the longer exposure to "at risk" plasma clozapine levels (Gaertner et al, 2001).

B) Toxic

1) Laboratory Parameters

a) AGRANULOCYTOSIS

1) A white blood cell (WBC) count and an absolute neutrophil count (ANC) should be obtained before beginning therapy. Do not start therapy if the WBC count is less than 3500 cells/cubic millimeter (mm (3)), if the ANC is less than 2000 cells/mm(3), or if the patient has a history of a myeloproliferative disorder or previous clozapine-induced granulocytopenia or agranulocytosis (Prod Info CLOZARIL(R) Tablets, 2005)). Sandoz Australia guidelines prohibit initiation of clozapine treatment in patients with a WBC count less than 3 x 10(9) cells/L and/or a neutrophil count less than 1.5 x 10(9) cells/L (Prod Info Clozaril(R) Australia, 1996).

2) Repeat WBC counts and ANC should be obtained weekly during the first 6 months of clozapine therapy . If the WBC count remains greater than or equal to 3500cells/mm(3) and the ANC remains greater than or equal to 2000cells/mm(3), then WBC and ANC may be monitored every 2 weeks for the next 6 months. Thereafter, if acceptable WBC counts and ANC have been maintained during the second 6 months of continuous therapy, WBC count and ANC can be monitored every 4 weeks. Weekly WBC counts and ANC should be continued for at least 4 weeks after the discontinuation of clozapine or until WBC count is greater than or equal to 3500/mm(3) and ANC is greater than or equal to 2000/mm (3) (Prod Info CLOZARIL(R) Tablets, 2005).

3) For interruptions in therapy, the following guidelines should be used for reinitiation of monitoring white blood cell counts (see below for guidelines on restarting therapy with specific abnormal blood counts) (Prod Info Clozaril(R), 2002):

Length of Therapy	Length of Break	History of Abnormal Blood Event (WBC less than 3500 cells/mm(3) or ANC less than 2000 cells/mm(3)	Recommended Monitoring (*reduced monitoring permitted only if all WBC counts are greater than or equal to 3500 and ANC is greater than or equal to 2000)
Less than 6 months	Less than 1 month	No	Continue 6 months of weekly testing
	Greater		

Less than 6 months	than 1 month	No	Restart 6 months of weekly testing
6 to 12 months	Less than 1 month	No	Weekly testing for 6 weeks, then return to every 2 weeks for 6 months*
6 to 12 months	Greater than 1 month	No	Weekly testing for 6 months, then return to every 2 weeks for 6 months*
Greater than 12 months	Less than 1 month	No	Weekly testing for 6 weeks, then return to every 4 weeks*
Greater than 12 months	Greater than 1 month	No	Weekly testing for 6 months, then every 2 weeks for 6 months, then return to every 4 weeks*

* Transition to reduced monitoring frequency only if all WBC >= 3500 AND >= 2000

4) If there is a substantial drop in WBC or ANC after starting therapy, a repeat WBC count and ANC should be done. A substantial drop is considered to be a single drop or cumulative drop within a 3-week period of 3000 more in the WBC count or 1500 or more of ANC. If the repeat WBC count and ANC reveal a total WBC count between 3000 and 3500 cells/mm(3) and an ANC above 2000 cells/mm(3), WBC counts and ANC should be monitored twice weekly (Prod Info CLOZARIL(R) Tablets, 2005); (Prod Info Clozaril(R) Australia, 1996).

5) If mild leukopenia (WBC count is 3000/mm(3) or greater but less than 3500/mm(3)) and/or mild granulocytopenia (ANC is 1000/mm(3) or greater but less than 1500/mm(3)) develop, monitoring should be twice-weekly until WBC count is greater than 3500/mm(3) and ANC is greater than 2000/mm(3). At this point, return to previous monitoring (Prod Info CLOZARIL(R) Tablets, 2005).

6) If moderate leukopenia (WBC count is 2000/mm(3) or greater but less than 3000/mm(3)) and/or moderate granulocytopenia (ANC is 1000/mm(3) or greater but less than 1500/mm(3)) develop, therapy should be interrupted. Monitor daily until WBC are greater than 3000/mm(3) and ANC is greater than 1500/mm(3), then twice-weekly until WBC is greater than 3500/mm(3) and ANC is greater than 2000/mm(3). Rechallenge may occur when WBC are greater than 3500/mm(3) and ANC is greater than 2000/mm(3). If rechallenged, monitor weekly for 1 year before returning to the usual monitoring schedule of every 2 weeks for 6 months and then every 4 weeks indefinitely (Prod Info CLOZARIL(R) Tablets, 2005).

7) If the total WBC count falls below 2000 cells/mm(3) and/or the ANC falls below 1000 cells/mm(3), clozapine therapy should be discontinued and patient should not be rechallenged. WBC counts and ANC should be monitored daily until WBC are greater than 3000 cells/mm(3) and the ANC returns to levels above 1500 cells/mm(3). Twice-weekly WBC counts and ANC should be taken until the total WBC counts return to levels above 3500 cells/mm(3) and ANC return to levels above 2000/mm(3). After WBC are greater than 3500/mm(3), monitor weekly (Prod Info CLOZARIL(R) Tablets, 2005).

b) PLASMA LEVEL

1) If an infectious, hypersensitivity, or inflammatory process is suspected, clozapine plasma levels should be closely monitored and the clozapine dose may need to be reduced by up to 50%. Toxic clozapine levels of 1100 to 2400 micrograms/liter (mcg/L) have been reported in several cases. However, toxic effects are possible at plasma levels of 1000 mcg/L and higher; and adverse effects are twice as likely at concentrations above 350 mcg/L (de Leon & Diaz, 2003; Haack et al, 2003).

2) Physical Findings

a) AGRANULOCYTOSIS

1) Monitor for any signs of infection including lethargy, weakness, fever, or sore throat (Prod Info CLOZARIL(R) Tablets, 2005).

b) CARDIOMYOPATHY

1) Signs and symptoms suggestive of cardiomyopathy include: exertional dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea and peripheral edema. If the diagnosis of cardiomyopathy is confirmed, discontinue clozapine unless the benefit to the patient clearly outweighs the risk (Prod Info CLOZARIL (R) Tablets, 2005).

c) DIABETES MELLITUS

1) Monitor patients with an established diagnosis of diabetes mellitus for worsening of glucose control during treatment with an atypical antipsychotic. Patients with risk factors for diabetes mellitus (ie, obesity, family history of diabetes) who are beginning treatment with atypical antipsychotics should undergo fasting blood glucose testing at the beginning of treatment and periodically throughout treatment (Prod Info CLOZARIL(R) Tablets, 2005).

d) HYPERGLYCEMIA

1) Monitor patients for signs and symptoms of hyperglycemia (ie, polydipsia, polyuria, polyphagia, and weakness). Patients who exhibit symptoms of hyperglycemia during atypical antipsychotic treatment should undergo fasting blood glucose testing. In some instances, hyperglycemia has resolved when the atypical antipsychotic was stopped; however, some patients required ongoing antidiabetic treatment despite discontinuation of the suspect medication (Prod Info CLOZARIL(R) Tablets, 2005).

e) MYOCARDITIS

1) If tachycardia develops, particularly during the first month of treatment, monitor closely for signs of

myocarditis. Patients who present with unexplained fatigue, dyspnea, tachypnea, fever, chest pain, palpitations, ST-T wave abnormalities, arrhythmias, or other signs or symptoms of heart failure should also be evaluated for myocarditis (Prod Info CLOZARIL(R) Tablets, 2005).

f) SEIZURE ACTIVITY

1) Patients who receive clozapine should be monitored for seizure activity, especially if there is a history of seizures or predisposing factors (Prod Info CLOZARIL(R) Tablets, 2005).

3) IMPORTANT NOTE

a) In the United States, the Clozaril(R) Patient Management System was phased out in May 1991 (Anon, 1991). Information on monitoring for agranulocytosis is available from the manufacturer (Prod Info CLOZARIL(R) Tablets, 2005).

4.2 Patient Instructions

A) Clozapine (By mouth)

Clozapine

Treats schizophrenia.

When This Medicine Should Not Be Used:
You should not use this medicine if you have had an allergic reaction to clozapine. You should not use this medicine if you have certain blood problems, a bone marrow disorder, uncontrolled seizures, bowel blockage, certain nervous system problems, or certain heart problems.

How to Use This Medicine:
Tablet, Dissolving Tablet

Your doctor will tell you how much of this medicine to use and how often. Your dose may need to be changed several times in order to find out what works best for you. Do not use more medicine or use it more often than your doctor tells you to.
You may take this medicine with or without food.
Drink extra fluids so you will pass more urine while you are using this medicine. This will keep your kidneys working well and help prevent kidney problems.

If a Dose is Missed:

If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next dose, wait until then to use the medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.
If for any reason you stop taking clozapine for longer than 2 days, do not start back on the same dose. Ask your doctor what dose you should take.

How to Store and Dispose of This Medicine:

Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after you have finished your treatment. You will also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, and herbal products.

There are many other drugs that can interact with clozapine. Make sure your doctor knows about all other medicines you are using.
Make sure your doctor knows if you are using fluvoxamine (Luvox®), paroxetine (Paxil®), cimetidine (Tagamet®), carbamazepine (Tegretol®), ciprofloxacin (Cipro®), erythromycin (Ery-tab®), phenytoin (Dilantin®), quinidine, or rifampin (Rifadin®, Rimactane®). Tell your doctor if you are using atropine, dicyclomine (Bentyl®), glycopyrrolate (Robinul®), hyoscyamine (Cystospaz®), propantheline (Pro-Banthine®), or scopolamine (Transderm Scop®).
Make sure your doctor knows if you are also using medicine to lower blood pressure (such as atenolol, hydrochlorothiazide [HCTZ], lisinopril, metoprolol, quinapril, Accupril®, Cozaar®, Diovan®, Lotrel®, Norvasc®, Toprol®, Zestril®) or medicine for heart rhythm problems (such as flecainide, encainide, propafenone, Rythmol®, Tambocor®).
Tell your doctor if you are also using other medicine to treat mental illness (such as chlorpromazine, haloperidol, risperidone, thioridazine, Haldol®, Mellaril®, Risperdal®, Thorazine®), medicine to treat anxiety (such as alprazolam, clonazepam, Ativan®, Valium®, Xanax®), medicine for nausea or vomiting (such as prochlorperazine, promethazine, Compazine®, Phenergan®), or medicine to treat depression (such as citalopram, venlafaxine, Celexa®, Effexor®).
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and allergy medicine, narcotic pain relievers, and sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:

Make sure your doctor knows if you are pregnant or breastfeeding, or if you ever had neuroleptic malignant syndrome (NMS). Tell your doctor if you have heart disease, liver disease, kidney disease, lung disease, an enlarged prostate, or a problem with your intestines. Tell your doctor if you have glaucoma, if you have ever had a head injury, or if you have a history of seizures.

Tell your doctor if you have diabetes, because this medicine may raise your blood sugar.

This medicine lowers the number of some types of blood cells in your body. Because of this, you may bleed or get infections more easily. To help with these problems, avoid being near people who are sick or have infections. Wash your hands often. Stay away from rough sports or other situations where you could be bruised, cut, or injured. Brush and floss your teeth gently. Be careful when using sharp objects, including razors and fingernail clippers.

This medicine can cause drowsiness or seizures. Avoid driving, swimming, climbing, using machines, or doing anything else that could be dangerous if you are not alert. You may also feel lightheaded when getting up suddenly from a lying or sitting position, so stand up slowly.

Your doctor will need to check your blood at regular visits while you are using this medicine. Be sure to keep all appointments.If you do not have your scheduled blood test, you may not be given your next week's supply of this medicine.

This medicine is not approved to treat behavior disorders in older people who have dementia. Using this medicine to treat this problem could increase the risk of death. This risk has not been shown for the approved uses of this medicine.

Tardive dyskinesia (a movement disorder) may occur and may not go away after you stop using the medicine. Check with your doctor right away if you have any of the following symptoms while taking this medicine: lip smacking or puckering, puffing of the cheeks, rapid or worm-like movements of the tongue, uncontrolled chewing movements, or uncontrolled movements of the arms and legs.

Make sure any doctor or dentist who treats you knows that you are using this medicine. You may need to stop using this medicine several days before having surgery or medical tests.

Do not stop using this medicine suddenly without asking your doctor. You may need to slowly decrease your dose before stopping it completely.

Possible Side Effects While Using This Medicine:

Call your doctor right away if you notice any of these side effects:

Blistering, red, or peeling skin rash.

Constant muscle movement that you cannot control, often in your face, lips, tongue, jaw, arms, or legs.

Dark-colored urine or pale stools.

Fever with chills, cough, sore throat, and body aches.

Fever with sweating, confusion, uneven heartbeat, or muscle stiffness.

Lightheadedness or fainting.

Nausea, vomiting, loss of appetite, or pain in your upper stomach.

Pain in your lower leg (calf).

Seizures.

Swelling in your hands, ankles, or feet.

Weak and rapid heartbeat, tiredness, chest pain, fever, trouble breathing.

Yellowing of your skin or the whites of your eyes.

If you notice these less serious side effects, talk with your doctor:

Blurred vision or vision problems.

Constipation.

Dry mouth, increased sweating.

Excess saliva or drooling.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Current users of atypical antipsychotic drugs (including clozapine) and typical antipsychotic drugs had a similar dose-dependent risk of sudden cardiac death, according to a retrospective cohort of 93,300 adult users of antipsychotic drugs and 186,600 matched controls. The study included patients age 30 to 74 years (mean 45.7 +/- 11.8 years) with similar cardiovascular risk at baseline who had at least one filled prescription and had 1 outpatient visit in each of the 2 preceding years. Sudden cardiac death was defined as occurring in the community and excluded deaths of patients admitted to the hospital, non-sudden deaths, deaths due to extrinsic causes, or causes not related to ventricular tachyarrhythmia. Current use was defined as the interval between the time the prescription was filled and the end of the day's supply. Low and high doses was defined as comparable to less than 100 milligrams (mg) of chlorpromazine, and doses comparable to chlorpromazine 300 mg or greater, respectively. The adjusted rate of sudden cardiac death (incidence-rate ratio) in current users of atypical antipsychotic drugs in 79,589 person-years was 2.26 (95% CI, 1.88 to 2.72, p less than 0.001) which was similar to the risk in current users of typical antipsychotic drugs in 86,735 person-years which was 1.99 (95% CI, 1.68 to 2.34, p less than 0.001). The risk of sudden cardiac death in current clozapine users in 4654 person-years was 3.67 (95% CI, 1.94 to 6.94, p less than 0.001). The risk of sudden cardiac death significantly increased with increasing dose in both the typical and atypical antipsychotic drug groups. In atypical antipsychotic use, the incidence rate ratio increased from 1.59 (95% CI, 1.03 to

2.46) in low-dose use to 2.86 (95% CI, 2.25 to 3.65) in high-dose use. To limit the effects of confounding of the study results, there was a secondary analysis performed in a cohort of patients matched by propensity score, which resulted in a similar risk of sudden death as the primary cohort analysis (Ray et al, 2009). In an editorial in The New England Journal of Medicine, it has been suggested that antipsychotic drugs continue to be used in patients with clear evidence of benefit, but in vulnerable populations with cardiac risk profiles (eg, elderly patients), there should be an age-dependent justification required prior to administration. It has also been suggested (although not formally tested) that ECGs be performed before and shortly after initiation of antipsychotic therapy to screen for existing or emergent QT interval prolongation (Schneeweiss & Avorn, 2009).
B) Clozapine is considered to be an atypical antipsychotic agent because of its limited propensity to cause extrapyramidal adverse effects often associated with other antipsychotic agents. The drug has demonstrated efficacy in the therapy of treatment-resistant schizophrenic patients (Conley, 1998; Bablenis et al, 1989).
C) Because of the higher risk of agranulocytosis, clozapine should be reserved for those treatment-resistant patients who have not responded to adequate trials of other antipsychotic agents (Prod Info Clozaril(R), 2002). Prior to the initiation of clozapine treatment, patients should be given at least two trials, each with a different standard drug product for schizophrenia at an adequate dose and for an adequate duration to insure safety and efficacy (Prod Info CLOZARIL(R) tablets, 2005). Clozapine may also be useful in patients who cannot tolerate other antipsychotics because of their associated extrapyramidal symptoms or in patients with tardive dyskinesia (Conley, 1998).
D) A number of studies by different investigators (Kane et al, 1988; Conley et al, 1988; Mattes, 1989) showed that treatment resistant schizophrenic patients responded to clozapine. Clozapine is a useful addition to therapy for long-term treatment of schizophrenia despite the risks and the need for frequent blood tests. Clozapine improves both positive and negative symptoms, and may improve organization of thoughts, and certain aspects of cognitive function (Conley, 1998).
See Drug Consult reference: FIRST- VS SECOND-GENERATION ANTIPSYCHOTIC AGENTS FOR SCHIZOPHRENIA

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) Clozapine is a neuroleptic agent with a tricyclic structure that is similar to the antidepressant dibenzepine.
2) Clozapine exhibits relatively potent serotonergic S2-, serotonergic S3-, alpha-1-adrenergic, histamine H1-, and muscarinic antagonism activity, and appears to induce preferential blockade of dopamine D1- (versus dopamine D2-) and Dy receptors in vivo (Kumar & Brecher, 1999; Shaikh et al, 1993; Fitton & Heel, 1990). Although the exact mechanism of action of clozapine has not been established, it has been suggested that the antipsychotic effects of clozapine might be related to central dopamine D1- or a combination of dopamine D1- and D2- receptor blockade with serotonergic, S2-receptor antagonism possibly playing a supplementary role. It has been postulated that the therapeutic effects of neuroleptics are mediated by mesolimbic and mesocortical dopaminergic pathways, while the neostriatum is associated with extrapyramidal side effects of these drugs. The low incidence of extrapyramidal side effects of clozapine might be attributable to a selective action on mesolimbic dopaminergic receptors (Fitton & Heel, 1990; Gudelsky et al, 1989).
3) A positive correlation was seen for the overall score on the Scale for the Assessment of Positive Symptoms (p=0.02) (and for the subscores for hallucination (p=0.02), and delusion (p=0.001)), and prolactin release as evoked by d-fenfluramine. The prolactin response to d-fenfluramine is a highly specific test of 5-HT function. The authors hypothesize that this 5-HT antagonism is therefore relevant to clozapine's efficacy in alleviating hallucinations and to the positive symptoms of schizophrenia (Jones et al, 1998).
4) A high degree of D2 dopamine receptor blockade by antipsychotic drugs is usually necessary for clinical response. However, about 30% of schizophrenic patients do not respond. To test this assumption, one author compared clinical response with central D2 dopamine receptor availability measured by I-123 iodobenzamide single photon emission tomography in two groups of schizophrenic patients. Six patients on typical antipsychotics showed poor therapeutic response despite D2 receptor blockade. Significant clinical improvement occurred in all 10 patients on the antipsychotic clozapine, but at a lower level of D2 blockade by the drug. These findings suggest a more complex relation between D2 blockade and clinical efficacy than was previously thought (Pilowsky et al, 1992).
5) Positron emission tomography (PET) has been used for quantification of D2 receptor occupancy induced by antipsychotic drugs in the basal ganglia. The classical neuroleptics have their antipsychotic effects mediated by a blockade of D2 receptors. In clozapine-treated patients, the D2 receptor occupancy was low, thus classifying it as an "atypical" antipsychotic. PET and the radioligand (11-C)N-methylspiperone were used to determine cortical 5-HT2 receptor occupancy in three psychotic patients treated with 125, 175, and 200 milligrams of clozapine daily (Nordstrom et al, 1993). The results show that clinical treatment with clozapine induces a high 5-HT2 receptor occupancy in psychotic patients at a low clozapine dosage. In another study, a very high degree of serotonin 5-HT(2a) receptor blockade was found with both clozapine and high doses of chlorpromazine. This lead the authors to hypothesize that it is actually the difference in the dopamine D(2) receptor occupancy that accounts for the differences in clinical properties between clozapine and the typical antipsychotic drugs (Trichard et al, 1998).
6) Dopamine D4 receptors have greater affinity for clozapine than for any other antipsychotic. The D4 receptor occurs in at least 7 polymorphic forms and can be rapidly identified. These polymorphic forms may influence the receptor to clozapine. It is concluded that response to clozapine is not pharmacogenetically dichoromous (Shaikh et al, 1993).
7) Results on assessing clozapine's effect on dopamine and serotonin metabolites have been inconsistent. The dopamine-serotonin relationship was reappraised in a group of 19 neuroleptic refractory and intolerant

schizophrenic patients treated with clozapine (Szymanski et al, 1993). Only a small change in cerebrospinal fluid and plasma homovanillic acid (HVA) and 5-hydroxyindoacetic acid (5-HIAA) levels was found. The modest relationship between HVA and 5-HIAA and treatment response suggests the involvement of both neurotransmitters in the pathophysiology of schizophrenia.
8) The plasma levels of dopamine, norepinephrine, and their metabolites homovanillic acid (HVA) and 3-methoxy-4-hydroxyphenylglycol (MHPG) were measured in eight schizophrenic patients treated with clozapine for 12 weeks. They found the plasma levels of HVA and MHPG decreased during the initial weeks of treatment in responders, but not in nonresponders; and plasma levels of dopamine and norepinephrine increased in both responders and nonresponders to clozapine treatment (Green et al, 1993).
9) It has been well established with other clinically active neuroleptics that elevations in serum prolactin occur (Langer et al, 1977; Meltzer et al, 1978). This is believed to result from the blockade of dopamine receptors in the pituitary. One study reported that the degree of acute prolactin elevation in man following the parenteral administration of a neuroleptic drug appeared to be highly correlated with the milligram for milligram antipsychotic potency (Langer et al, 1977). However, various reports (Sachar et al, 1976; Nair et al, 1979; Meltzer et al, 1979) have shown that clozapine may cause no increase or only a minimal increase of prolactin secretion in man. They observed a 17% elevation in basal serum prolactin levels but also saw a marked inhibition of growth hormone response to 0.75 mg apomorphine which was administered subcutaneously in 6 of 7 subjects. In one study, data suggest that clozapine can block dopamine receptors responsible for apomorphine growth hormone effect without effecting the pituitary dopamine receptors involved in prolactin response. Ten schizophrenic male patients received a maximum clozapine dose of 100 mg/day and a total of 200 mg during the 3-day study (Nair et al, 1979). Based on this, one author has suggested that this may indicate a difference between the hypothalamic and pituitary dopamine receptors (Meltzer et al, 1979).
10) Clozapine differed from haloperidol, chlorpromazine, and fluphenazine in that clozapine produced only a brief elevation of serum prolactin but a marked increase of corticosterone and ACTH. Moreover, it increased the activity of tuberoinfundibular dopamine neurons. In view of the lack of propensity of clozapine to induce extrapyramidal symptoms, it has been hypothesized that clozapine selectively affects mesocorticolimbic dopamine function (Owen et al, 1993; Gudelsky et al, 1989). It has been proposed that schizophrenia may involve a dysregulation of 5-HT-2 and D-2-mediated neurotransmission and that a more normal balance in serotonergic and dopaminergic eurotransmission is at least partially restored by clozapine (Meltzer, 1989).
11) Clozapine is highly anticholinergic and stimulates higher human brain anticholinergic activity than risperidone (Tracy et al, 1998). However, it may still be less than other traditional neuroleptics such as haloperidol.

B) REVIEW ARTICLES
1) Optimization of clozapine therapy has been reviewed (Naber, 1999; Conley, 1998a).
2) The pharmacokinetics and pharmacodynamics of clozapine have been reviewed in patients with schizophrenia (Jann et al, 1993).
3) Clozapine and agranulocytosis has been reviewed (Pirmohamed & Park, 1997; Feldman, 1996).
4) Clozapine for the treatment of psychosis in Parkinson's disease has been reviewed (Auzou et al, 1996).
5) A comprehensive review of clozapine's use in treating movement disorders, including Parkinson's disease, essential tremor, Huntington's disease and tardive dyskinesia is available (Factor & Friedman, 1997).
6) Evaluations of the clinical studies on new drug therapies for treatment-resistant schizophrenia (Kane, 1996) and schizoaffective disorder have been reviewed (Keck et al, 1996).
7) The use of atypical antipsychotic medications in adults (Markowitz et al, 1999; Brown et al, 1999), older adults (Chan et al, 1999), and children (Lewis, 1998; Toren et al, 1998) has been reviewed.
8) A review on clozapine use in schizophrenia has been included in the American Psychiatric Association's Practice Guideline for the Treatment of Patients with Schizophrenia (Anon, 1997).
9) Review articles evaluating the adverse effect profiles of clozapine (Miller, 2000) along with other antipsychotic agents in the elderly (Masand, 2000) and in bipolar disorder (Zarate, 2000) are available.
10) A review of published, comparative data of clozapine versus other atypical antipsychotic agents is available (Fleischhacker, 1999).

4.5 Therapeutic Uses

Aggressive behavior

Anorexia nervosa

Bipolar disorder

Borderline personality disorder

Catatonia

Cognitive function finding

Dementia

Depression

Excessive thirst

Extrapyramidal disease

Gilles de la Tourette's syndrome

HIV infection - Psychotic disorder

Movement disorder, Involuntary

Multiple sclerosis - Psychotic disorder

Parkinson's disease

Parkinson's disease - Psychotic disorder

Postpartum psychosis

Schizoaffective disorder, Refractory

Schizoaffective disorder - Suicidal behavior, Recurrent

Schizophrenia, Treatment-resistant

Schizophrenia - Suicidal behavior, Recurrent

Tardive dyskinesia

4.5.A Aggressive behavior

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Appears beneficial for the treatment of aggressive behavior
Sedative effects may contribute to the beneficial results

3) Adult:

a) Clozapine was effective in lessening frequency and intensity of aggressive and SELF-DESTRUCTIVE BEHAVIOR in 80% of 42 non-psychotic hospitalized patients. Patients received clozapine 15 to 75 milligrams daily (Balassa et al, 1971).

4.5.B Anorexia nervosa

See Drug Consult reference: ANOREXIA NERVOSA - DRUG THERAPY

4.5.C Bipolar disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence is inconclusive
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective in patients with bipolar or schizoaffective disorder with refractory MANIA in uncontrolled trials
Effective in patients with psychotic bipolar disorder in a small prospective cohort study

3) Adult:

a) Clozapine was effective and relatively well tolerated in acute and long-term treatment of patients with psychotic bipolar disorder who have not responded to conventional pharmacotherapies. A small cohort prospective study included 34 bipolar disorder patients with psychotic features who were treated with clozapine at flexible doses (25 mg to 600 mg per day) over a 24-month period. All patients showed significant improvement 24 months from intake as assessed by the Brief Psychiatric Rating Scale and the Clinical Global Impressions-Severity of Illness scale (p less than 0.001). Such improvement was significantly greater among patients with bipolar disorder than with schizophrenia (p less than 0.05). For patients with bipolar disorder with psychotic features who are resistant to or intolerant of usual treatment options, clozapine may be an effective alternative (Ciapparelli et al, 2000).

b) Clozapine was more effective in a group of schizophrenic patients with bipolar features (n=41) than those without bipolar features (n=19) (Cassano et al, 1997). In an open, follow-up study, both groups received clozapine 75 to 600 milligrams (mg) and other drugs necessary for the relief of their symptoms. The average dose after 1 year for the bipolar group was 261 mg versus 298 mg for the group without bipolar features. After 12 months of treatment, according to the Brief Psychiatric Rating Scale scores, patients with bipolar features tended to respond significantly better (p less than 0.001 versus baseline) than those without bipolar features (p less than 0.05 versus baseline).

c) An open-label trial demonstrated the effectiveness of add-on clozapine for up to 1 year in treatment-resistant patients with a history of mania. Subjects had diagnoses of schizoaffective disorder, bipolar type (n=12) or bipolar I disorder (n=26) and were randomized to add-on clozapine or optimization of standard therapy for 1 year. The average daily dose of clozapine differed by diagnosis: 623 milligrams (mg)/day for schizoaffective and 234 mg/day for bipolar I (p=0.008). The dropout rates due to intolerance were 16% for clozapine and 47% for standard therapy (who were then crossed over to clozapine). Five of six psychiatric rating scales showed significantly greater improvement with add-on clozapine versus standard therapy alone. The Brief Psychiatric Rating scale score improved at least 30% from baseline to 6 months in 82% and 57% of clozapine recipients and the comparator group, respectively. Clozapine's additive efficacy permitted significant decreases in the concurrent medication regimen. Individuals without psychotic features benefited from clozapine to a similar degree as those with psychotic features. As evaluated via somatic complaint questionnaire, the incidence and severity of adverse effects did not differ between groups. Lack of blinding may have introduced bias into the study; further research is warranted (Suppes et al, 1999).

d) Clozapine has been shown to be an effective therapy for treatment of mania in resistant bipolar disorder patients (N=10) and schizoaffective disorder patients (N=15). In a prospective, open trial of clozapine, patients who had either a poor response or were intolerant of lithium, failed at least 2 neuroleptics, and failed either valproate or carbamazepine were treated with clozapine. Marked improvement (defined as a 50% improvement in score) was noted in 72% of the patients on the Young Mania Rating Scale and 32% exhibited marked improvement on the Brief Psychiatric Rating Scale (Calabrese et al, 1996).

e) In a non-controlled study, clozapine was used in the treatment of 17 bipolar disorder patients who had either failed or were intolerant to trials of lithium, valproate, carbamazepine, or neuroleptics. The study suggests that clozapine monotherapy is an effective mood stabilizer that reduces the number of affective episodes and rehospitalizations in patients with severe refractory bipolar illness. A controlled study is needed (Zarate et al, 1995).

f) Another author reported marked improvement in seven patients treated with clozapine for bipolar disorder, characterized by dysphonic mania with psychotic features and chronic disability refractory to standard treatments and anticonvulsants. During the subsequent follow up (3 to 5 years) most of the patients sustained gains in psychosocial function, and 6 of the 7 patients remaining on clozapine required no further hospitalization (Suppes et al, 1992).

4) Pediatric:

a) A 15-year-old male adolescent with severe treatment refractory bipolar disorder with psychotic features experienced a dramatic improvement in mood and psychotic symptoms when clozapine 300 milligrams (mg) per day was added to lithium 1350 mg per day. He had previously been treated with combinations of lithium, carbamazepine, and typical neuroleptics. Ten days after starting clozapine in combination with lithium, clinical improvement in restlessness, insomnia, and speech became apparent. Three weeks after beginning clozapine, Brief Psychiatric Rating Scale decreased from 74 to 37, Children Global Assessment Scale changed from 25 to 72, and Clinical Global Impression Severity of Illness subscale decreased from 7 to 3. Side effects included mild sedation and an increase in body weight. The patient continued to do well after nine months of therapy with lithium and clozapine 200 mg daily (Masi & Milone, 1998).

4.5.D Borderline personality disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Lead to improvements in symptomatology in a small sample of patients with borderline personality disorder

3) Adult:

a) Clozapine treatment greatly reduced the need for hospitalization in 7 patients with borderline personality

disorder (BPD), whether or not they had comorbid psychosis. Retrospective analysis of the records of patients who had been hospitalized for BPD and treated with clozapine revealed that, for the 7 patients who were initially discharged on clozapine treatment (average dose 334 milligrams/day; range 175 to 550 milligrams/day), state hospital use was reduced from an average of 110 days per year to 6.3 days per year (Brickman et al, 2002).

b) Preliminary data from a case series (n=7) of severe borderline personality disorder suggest that clozapine (mean dose: 421 milligrams/day) may decrease self- mutilation and aggressive behavior. The subjects were Caucasian females (mean age: 37 years) at state psychiatric facilities who were refractory to various combinations of psychotropic medications. Investigators reviewed patients' medical records to compare outcomes during 1 year before versus 1 year after the index date of clozapine initiation. Average Global Assessment of Functioning scores improved 48%; hospital privileges increased 60%; concurrent anxiolytic and antipsychotic medication use decreased 67% and 89%, respectively; and injuries to staff and peers dropped 93%. Both the number and duration of seclusion and restraint incidents (as proxy measures for self-mutilation) were reduced by 91% to 98% (Chengappa et al, 1999).

c) In a 4-month, open-label trial, low-dose clozapine improved symptomatology in patients (n=12) with severe borderline personality disorder (BPD) (Benedetti et al, 1998). BPD patients with severe psychotic-like symptoms who had failed a previous therapeutic program received clozapine starting at 12.5 milligrams (mg) and titrated to the lowest effective dose. Clozapine doses ranged from 25 to 100 mg/day (mean 43.8 mg/day). Since no available rating scale is specifically structured to assess changes in symptomatology of BPD patients, outcomes were difficult to measure. Utilizing the 5 items from the Brief Psychiatric Rating Scale relating to psychotic-like symptoms (items 4, 8, 11, 12, 15), 6 of 12 patients showed a 50% reduction in score after 1 month and 8 of 12 patients showed a 50% reduction after 4 months.

4.5.E Catatonia

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective in 1 case report

3) Adult:

a) A 56-year-old woman with organic catatonia following frontal lobe injury responded to clozapine therapy (Rommel et al, 1998). Her catatonia manifested as restlessness, and rhythmic repetitive movements of her arms with rocking motion of her trunk. She did not respond to phenothiazines or haloperidol decanoate. Clozapine 350 milligrams made her symptoms slowly resolve. After 2 months, clozapine was withdrawn and symptoms reappeared 2 days later. Clozapine was successfully restarted and then gradually withdrawn after 1 year without relapse.

4.5.F Cognitive function finding

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

May improve cognitive function in schizophrenic patients

3) Adult:

a) Data from 12 published trials suggest that clozapine may improve some aspects of cognitive functioning in schizophrenia. The author of a review article reported positive results with clozapine for the following parameters: verbal fluency (6 of 7 studies); attention/ psychomotor speed (7 of 10 studies); verbal learning and memory (5 of 8 studies). The latter component is important in terms of employment potential. Mixed or equivocal results were noted for executive functioning, verbal working memory, and visual learning and memory. Two trials showed no cognitive improvements with clozapine (McGurk, 1999).

b) One study reported improved cognitive function, especially attention and verbal fluency in both treatment-resistant and non-treatment-resistant schizophrenia after clozapine therapy, for at least six weeks, with major improvement noted at six months. The data also suggest that clozapine treatment was superior to typical neuroleptics in improving cognitive function in schizophrenia (Lee et al, 1994).

4.5.G Dementia

See Drug Consult reference: BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA

4.5.H Depression

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive

Recommendation: Adult, Class III
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Conflicting data regarding the efficacy of clozapine in patients with depression (Ayd, 1974; Nahunek et al, 1973)

3) Adult:
a) A case of recurrent psychotic depression, unresponsive to multiple drug therapies and electroconvulsive therapy, responded to clozapine treatment (Dassa et al, 1993).
b) A 45-year-old woman with psychotic depression responded to a trial of clozapine instituted because of concomitant parkinsonian syndrome. The patient was resistant to conventional therapy (Parsa et al, 1991).

4.5.I Excessive thirst

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
May be of value in reducing the severity of psychogenic polydipsia in patients with chronic schizophrenia
Unknown mechanism of action (Lee et al, 1991)

3) Adult:
a) Patients with polydipsia-hyponatremia syndrome improved after switching to clozapine therapy from their previous conventional neuroleptic agent (Canuso & Goldman, 1999). In an open study, 10 patients with polydipsia and hyponatremia (plasma sodium less than 125 milliequivalents/liter (mEq/L) were switched to clozapine therapy at 300, 600, and 900 milligrams (mg). Two patients were unable to tolerate the clozapine 900-mg dose. However, plasma osmolality normalized with clozapine 300 mg/day and the 2 higher doses were found to have no further effect. Plasma osmolality rose an average of 15.2 milliosmoles/kilogram above the patients' mean values. No fluid restrictions were required during the 18 weeks of clozapine therapy.

4.5.J Extrapyramidal disease

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
May ameliorate classic neuroleptic-induced extrapyramidal syndrome consisting of concurrent chronic akathisia, parkinsonism, TARDIVE DYSKINESIA and dystonia.

3) Adult:
a) Drug-induced LARYNGEAL DYSTONIA resolved after clozapine was substituted for other drugs being used to treat schizophrenia in a 26-year-old woman. The woman presented in a florid psychotic state and with acute laryngeal dysfunction, including dysphonia and dysphagia. She showed no other extrapyramidal side effects. Her current medications (thioridazine, haloperidol, and zuclopentixol) were tapered and discontinued. She was given 2 other regimens (chlorpromazine and biperiden; promethazine, gabapentin, and biperiden), which were discontinued because of persistence of dysphonia and psychosis. Six days after admission she had an episode of food asphyxiation. Clozapine was prescribed, with the dose increased to 550 milligrams/day over 3 weeks. Improvement of laryngeal dysfunction was evident in the first week. Vocalization problems eventually resolved. There was also improvement of her psychotic state. The authors attributed the improvement in dystonia to a direct action of clozapine as an antidystonic agent (Lanzaro et al, 2001).
b) Clozapine successfully managed severe, disabling neuroleptic-induced blepharospasm, a rare form of tardive dystonia, in a case series (n=4). With slow titration to doses ranging from 100 to 200 milligrams (mg)/day, clozapine completely suppressed the symptoms of blepharospasm within 3 to 4 months with no psychotic exacerbations. In one instance, discontinuation of clozapine "unmasked" blepharospasm, which disappeared again with the reinstitution of clozapine. Clozapine continued to control blepharospasm for up to 5 years of follow-up (Levin & Reddy, 2000).
c) In an 18-week open, prospective trial, clozapine demonstrated efficacy in the treatment of all 3 co-existing aspects of neuroleptic-induced extrapyramidal syndrome in 20 patients with refractory schizophrenia. By the end of the study, clozapine (average dose 209 milligrams/day) significantly improved akathisia, parkinsonism and tardive dyskinesia by 78%, 69% and 74%, respectively, as assessed by standard rating scales (p less than 0.0001). Subjects also experienced statistical improvement in scores for psychosis, depression and anxiety (Spivak et al, 1997a).
d) Cases of disabling tardive dystonia and psychosis not responding well to antipsychotics, but

progressively improving with clozapine treatment were presented (Bassitt & Neto, 1998a; Raja et al, 1996a; Friedman, 1994a).
e) Case studies have shown that low doses of clozapine (mean dose 26.4 milligrams at bedtime) were found effective for the relief of nocturnal akathisia in nine patients with Parkinson's disease (Linazasoro et al, 1993). Three patients also experienced a marked improvement in resting tremor and five patients experienced a resolution of the confused state accompanying the akathisia.
f) Tardive dyskinesia response to clozapine was variable in 37 patients treated over a 4-year period. It was thought that those with the dystonic subtype may be effectively treated with clozapine (Lieberman et al, 1989). A review of 8 published studies reported similar findings (Lieberman et al, 1991).

4.5.K Gilles de la Tourette's syndrome

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Effective in 1 case report of TICS

3) Adult:
a) A 30-year-old man with acute paranoid syndrome and a long history of tics achieved total remission of his tics with clozapine therapy (Schmider, 1998). He was considered to have a nongenetic form of tics with multiple simple motor tics of the limbs and face, and simple and complex vocal tics. Clozapine was increased to 350 milligrams/day with a stable remission reported 1 month later.

4.5.L HIV infection - Psychotic disorder

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Pilot data suggest possible benefit with clozapine

3) Adult:
a) Clozapine was efficacious in relieving both psychotic and neuroleptic-induced parkinsonian symptoms in an open-label pilot study of 6 patients with acquired immunodeficiency syndrome. After a one-week neuroleptic washout, subjects received clozapine 12.5 milligrams (mg)/day with upward titration. Psychotic symptoms decreased significantly from baseline to month 3 of treatment at a mean dose of 27 mg/day, as evidenced by changes in average Brief Psychiatric Rating Scale scores (54 to 24 points, p less than 0.001) and Clinical Global Impression scores (2 to 8 points, p less than 0.001). The mean Unified Parkinson's Disease Rating scale also improved significantly over the same time period (14.5 to 3.4 points, p less than 0.001). The only adverse effect was leukopenia necessitating clozapine discontinuation and colony stimulating factor support (n=1) (Lera & Zirulnik, 1999).

4.5.M Movement disorder, Involuntary

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
May reduce involuntary movements in patients with Huntington's disease or Parkinson's disease
Also effective in 1 case of paroxysmal hemidystonia, 4 cases of generalized dystonia and 1 case of Meige syndrome, although adverse effects were often treatment-limiting

3) Adult:
a) A case series of generalized dystonia (n=4) and Meige syndrome (n=1) refractory to multiple prior medications revealed beneficial effects with clozapine. The patients ranged in age from 23 to 65 years with illness durations of 2 to 20 years. The Burke-Fahn-Marsden Evaluation Scale for Dystonia showed average 32% and 38% improvements on movement score and disability score, respectively. Patients' visual analog scale ratings of subjective feelings of normalcy increased from a mean of 10% to 37% on clozapine. Three of five patients reported some degree of pain relief with clozapine. Efficacy was not found to be dose-related. Despite gradual dose titration, clozapine-induced adverse effects were problematic, necessitating dose reductions in all patients and discontinuation in one patient (Karp et al, 1999).
b) In a small number of patients (n=18) with Huntington's disease or Parkinson's disease, clozapine reduced or suppressed involuntary movements. Doses received were between 12.5 and 500 milligrams/day. Patients with Huntington's disease experienced improvement in 3 to 5 weeks; patients with Parkinson's

experienced improvement in 1 to 2 days (Bonuccelli et al, 1994; Bennett et al, 1994; Friedman & Lannon, 1990; Caine et al, 1979). Patients with Gilles de la Tourette's syndrome and atypical persistent DYSKINESIAS failed to improve.

c) In an open-label study of 10 patients with idiopathic Parkinson's disease and LEVODOPA-INDUCED DYSKINESIAS, clozapine in a mean daily dose of 30 milligrams (mg) significantly reduced dyskinesias as rated by the Abnormal Involuntary Movements Scale (AIMS). Patients had a mean duration of Parkinson's symptoms of 11 years, a Hoehn & Yahr score of three, and had taken levodopa for 10 years. Improvement in the AIMS began 1 week after initiation of therapy and continued for 4 months of observation. Beginning in the third week of clozapine therapy, significant improvements in AIMS score was seen at 30, 60, 90, 120, and 150 minutes following levodopa dose, when compared to baseline conditions (p less than 0.05). Six patients experienced optimal response to clozapine (decrease in AIMS score by more than 60%). No significant differences were noted over the four months in the United Parkinson's Disease Rating Scale III. One patient experienced orthostatic hypotension and was taken off clozapine and four other patients experienced sedation and were not titrated above a clozapine 25-mg dose. No patients experienced neutropenia (Pierelli et al, 1998).

d) A 54-year-old woman with delayed-onset PAROXYSMAL HEMIDYSTONIA improved with clozapine therapy (Maurer et al, 1998). She also had fixed dystonia of the foot in combination with symptomatic epilepsy and secondary generalized seizures. Her paroxysmal involuntary movements had begun at the age of 15 years and occurred intermittently every other day for less than 1 minute. She was wheelchair-bound and treated with anticonvulsants. There was no response to tiapride or levodopa. After clozapine 75 milligrams (mg) was initiated, there were no paroxysmal movements for the next 10 days. Clozapine had no effect on the fixed dystonia. She was maintained on clozapine 125 mg daily.

e) Clozapine effectively reduced mixed tremor (both resting and postural) associated with Parkinson's disease in a prospective trial (n=17). A single 12.5 milligram (mg) clozapine dose resulted in moderate to marked tremor improvement in 88% of subjects. Chronic use over 15.5 months at an average dose of 45 mg/day revealed sustained efficacy without adverse effects. Initial sedation disappeared with continued use of clozapine. The authors recommend a trial of clozapine for the treatment of mixed tremor in Parkinson's disease before resorting to neurosurgery (Bonuccelli et al, 1997).

f) Clozapine was administered in increasing doses of 25, 50, and 150 milligrams/day for three weeks to a group of five patients with abnormal involuntary movements of Huntington's chorea (Bonuccelli et al, 1994). They reported reduction of chorea, with moderate to marked reduction of abnormal involuntary movements and improvement of activities of daily living. No significant side effects were noted. In another case report, gradual and modest improvement in depression and psychotic symptoms were noted but there was no effect on abnormal movements (Sajatovic et al, 1991).

g) The effect of clozapine on resting tremor in five parkinsonian patients who previously failed to respond to standard parkinsonian drugs was studied. One patient had dramatic improvement of severe resting tremors and four others had significant improvement. The clozapine dose ranged between 12.5 to 25 milligrams daily. The tremor controlling effects of clozapine were observed within 1 to 2 days. The most common adverse effects were weight gain and sedation. One patient had worsening of his shuffling gait (Friedman & Lannon, 1990). Another author reported that the addition of clozapine therapy (100 to 200 milligrams/day) to six patients with advanced Parkinson's disease suppressed the L-DOPA-induced dyskinesias without altering relief of Parkinsonism. (Bennett et al, 1994).

4.5.N Multiple sclerosis - Psychotic disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective in treating psychosis associated with multiple sclerosis in 1 case

3) Adult:

a) The successful use of clozapine to treat psychosis (paranoid delusions, thought disorder, and deterioration of self-care) in a 43-year-old woman with multiple sclerosis (MS) was described (Chong & Ko, 1997). Similar to other MS patients, this woman had a poor response to typical neuroleptics and easily developed extrapyramidal symptoms. Over 1 year on clozapine 125 milligrams/day, she improved her Brief Psychiatric Rating Scale score from 71 to 34. However, she did have 3 attacks of weakness in her lower limbs that lasted 1 to 2 days each time.

4.5.O Parkinson's disease

See Drug Consult reference: PARKINSON'S DISEASE - DRUG OVERVIEW

4.5.P Parkinson's disease - Psychotic disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb

Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Clozapine therapy has been effective in treating psychosis associated with Parkinson's disease
Clozapine did not worsen Parkinson's symptoms
See Drug Consult reference: THERAPY OF PSYCHOTIC DISTURBANCES IN PARKINSONIAN PATIENTS

3) Adult:

a) The authors of a review article recommend clozapine as the second-line antipsychotic for patients with Parkinson's-associated psychosis. Two controlled trials plus numerous open studies and case reports attest to the efficacy and safety of clozapine for this indication. Daily clozapine doses are much lower (6.25 to 50 milligrams) than required for schizophrenia. The major advantage of clozapine in this setting is its lack of parkinsonian adverse effects. However, the risk of agranulocytosis coupled with the expense and inconvenience of weekly blood monitoring prompted the authors to consider quetiapine as the first-line antipsychotic despite relatively limited efficacy data (Friedman & Factor, 2000).

b) In a double-blind, placebo-controlled trial (n=60), clozapine improved drug-induced psychosis in patients with Parkinson's disease, even though the patients continued to take antiparkinsonian drugs. Clozapine did not worsen the symptoms of Parkinson's disease and actually decreased motor tremor. Subjects (mean age: 71 years, disease duration: 10 years) were randomized to 4 weeks of therapy with either placebo or clozapine, titrated from 6.25 milligrams (mg)/day to a maximum of 50 mg/day. At a mean dose of 25 mg/day, clozapine produced significant improvements in the Clinical Global Impression (CGI) scale (in comparison to placebo ,p less than 0.001) and the Brief Psychiatric Rating Scale (BPRS) (in comparison to placebo, p=0.02) Changes (from baseline) in total score and motor score on the Unified Parkinson's Disease Rating Scale (UPDRS) were not statistically different for clozapine and placebo, but the improvement in tremor score was significantly better with clozapine than with placebo (p=0.02). Three patients withdrew from the clozapine group: one because of leukopenia, one because of myocardial infarction, and one because of sedation. Three patients in the placebo group discontinued the study (Anon, 1999a). In a 12-week, open label extension of this trial, 52 patients were all given clozapine, starting with 6.25 mg per day, with no ceiling dose. Those patients who had received placebo in the double-blind portion of the trial improved to a degree similar to that of the patients originally randomized to clozapine. Improvement was maintained in both groups through week 16. Clozapine did not worsen motor scores. The average dose of clozapine was 28.8 mg/day, similar to that in the double-blind portion of the study, when there was a 50 mg ceiling. Of the original 60 patients, 6 patients died and another 12 were hospitalized. The most common cause was pulmonary (usually pneumonia). The relation of the high morbidity and mortality to clozapine treatment is uncertain (Factor et al, 2001).

c) In a retrospective chart review, 172 patients with Parkinson's disease at 4 centers benefited from clozapine (mean dose 31.4 milligrams; mean duration 16.7 months) (Trosch et al, 1998a). Visual hallucinations that were present in 114 of the patients improved in 89.5% with clozapine therapy. Auditory hallucinations, present in 9 patients had an 89% improvement rate. Delusions in 64 patients showed an improvement rate of 91%. Clozapine was discontinued in 40 patients (23%) due to adverse affects. Agranulocytosis was not seen at any site.

d) Patients with Parkinson's disease (n=49) received clozapine (16 to 31 milligrams/day) with 3 of 49 patients (6%) having complete relief of their psychotic symptoms. Improvement was seen in 76% of patients at 3 months, in 70% at 6 months, in 84% at 12 months, and in 70% at 18 months. Similar results were reported in 18 additional patients with Parkinson's disease and psychosis (Wagner et al, 1996; Lew & Waters, 1993; Wolk & Douglas, 1992; Friedman & Lannon, 1989).

e) An 81-year-old man with zoophilia, intermittent hypersexuality, and impulsivity due to his dopaminergic medication for Parkinson's disease benefited from clozapine therapy (Fernandex & Durso, 1998). He was receiving carbidopa/levodopa with pergolide with good control of his parkinsonian symptoms when the hypersexuality began. Clozapine 12.5 milligrams was begun and titrated up to 50 mg with no recurrence of the hypersexuality or impulsivity and a decrease in hallucinations.

f) In an open-label study, it was concluded that clozapine can improve hallucinations and psychosis without compromising motor function in patients with advanced Parkinson's disease (PD). Eleven patients with PD complicated by psychosis received clozapine long term (Kahn et al, 1991).

g) Mixed results on the efficacy and side effects of clozapine were reported in five parkinsonian patients with levodopa-induced hallucinations (Pfeiffer et al, 1990a).

4.5.Q Postpartum psychosis

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Postpartum psychosis has been successfully treated in one case report

3) Adult:

a) Postpartum psychosis was managed successfully in a lactating 28-year-old patient with mastitis. The psychosis was treated initially with zuclopenthixol 600 milligram (mg) that produced severe extrapyramidal

side effects, and the mastitis was treated with bromocriptine 7.5 mg. Bromocriptine was discontinued and zuclopenthixol was gradually replaced with clozapine at a final dose of 200 milligrams. Both the psychosis and mastitis resolved within a few days. Because clozapine does not cause long-term increases in serum prolactin, the authors recommend it as the drug of choice in postpartum psychosis in lactating patients with mastitis (Kornhuber & Weller, 1991). However, breast-feeding during clozapine treatment is not recommended by the manufacturer; clozapine has been detected in breast milk in animal studies (Prod Info Clozaril(R) Australia, 1996).

4.5.R Schizoaffective disorder, Refractory

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Combination therapy with lithium and clozapine was beneficial for patients with schizoaffective disorder but not for schizophrenic patients

Effective in patients with schizoaffective disorder in a small, prospective cohort study

3) Adult:

a) The addition of lithium to maintenance clozapine therapy was beneficial for patients with treatment-resistant schizoaffective disorder but not for schizophrenic patients. In a randomized, placebo-controlled, double-crossover study, hospitalized patients with treatment-resistant schizoaffective disorder (n=10) or schizophrenia (n=10) and on a stable clozapine regimen (range, 100 to 800 milligrams (mg)/day) received alternating augmentation therapy with lithium (initial, 300 mg every 12 hours; target plasma level, 0.5 mmol/L) or placebo for four 4-week phases. At the end of the first crossover, lithium treatment was associated with significantly better improvements on the Clinical Global Improvement (CGI) scale and the Positive and Negative Symptom Scale (PANSS) total score in schizoaffective patients (p less than or equal to 0.01 and p less than or equal to 0.02, respectively). The PANSS Negative score was significantly more improved with lithium therapy in the schizoaffective patients at the end of both crossover periods (p less than or equal to 0.01). Significant improvements in CGI and PANSS scores were not found with clozapine and lithium combination therapy in patients with schizophrenia, however, two (20%) of the patients in this group developed transient neurological impairments, typical of lithium toxicity, during the first week of lithium administration. Overall, safety data showed significant increases in absolute neutrophil counts and total white blood cell counts with each phase of lithium treatment. Commonly reported adverse effects included hypersalivation, sedation, tremor, and polyuria (Small et al, 2003).

b) Clozapine was effective and relatively well tolerated in acute and long-term treatment of patients with schizoaffective disorder who have not responded to conventional pharmacotherapies. A small cohort prospective study included 26 schizoaffective disorder patients who were treated with clozapine at flexible doses (25 mg to 600 mg per day) over a 24-month period. All patients showed significant improvement 24 months from intake as assessed by the Brief Psychiatric Rating Scale and the Clinical Global Impressions-Severity of Illness scale (p less than 0.001). Such improvement was significantly greater among patients with schizoaffective disorder than with schizophrenia (p less than 0.05). For patients with schizoaffective disorder who are resistant to or intolerant of usual treatment options, clozapine is an effective alternative (Ciapparelli et al, 2000).

4.5.S Schizoaffective disorder - Suicidal behavior, Recurrent

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Shown to be effective in decreasing the number of suicide attempts in patients with schizophrenia and schizoaffective disorder at high risk for suicide

3) Adult:

a) In the International Suicide Prevention Trial (InterSePT), clozapine was shown to be more effective than olanzapine in reducing suicidal behavior in high-risk, adult, patients with schizophrenia or schizoaffective disorder. Men and women between the ages of 18 to 65 years, at high risk of committing suicide, were recruited to participate in this 2-year, prospective, randomized, international, parallel group, study. The endpoints in this study included significant suicide attempts (including completed suicides) or hospitalization due to imminent suicide risk (type 1 events) or ratings of "much worse" or "very much worse" on the Clinical Global Impression of Suicide Severity (CGI-SS) scale (type 2 events). Of the total sample of 980 patients enrolled in the study, 62% (609) were diagnosed as having schizophrenia and 38% (371) were diagnosed with schizoaffective disorder. Twenty-seven percent (263) of these patients were considered treatment resistant. The patients were divided into two treatment groups (clozapine or olanzapine) and did not differ

significantly in terms of age, sex, race, diagnosis, treatment resistance, number of previous suicide attempts, or baseline concomitant medications. Both groups had weekly or biweekly clinical contact. Dropout rates for the two groups were similar with 192 discontinuing treatment with clozapine and 187 with olanzapine. Clozapine showed a hazard ratio of 0.76 (95% CI, 0.58-0.97) for type 1 events (p=.03) and 0.78 (95% CI, 0.61-0.99) for type 2 events (p=.04) compared to olanzapine. The most frequently reported adverse events for the olanzapine group were weight gain, somnolence, dry mouth, and dizziness, while salivary hypersecretion, somnolence, weight gain, and dizziness were the most frequently reported adverse events reported for the clozapine group. The overall number of adverse events did not differ significantly between the two groups. Decreased white blood cell counts occurred in 5.8% of clozapine-treated patients and in 0.8% of olanzapine-treated patients, but there were no reports of agranulocytosis or deaths due to granulocytopenia in either group. There was a total of 8 suicide deaths in the two groups (5 clozapine and 3 olanzapine). The mean daily olanzapine dosage was 16.6 +/- 6.4 mg and the mean daily clozapine dosage was 274.2 +/- 155.0 mg (Meltzer et al, 2003a).

b) It has been reported that clozapine reduces the risk of suicide by 75% to 80%. The International Suicide Prevention Trial (InterSePT) is a prospective study investigating the effect of clozapine (300 mg to 900 mg daily) versus olanzapine (10 mg to 20mg daily) on suicidal rates of patients with schizophrenia (Meltzer et al, 2000).

4.5.T Schizophrenia, Treatment-resistant

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Indicated for the management of severely ill schizophrenic patients who fail to respond adequately to standard antipsychotic drug treatment

3) Adult:

a) GENERAL INFORMATION

1) Clozapine was effective and relatively well tolerated in acute and long-term treatment of patients with refractory schizophrenia who have not responded to conventional pharmacotherapies. A small cohort prospective study included 31 refractory schizophrenia patients who were treated with clozapine at flexible doses (25 mg to 600 mg per day) over a 24-month period. All patients showed significant improvement 24 months from intake as assessed by the Brief Psychiatric Rating Scale and the Clinical Global Impressions-Severity of Illness scale (p less than 0.001). For patients with refractory schizophrenia who are resistant to or intolerant of usual treatment options, clozapine is an effective alternative (Ciapparelli et al, 2000).

2) Results from short- and long-term retrospective, noncomparative studies indicate that 30% to 60% of patients with treatment-resistant schizophrenia show a marked improvement with clozapine as compared to previous standard antipsychotic agents (Alvarez et al, 1997; Fitton & Heel, 1990a). Positive schizophrenic symptoms, mainly hallucinations, delusions, unusual thought content, psychomotor hyperactivity, hostility and aggression appear to be significantly alleviated by clozapine (Keck et al, 2000; Volavka, 1999; Lindstrom, 1988) possibly even better than with haloperidol (Buchanan et al, 1998). Some evidence suggests that clozapine may decrease comorbid depressive symptoms, substance abuse and SUICIDAL BEHAVIOR (Keck et al, 2000; Zimmet et al, 2000; Volavka, 1999; Meltzer, 1999). In comparative studies of patients refractory to classic antipsychotics, clozapine (less than or equal to 900 milligrams/day) had significant superior overall antipsychotic efficacy (in terms of Brief Psychiatric Rating Scale score) to chlorpromazine (less than or equal to 1800 milligrams/day) over a 6-week treatment period (Conley et al, 1988a; Herrera et al, 1988; Kane et al, 1988b). Results from various studies in treatment-resistant schizophrenia indicate that patients intolerant to classic neuroleptics and presenting tardive dyskinesia/extrapyramidal side effects have improved response to clozapine therapy (greater than or equal to 3 months' duration) when compared to previous antipsychotic therapy (Lieberman et al, 1994; Kane et al, 1994; Maier, 1992; Davies et al, 1991; Meltzer et al, 1990; Meltzer et al, 1989). Patients have continued to improve even after 5 to 10 years of therapy with clozapine (Lindstrom & Lundberg, 1997).

3) A meta-analysis of 30 randomized trials comparing clozapine to conventional neuroleptics determined that clozapine was generally superior in terms of clinical outcome (rating scale scores) and relapse rates in short-term treatment of hospitalized adults. Adverse effects such as blood dyscrasias, hypersalivation, fever and sedation were generally more frequent with clozapine, while extrapyramidal symptoms and dry mouth were more common with traditional agents. The authors noted that more long-term, community-based studies are needed with evaluation of global and social functioning, ability to work, patient satisfaction and family burden. More controlled data are also required to assess clozapine therapy in special patient populations (ie, children, adolescents, various comorbidities) (Wahlbeck et al, 1999).

4) Combination therapies of clozapine and fluoxetine, and clozapine, risperidone, and paroxetine have been used successfully in refractory schizophrenia (Patel et al, 1997; Cassady & Thaker, 1992). The

combination of clozapine and paroxetine was effective in schizophrenia with comorbid obsessive-compulsive symptoms in a case report (Strous et al, 1999). Combination clozapine and electroconvulsive therapy has also been used (James & Gray, 1999).

5) In a comparison of responders and non-responders, characteristics which were associated with response to CLOZAPINE included (1) lower severity of illness at baseline according to the Clinical Global Impressions-Severity of Illness (CGI-S) scale, (2) lower baseline level of negative symptoms as assessed on the Scale for the Assessment of Negative Symptoms (SANS), and (3) lower level of acute extrapyramidal symptoms at baseline. After controlling for the foregoing characteristics, a higher total score on the Brief Psychiatric Rating Scale (BPRS) was predictive of a positive response to clozapine. Patient history did not influence response to clozapine. Subjects in this study (n=37) were partially treatment-refractory outpatients diagnosed with schizophrenia or schizoaffective disorder (DSM-III-R), of which 22 (59%) responded to clozapine given for 29 weeks (ie, showed a 20% decrease in BPRS psychosis factor scores). Targeted clozapine dose titration was to reach 500 milligrams (mg)/day by the end of week 5 (minimum 250 mg/day; maximum 850 mg/day) (Umbricht et al, 1994a).

b) SINGLE DRUG THERAPY

1) A reduction in left caudate nucleus volume (CNV) was correlated with improvement in positive symptoms and general symptoms of schizophrenia, though not in negative symptoms, in patients who had been unresponsive to conventional antipsychotropic drugs but who responded to clozapine. Treatment with conventional antipsychotropic drugs was associated with an increase in left CNV in this population of 28 patients. Treatment was switched to clozapine (mean dose 346 milligrams/day) and CNV was assessed again at 24 weeks and 52 weeks of treatment. In responders to clozapine, but not in nonresponders, left (but not right) CNV was significantly reduced by 24 weeks (p less than 0.005). The change in CNV between weeks 24 and 52 was not significant. Scores on the Positive and Negative Syndrome scale showed significant improvement at 24 weeks compared to baseline scores (p less than 0.001) and continued to improve through week 52 (p less than 0.01 for comparison to 24-week scores). These results suggest that the caudate nucleus may play a role in the positive and general symptoms of schizophrenia (Scheepers et al, 2001).

2) In an open-label 12-week study of treatment-refractory schizophrenic patients, clozapine (n=21) and risperidone (n=14) significantly improved psychopathology as rated by the Positive and Negative Syndrome Scale (PANSS), p less than 0.003. Patients were included if they met DSM-IV criteria for schizophrenia, had poor response to two prior neuroleptic treatments, had a minimum baseline Brief Psychiatric Rating Scale score of 46, and persistently poor functioning for at least 2 years. Patients had a mean age of 39 years and a mean duration of illness of 18 years. Improvements in the Clinical Global Impressions scale were seen with both treatments (p less than 0.011). Neurocognitive measures did not improve greatly over the 12-week treatment period. Patients receiving risperidone (mean dose 9 milligrams per day) experienced improvements within the first 2 weeks of therapy and remained stable over the treatment period; however, patients receiving clozapine (mean dose 363 milligrams per day) continued to improve over the 12-week treatment period. Extrapyramidal symptoms improved significantly in the clozapine group (p less than 0.01), but not the risperidone group. Tardive dyskinesia symptoms did not change significantly with either group (Lindenmayer et al, 1998).

3) In a prospective, 12-month study, clozapine elicited therapeutic responses in 68% of 50 inpatients with schizophrenia. Subjects were refractory to at least 2 adequate trials of antipsychotic drug therapy, in addition to a 6-week trial of haloperidol or perphenazine just prior to study entry. Clozapine was initiated at 25 milligrams (mg)/day, then titrated slowly to 400 to 450 mg/day within 3 weeks. Doses were advanced as necessary every 6 weeks thereafter to a maximum of 900 mg/day. The average onset and dose for therapeutic response were 82 days and 468 mg/day, respectively. Investigators concluded that an 8-week trial is sufficient to assess response after a dose change (Conley et al, 1997).

4) Fifty percent of treatment-refractory patients and 76% of treatment-intolerant patients had a favorable response to clozapine. The clinical responses of 84 schizophrenic patients who were either intolerant or refractory to other neuroleptic agents were evaluated for a period of up to 52 weeks (Lieberman et al, 1994). The authors suggested that predictors of a good response to clozapine include the presence of extrapyramidal side effects during previous treatment with classic neuroleptics and a diagnosis of paranoid schizophrenia.

5) Data from a retrospective review (n=33) support the efficacy and tolerability of clozapine in patients with mental retardation and comorbid treatment-resistant psychotic illness. All had failed three or more traditional antipsychotics with or without mood stabilizers and required hospitalization for acute exacerbation. Patients categorized as having mild (58%), moderate (39%) or severe (3%) mental retardation were initiated on clozapine 25 milligrams (mg)/day and titrated to a median dose of 400 mg/day. After a mean inpatient stay of 40 days, the average Clinical Global Impression (CGI)-Improvement score indicated much improvement, while the mean CGI-Efficacy Index score indicated decided improvement, partial symptom remission and no or minimal adverse effects. The clinical benefits were sustained for a mean follow-up of 25 months (Antonacci & de Groot, 2000). Four out of five MENTALLY RETARDED patients responded to clozapine therapy with progressive improvement in psychopathology, social functioning and ability to participate in daily activities. Clozapine was studied in a group of five patients with treatment-resistant schizophrenia or schizoaffective disorder and borderline intellectual function or mental retardation (Sajatovic et al, 1994).

c) COMBINATION THERAPY

1) The addition of lithium to maintenance clozapine therapy was beneficial for patients with treatment-

resistant schizoaffective disorder but not for schizophrenic patients. In a randomized, placebo-controlled, double-crossover study, hospitalized patients with treatment-resistant schizoaffective disorder (n=10) or schizophrenia (n=10) and on a stable clozapine regimen (range, 100 to 800 milligrams (mg)/day) received alternating augmentation therapy with lithium (initial, 300 mg every 12 hours; target plasma level, 0.5 mmol/L) or placebo for four 4-week phases. At the end of the first crossover, lithium treatment was associated with significantly better improvements on the Clinical Global Improvement (CGI) scale and the Positive and Negative Symptom Scale (PANSS) total score in schizoaffective patients (p less than or equal to 0.01 and p less than or equal to 0.02, respectively). The PANSS Negative score was significantly more improved with lithium therapy in the schizoaffective patients at the end of both crossover periods (p less than or equal to 0.01). Significant improvements in CGI and PANSS scores were not found with clozapine and lithium combination therapy in patients with schizophrenia, however, two (20%) of the patients in this group developed transient neurological impairments, typical of lithium toxicity, during the first week of lithium administration. Overall, safety data showed significant increases in absolute neutrophil counts and total white blood cell counts with each phase of lithium treatment. Commonly reported adverse effects included hypersalivation, sedation, tremor, and polyuria (Small et al, 2003).

2) Treatment-resistant schizophrenic patients refusing to give blood or swallow tablets benefited from combined electroconvulsive therapy (ECT) and clozapine (James & Gray, 1999). Six patients received ECT (2 treatments) before beginning clozapine therapy on day 6. Clozapine was then titrated to 300 mg daily by the end of ECT (10 more treatments) at week 6. At the end of the ECT, all patients consented voluntarily to weekly blood testing. Scores on the Brief Psychiatric Rating Scale had increased by 32%. Improvement persisted for 4 to 8 weeks post-ECT. After 6 months, all patients were still receiving clozapine with 3 freely compliant, 2 compliant with difficulty, and 1 threatening to refuse medication.

3) Two SEVERELY PSYCHOTIC patients, both of whom had a diagnosis of schizoaffective disorder, were successfully treated with electroconvulsive therapy (ECT) which facilitated clozapine administration and clinical stability (Green et al, 1994). The authors concluded that ECT may be useful in patients whose behavior is so disruptive that they cannot or will not take oral medication, and in cases where rapid control of behavior is necessary for the safety of themselves and others. In the two reported cases, following pretreatment with ECT, both patients have been successfully maintained on clozapine therapy for up to three years. Similar cases have been reported (Poyurovsky & Weizman, 1996).

4) Pediatric:

a) Clozapine has been reported to be effective in the treatment of young adolescents (ages 12 to 17 years) with severe symptoms of schizophrenia refractory to other neuroleptics (Turpeinen, 1996; Frazier et al, 1994; Jacobsen et al, 1994; Towbin et al, 1994). Usual side effects were observed, with precautionary measures taken to avoid seizures and agranulocytosis.

b) Clozapine has been successful in treating 4 children (ages 10 to 12) with schizophrenia. Early onset schizophrenic patients generally do not respond well to treatment with other conventional neuroleptics (Mozes et al, 1994).

4.5.U Schizophrenia - Suicidal behavior, Recurrent

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Shown to be effective in decreasing the number of suicide attempts in patients with schizophrenia and schizoaffective disorder at high risk for suicide

3) Adult:

a) In the International Suicide Prevention Trial (InterSePT), clozapine was shown to be more effective than olanzapine in reducing suicidal behavior in high-risk, adult, patients with schizophrenia or schizoaffective disorder. Men and women between the ages of 18 to 65 years, at high risk of committing suicide, were recruited to participate in this 2-year, prospective, randomized, international, parallel group, study. The endpoints in this study included significant suicide attempts (including completed suicides) or hospitalization due to imminent suicide risk (type 1 events) or ratings of "much worse" or "very much worse" on the Clinical Global Impression of Suicide Severity (CGI-SS) scale (type 2 events). Of the total sample of 980 patients enrolled in the study, 62% (609) were diagnosed as having schizophrenia and 38% (371) were diagnosed with schizoaffective disorder. Twenty-seven percent (263) of these patients were considered treatment resistant. The patients were divided into two treatment groups (clozapine or olanzapine) and did not differ significantly in terms of age, sex, race, diagnosis, treatment resistance, number of previous suicide attempts, or baseline concomitant medications. Both groups had weekly or biweekly clinical contact. Dropout rates for the two groups were similar with 192 discontinuing treatment with clozapine and 187 with olanzapine. Clozapine showed a hazard ratio of 0.76 (95% CI, 0.58-0.97) for type 1 events (p=.03) and 0.78 (95% CI, 0.61-0.99) for type 2 events (p=.04) compared to olanzapine. The most frequently reported adverse events for the olanzapine group were weight gain, somnolence, dry mouth, and dizziness, while salivary

hypersecretion, somnolence, weight gain, and dizziness were the most frequently reported adverse events reported for the clozapine group. The overall number of adverse events did not differ significantly between the two groups. Decreased white blood cell counts occurred in 5.8% of clozapine-treated patients and in 0.8% of olanzapine-treated patients, but there were no reports of agranulocytosis or deaths due to granulocytopenia in either group. There was a total of 8 suicide deaths in the two groups (5 clozapine and 3 olanzapine). The mean daily olanzapine dosage was 16.6 +/- 6.4 mg and the mean daily clozapine dosage was 274.2 +/- 155.0 mg (Meltzer et al, 2003a).
b) It has been reported that clozapine reduces the risk of suicide by 75% to 80%. The International Suicide Prevention Trial (InterSePT) is a prospective study investigating the effect of clozapine (300 mg to 900 mg daily) versus olanzapine (10 mg to 20mg daily) on suicidal rates of patients with schizophrenia (Meltzer et al, 2000).

4.5.V Tardive dyskinesia
See Drug Consult reference: TARDIVE DYSKINESIA - DRUG THERAPY

4.6 Comparative Efficacy / Evaluation With Other Therapies

Chlorpromazine

Haloperidol

Olanzapine

Risperidone

4.6.A Chlorpromazine

4.6.A.1 Schizophrenia
a) Clozapine was more effective and induced fewer adverse effects than chlorpromazine for the treatment of schizophrenia (Claghorn et al, 1987). One hundred fifty-one schizophrenic patients were enrolled in a double-blind, randomized, placebo-controlled multicenter study. Each patient received either clozapine 150 to 900 milligrams/day or chlorpromazine 300 to 1800 milligrams/day over a 28-day period. Eleven chlorpromazine patients compared with one clozapine patient were dropped from the study due to extrapyramidal side effects. As measured by the Brief Psychiatric Rating and Clinical Global Impression scales, clozapine was superior to chlorpromazine (Claghorn et al, 1987).
b) In a double-blind follow-up for a year following the initiation of a clinical trial comparing chlorpromazine and clozapine, a higher percentage of clozapine patients were evaluated as clinically recovered as compared with chlorpromazine patients. Patients receiving clozapine received a mean dose of 600 milligrams/day as compared with 600 milligrams of chlorpromazine per day. During the initial 6-week study, 92% clozapine and 60% of chlorpromazine patients were evaluated as clinically recovered. At both the 3-year and the 4-year follow-up evaluation, the difference in clozapine and chlorpromazine continued. The results of this study must be viewed with caution, however, since both chlorpromazine and clozapine were dosed in equal doses and other investigators (Meltzer et al, 1979a) have found that the mean clinical antipsychotic dose of clozapine was 241 +/- 162 mg/day in contrast with the mean clinical antipsychotic dose of chlorpromazine of 691 +/- 411 mg/day. In the study by Leon, more equivalent results may have been obtained if equivalent antipsychotic doses had been used (Leon, 1979).
c) Clozapine was found to be more effective than chlorpromazine in the treatment of acutely psychotic schizophrenic individuals. Unlike chlorpromazine, no extrapyramidal reactions occurred in those patients taking clozapine. Characteristic clinical side effects of clozapine included sedation, hypotension, and increased salivation (Shopsin et al, 1979). Similar results have also been reported from investigators in Canada (Guirguis et al, 1977).

4.6.B Haloperidol

Hostile behavior

Schizophrenia, Refractory

4.6.B.1 Hostile behavior
a) Clozapine reduced hostility in patients with schizophrenia and was superior to haloperidol and risperidone in that regard. One hundred fifty seven patients with a diagnosis of schizophrenia or schizoaffective disorder and a history of poor response to drug treatment were randomly assigned to receive

clozapine, olanzapine, risperidone, or haloperidol in cross-titration with the antipsychotic drug used prior to the start of the study. Concomitant mood stabilizers and antidepressants had been phased out earlier. Daily doses of olanzapine, risperidone, and haloperidol were escalated within the first week to the target doses of 20, 8, and 20 milligrams (mg), respectively. Patients receiving clozapine were scheduled to achieve the target daily dose of 500 mg on day 24. Doses remained fixed for the remainder of the initial 8-week period. In a second (6-week) period, doses were allowed to vary: 200 to 800 mg for clozapine, 10 to 40 mg for olanzapine, 4 to 16 mg for risperidone, and 10 to 30 mg for haloperidol. Hostility, measured by the hostility item of the Positive and Negative Syndrome Scale (PANSS), improved significantly (in comparison to baseline) in the clozapine group only (p=0.019). This effect was independent of effects on psychotic symptoms (delusional thinking, hallucinations) or on sedation. The effect of clozapine on hostility was superior to that of haloperidol (p=0.021) or risperidone (p=0.012) but not to that of olanzapine (Citrome et al, 2001).

4.6.B.2 Schizophrenia, Refractory

a) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in patients with schizophrenia or schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double-blind study, inpatients were given clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26) 4 to 16 mg day, or haloperidol (n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risperidone 8 mg/day, haloperidol 20 mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 weeks, dosages were adjusted individually (generally increased if response was insufficient, but sometimes reduced because of adverse effects). Improvement over time in global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual organization and in processing speed and attention, improvement was seen with olanzapine. In simple motor function, there was improvement with clozapine. Changes in global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximately 8 to 9 "IQ equivalents") but large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive gains, patients still had significant impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits were associated with improvements in negative symptoms (Bilder et al, 2002).

b) Schizophrenic patients treated with clozapine were more likely to be rated as improved and less likely to discontinue treatment due to lack of efficacy than a matched group treated with haloperidol. Seventy-one patients between the ages of 20 to 55 years with a diagnosis of schizophrenic or schizoaffective disorder were enrolled in this 6-month, double-blind, prospective, randomized trial. These outpatients, were documented as poor or partial responders to antipsychotic therapy and had a rating of at least moderate on 1 of 4 Brief Psychiatric Rating Scale (BSRS) items (conceptual disorganization, suspiciousness, hallucinatory behavior, or unusual thought content). The two major outcome measures for this study were time to discontinuation of study medication due to lack of clinical response and 20% improvement in the 4 item BPRS cluster during two consecutive rating periods. The haloperidol group (n=34) was targeted to receive 10 milligrams (mg)/day, along with 2 mg/day of benztropine, while the clozapine group was to receive 500 mg/day (n=37). Doses could be adjusted in either group to a range of 4 to 16 mg/day for the haloperidol group and 200 to 800 mg/day for the clozapine group depending upon the patient's clinical course. At the end of 29 weeks, 50.5% of the haloperidol-treated group (mean dose 18.9 mg/day) and 11.6% of the clozapine group (mean dose 523 mg/day) had discontinued treatment due to lack of efficacy (p=0.02). The mean BPRS ratings at the end of the study were 3.2 and 4.2 for the clozapine and haloperidol groups respectively (p less than 0.001). There was no difference found between the groups as measured by the Schedule for Assessment of Negative Symptoms (SANS) score using the sum of the 4 global ratings. Haloperidol-treated patients experienced more dry mouth and decreased appetite, while the clozapine-treated group reported more salivation, sweating, and dizziness. Three haloperidol and 2 clozapine-treated patients dropped-out of the study due to adverse drug effects (Kane et al, 2001).

c) Clozapine exhibited improved efficacy with fewer adverse effects as compared to haloperidol in a randomized, double-blind, 12-month study conducted at Veterans Affairs medical centers (n=423 with refractory schizophrenia). Using intention-to-treat analysis, schizophrenia symptom scores were significantly improved with clozapine over haloperidol at 6 weeks (p equals 0.008) and 6 months (p equals 0.001), with no statistical difference in quality of life measures. When crossover cases were excluded, quality of life measures were significantly better in the clozapine group at 3 months and 1 year (p equals 0.02). Clozapine also reduced scores for tardive dyskinesia, akathisia and extrapyramidal syndrome. Clozapine's higher costs for drug acquisition and laboratory monitoring were offset by decreased inpatient hospital stays (Rosenheck et al, 1997).

d) These investigators later evaluated compliance with clozapine versus haloperidol. The results confirmed that clozapine established better medication continuation and regimen compliance. Patients taking clozapine continued taking the study drug for a mean of 35.5 weeks as compared with on 27.2 weeks among haloperidol patients (p=0.0001). No differences were found between the groups in the proportion of prescribed pills that were returned at any time point. Continuation with medication is greater with clozapine than haloperidol and is partly explained by greater symptom improvement and reduced side effects. No differences were discovered in regimen compliance (Rosenheck et al, 2000).

4.6.B.3 Adverse Effects

a) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence

of PANCREATITIS than patients receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of pancreatitis were identified in patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), risperidone, (mean dose, 4 mg/day) or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatment with the atypical antipsychotic medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which were related to the conventional neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of treatment (Koller et al, 2003).
b) No significant difference was found in sexual disturbances occurring in clozapine-treated versus haloperidol-treated patients (Hummer et al, 1999). Inpatients receiving either clozapine (n=100) or haloperidol (n=53) were screened. The most common adverse event in both groups was diminished sexual desire occurring in 4 (33.3%) of the haloperidol-treated women, 26 (63.4%) of the haloperidol-treated men, 7 (28%) of the clozapine-treated women, and 43 (57.3%) of the clozapine-treated men. Among women treated, amenorrhea occurred in 4 (33.3%) of the haloperidol patients and in 3 (12%) of the clozapine patients. Larger studies may be needed to show differences.
c) In a prospective study, the incidence of alanine aminotransferase (ALT) elevation to more than twice the upper normal limit was statistically greater with clozapine (37%, n=167) than with haloperidol (17%, n=71). Among those receiving clozapine, the rates of elevations in aspartate aminotransferase (AST) and gamma-glutamyl transpeptidase (GGT) to more than twice the upper normal limit were 12% and 15%, respectively. No such increases in bilirubin or alkaline phosphatase occurred in clozapine-treated patients. These effects were transient in the majority of patients (disappearing by week 13) with no clinical manifestations reported (Hummer et al, 1997).

4.6.C Olanzapine

Bipolar disorder

Drug-induced psychosis

Hostile behavior

Schizophrenia

Schizophrenia - Suicidal intent

4.6.C.1 Bipolar disorder

a) In a retrospective study of 50 consecutive patients treated for bipolar disorder with atypical antipsychotic medications, clozapine (n=5), olanzapine (n=20), and risperidone (n=25), along with standard mood stabilizers, showed similar efficacy. Overall, 68% of patients showed improvement of at least 1 point in their Clinical Global Impressions assessment over the 12-week study. Mean dosages were 210 milligrams (mg) per day for clozapine, 11.7 mg/day for olanzapine, and 1.7 mg day for risperidone. The only serious adverse event to occur during the study was a seizure in a patient taking clozapine. Extrapyramidal symptoms (EPS) were reported in 12 of 42 subjects (28.6%). Parkinsonism occurred in 4 of 25 patients taking risperidone, 1 of 20 taking olanzapine, and 1 of 5 taking clozapine. Weight gain was more extreme in patients taking clozapine and olanzapine than in those taking risperidone. Weight gain, which was greater than reported in other studies, may have been affected by concurrent mood enhancing medications (Guille et al, 2000).

4.6.C.2 Drug-induced psychosis

a) In a small (n=18), open study, clozapine and olanzapine were both effective in reducing symptoms of dopaminergic drug-induced psychosis in patients with Parkinson's disease. However, olanzapine and not clozapine caused worsening of Parkinsonian symptoms. The starting dose of clozapine was 6.25 to 25 milligrams (mg) per day and was increased at weekly intervals as necessary to optimize clinical status. The final mean dose of clozapine at the end of the 8-week study was 16.9 mg /day (range: 6.25 to 37.5 mg/day). Olanzapine was started at 2.5 to 5 mg/day. The final mean dose of olanzapine for the 6 patients completing the study was 4.7 mg/day (range: 2.5 to 10 mg/day). Three patients dropped out of the study after receiving the starting dose of olanzapine (2.5 mg for 2 patients, 5 mg for 1 patient) because of worsening of parkinsonism. All patients in the clozapine group completed the study, despite side effects of somnolence, falls, orthostatic hypotension, and syncope. Neuropsychiatric symptoms markedly improved with both medications (72% and 65% reduction in Neuropsychiatric Inventory global scores for clozapine and olanzapine, respectively). Parkinsonian motor scores (raw scores) improved by 20% in the clozapine group and worsened by 25% in the olanzapine group. It is possible that the differences observed were due to non-equivalence of the doses and that the dosage of olanzapine was excessive (Gimenez-Roldan & Mateo D Navarro, 2001).

4.6.C.3 Hostile behavior

a) Clozapine reduced hostility in patients with schizophrenia and was superior to haloperidol and risperidone in that regard. One hundred fifty seven patients with a diagnosis of schizophrenia or schizoaffective disorder and a history of poor response to drug treatment were randomly assigned to receive clozapine, olanzapine, risperidone, or haloperidol in cross-titration with the antipsychotic drug used prior to the start of the study. Concomitant mood stabilizers and antidepressants had been phased out earlier. Daily doses of olanzapine, risperidone, and haloperidol were escalated within the first week to the target doses of 20, 8, and 20 milligrams (mg), respectively. Patients receiving clozapine were scheduled to achieve the target daily dose of 500 mg on day 24. Doses remained fixed for the remainder of the initial 8-week period. In a second (6-week) period, doses were allowed to vary: 200 to 800 mg for clozapine, 10 to 40 mg for olanzapine, 4 to 16 mg for risperidone, and 10 to 30 mg for haloperidol. Hostility, measured by the hostility item of the Positive and Negative Syndrome Scale (PANSS), improved significantly (in comparison to baseline) in the clozapine group only (p=0.019). This effect was independent of effects on psychotic symptoms (delusional thinking, hallucinations) or on sedation. The effect of clozapine on hostility was superior to that of haloperidol (p=0.021) or risperidone (p=0.012) but not to that of olanzapine (Citrome et al, 2001a).

4.6.C.4 Schizophrenia

a) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in patients with schizophrenia or schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double-blind study, inpatients were given clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26) 4 to 16 mg day, or haloperidol (n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risperidone 8 mg/day, haloperidol 20 mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 weeks, dosages were adjusted individually (generally increased if response was insufficient, but sometimes reduced because of adverse effects). Improvement over time in global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual organization and in processing speed and attention, improvement was seen with olanzapine. In simple motor function, there was improvement with clozapine. Changes in global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximately 8 to 9 "IQ equivalents") but large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive gains, patients still had significant impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits were associated with improvements in negative symptoms (Bilder et al, 2002a).

4.6.C.5 Schizophrenia - Suicidal intent

a) In the International Suicide Prevention Trial (InterSePT), clozapine was shown to be more effective than olanzapine in reducing suicidal behavior in high-risk, adult, patients with schizophrenia or schizoaffective disorder. Men and women between the ages of 18 to 65 years, at high risk of committing suicide, were recruited to participate in this 2-year, prospective, randomized, international, parallel group, study. The endpoints in this study included significant suicide attempts (including completed suicides) or hospitalization due to imminent suicide risk (type 1 events) or ratings of "much worse" or "very much worse" on the Clinical Global Impression of Suicide Severity (CGI-SS) scale (type 2 events). Of the total sample of 980 patients enrolled in the study, 62% (609) were diagnosed as having schizophrenia and 38% (371) were diagnosed with schizoaffective disorder. Twenty-seven percent (263) of these patients were considered treatment resistant. The patients were divided into two treatment groups (clozapine or olanzapine) and did not differ significantly in terms of age, sex, race, diagnosis, treatment resistance, number of previous suicide attempts, or baseline concomitant medications. Both groups had weekly or biweekly clinical contact. Dropout rates for the two groups were similar with 192 discontinuing treatment with clozapine and 187 with olanzapine. Clozapine showed a hazard ratio of 0.76 (95% CI, 0.58-0.97) for type 1 events (p=.03) and 0.78 (95% CI, 0.61-0.99) for type 2 events (p=.04) compared to olanzapine. The most frequently reported adverse events for the olanzapine group were weight gain, somnolence, dry mouth, and dizziness, while salivary hypersecretion, somnolence, weight gain, and dizziness were the most frequently reported adverse events reported for the clozapine group. The overall number of adverse events did not differ significantly between the two groups. Decreased white blood cell counts occurred in 5.8% of clozapine-treated patients and in 0.8% of olanzapine-treated patients, but there were no reports of agranulocytosis or deaths due to granulocytopenia in either group. There was a total of 8 suicide deaths in the two groups (5 clozapine and 3 olanzapine). The mean daily olanzapine dosage was 16.6 +/- 6.4 mg and the mean daily clozapine dosage was 274.2 +/- 155.0 mg (Meltzer et al, 2003).

4.6.C.6 Adverse Effects

a) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence of PANCREATITIS than patients receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of pancreatitis were identified in patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), risperidone, (mean dose, 4 mg/day) or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatment with the atypical antipsychotic medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which were related to the conventional neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of treatment (Koller et al, 2003a).

b) Results of a retrospective analysis showed that olanzapine treatment was associated with a lower rate of

extrapyramidal symptoms (EPS) than haloperidol, but was similar to rates occurring with risperidone and clozapine therapy. In a pooled analysis of 23 randomized, controlled clinical trials in 4611 patients with schizophrenia, frequency and severity of EPS associated with olanzapine therapy (2.5 to 20 milligrams (mg)/day) was compared with that of haloperidol (1 to 20 mg/day), risperidone (4 to 12 mg/day), clozapine (25 to 625 mg/day), and placebo. Dystonic events (ie, dystonia, oculogyric crisis, opisthotonos, torticollis) occurred in significantly fewer patients during olanzapine treatment as compared with haloperidol (0.5% vs 5.6%, respectively; p less than 0.001) or risperidone (1% vs 3.2%, respectively; p=0.047) treatment, while no significant difference was found between olanzapine- and clozapine-treated patients. As compared with olanzapine-treated patients, a significantly higher percentage of haloperidol-treated patients experienced parkinsonian events (ie, akinesia, cogwheel rigidity, extrapyramidal syndrome, hypertonia, hypokinesia, masked facies, and tremor) (9.3% vs 28.3%, respectively; p less than 0.001) or akathisia events (ie, akathisia, hyperkinesia) (6.7% vs 20.4%, respectively; p less than 0.001) during therapy. However, no significant difference was observed between the olanzapine group as compared with the placebo, risperidone, or clozapine groups in regard to the occurrence of parkinsonian or akathisia events. Overall, EPS occurred in significantly more patients treated with haloperidol as compared with olanzapine (44.4% vs 16.2%, respectively; p less than 0.001) and in fewer patients treated with clozapine as compared with olanzapine (2.6% vs 6.8%, respectively; p=0.047). The overall rate of EPS was similar between the placebo and risperidone groups as compared with olanzapine. Significantly fewer patients received anticholinergic medications in the olanzapine group as compared with the haloperidol (p less than 0.001) or risperidone (p=0.018) groups. No difference was found between olanzapine-treated patients as compared with placebo or clozapine in regard to percentage of patients given anticholinergic drugs during therapy (Carlson et al, 2003).

c) In an open-label trial (n=24), olanzapine-treated patients had significantly lower levels of serum anticholinergic activity than clozapine-treated patients. Prior to enrollment, subjects were stabilized on therapeutic doses, averaging 15 milligrams (mg)/day and 444 mg/day for olanzapine and clozapine, respectively. The mean serum anticholinergic levels were 0.96 and 5.47 picomoles/atropine equivalents in the olanzapine and clozapine groups, respectively (p less than 0.001). Scores assessing clinical anticholinergic effects were significantly higher for salivation, constipation, micturition disturbances and palpitations/tachycardia in clozapine versus olanzapine recipients (p less than 0.05). Dry mouth was more problematic with olanzapine therapy (p less than 0.0008). The groups did not differ cognitively with respect to Mini Mental State Exam scores. Although efficacy was not a primary endpoint, the Brief Psychiatric Rating Scale scores favored clozapine (p=0.002), with no statistical difference in Clinical Global Impression Scale, Severity subscale scores. No patients in either group discontinued therapy due to adverse effects (Chengappa et al, 2000).

4.6.D Risperidone

Bipolar disorder

Hostile behavior

Parkinson's disease - Psychotic disorder

Schizophrenia

4.6.D.1 Bipolar disorder

a) In a retrospective study of 50 consecutive patients treated for bipolar disorder with atypical antipsychotic medications, clozapine (n=5), olanzapine (n=20), and risperidone (n=25), along with standard mood stabilizers, showed similar efficacy. Overall, 68% of patients showed improvement of at least 1 point in their Clinical Global Impressions assessment over the 12-week study. Mean dosages were 210 milligrams (mg) per day for clozapine, 11.7 mg/day for olanzapine, and 1.7 mg day for risperidone. The only serious adverse event to occur during the study was a seizure in a patient taking clozapine. Extrapyramidal symptoms (EPS) were reported in 12 of 42 subjects (28.6%). Parkinsonism occurred in 4 of 25 patients taking risperidone, 1 of 20 taking olanzapine, and 1 of 5 taking clozapine. Weight gain was more extreme in patients taking clozapine and olanzapine than in those taking risperidone. Weight gain, which was greater than reported in other studies, may have been affected by concurrent mood enhancing medications (Guille et al, 2000a).

4.6.D.2 Hostile behavior

a) Clozapine reduced hostility in patients with schizophrenia and was superior to haloperidol and risperidone in that regard. One hundred fifty seven patients with a diagnosis of schizophrenia or schizoaffective disorder and a history of poor response to drug treatment were randomly assigned to receive clozapine, olanzapine, risperidone, or haloperidol in cross-titration with the antipsychotic drug used prior to the start of the study. Concomitant mood stabilizers and antidepressants had been phased out earlier. Daily doses of olanzapine, risperidone, and haloperidol were escalated within the first week to the target doses of

20, 8, and 20 milligrams (mg), respectively. Patients receiving clozapine were scheduled to achieve the target daily dose of 500 mg on day 24. Doses remained fixed for the remainder of the initial 8-week period. In a second (6-week) period, doses were allowed to vary: 200 to 800 mg for clozapine, 10 to 40 mg for olanzapine, 4 to 16 mg for risperidone, and 10 to 30 mg for haloperidol. Hostility, measured by the hostility item of the Positive and Negative Syndrome Scale (PANSS), improved significantly (in comparison to baseline) in the clozapine group only (p=0.019). This effect was independent of effects on psychotic symptoms (delusional thinking, hallucinations) or on sedation. The effect of clozapine on hostility was superior to that of haloperidol (p=0.021) or risperidone (p=0.012) but not to that of olanzapine (Citrome et al, 2001b).

4.6.D.3 Parkinson's disease - Psychotic disorder

a) In subjects with Parkinson's Disease (PD), risperidone may be considered as an alternative to clozapine however, risperidone may worsen extrapyramidal symptoms more than clozapine and therefore must be used with caution. A small (n=10) double-blind trial compared the efficacy and safety of risperidone and clozapine for the treatment of psychosis in patients with PD. Five patients were randomized to receive clozapine and five patients received risperidone. Clozapine was started at 12.5 mg at bedtime and risperidone was started at 0.5 mg per day and both were titrated to symptomatic improvement was achieved or intolerable side effects emerged. Each subject received drug for 3 months and was assessed prior to initiation of treatment and after 2, 4, 8, and 12 weeks of treatment. Assessment was based on scores from the Brief Psychiatric Rating Scale and the Unified Parkinson's Disease Rating Scale. Mean improvement in the Brief Psychiatric Rating Scale psychosis score was similar in the clozapine and the risperidone groups (p=0.23). Although the mean motor Unified Parkinson's Disease Rating Scale scores worsened in the risperidone group and improved in the clozapine group, this difference did not reach statistical significance. Risperidone may be a reasonable alternative to clozapine in the treatment of psychosis in patients with PD however, it must be used with caution since it may worsen extrapyramidal side effects (Ellis et al, 2000).

4.6.D.4 Schizophrenia

a) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in patients with schizophrenia or schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double-blind study, inpatients were given clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26) 4 to 16 mg day, or haloperidol (n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risperidone 8 mg/day, haloperidol 20 mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 weeks, dosages were adjusted individually (generally increased if response was insufficient, but sometimes reduced because of adverse effects). Improvement over time in global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual organization and in processing speed and attention, improvement was seen with olanzapine. In simple motor function, there was improvement with clozapine. Changes in global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximately 8 to 9 "IQ equivalents") but large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive gains, patients still had significant impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits were associated with improvements in negative symptoms (Bilder et al, 2002b).

b) Clozapine was superior to risperidone for improving positive and negative symptoms of schizophrenia in patients with poor previous response to treatment. In a prospective, double-blind study, patients meeting DSM-IV criteria for schizophrenia and having had poor response to previous treatment underwent a single-blind placebo run-in period when all psychotropic and anticholinergic medications were withdrawn. They were then randomly assigned to treatment with clozapine (n=138) or risperidone (n=135). Starting with daily doses of clozapine 12.5 milligrams (mg) and risperidone 1 mg, dosages were titrated over a period of 4 weeks to a minimum of 300 mg/day and 4 mg/day, respectively, and possibly to 600 mg/day and 6 mg/day. Patients unable to tolerate the minimum dose were withdrawn from the study. During the next 8 weeks, doses were adjusted at 2-week intervals within the range of 200 to 900 mg/day for clozapine and 2 to 15 mg/day for risperidone. For patients who completed the 12-week study (n=201), median final daily doses were 600 mg for clozapine and 9 mg for risperidone. Changes in the Positive and Negative Syndrome Scale of the BPRS (Brief Psychiatric Rating Scale) and in the Clinical Global Impression (CBI) scale were significantly greater in the clozapine group than in the risperidone group for the intent-to-treat population (those who received at least one dose of treatment medication and had one post-dose BPRS evaluation) and in the per- protocol population (those who completed the 28-day dose-setting period) (p less than 0.008 for all comparisons). Eighty-six percent of patients in the clozapine per-protocol population and 70% in the risperidone per-protocol population showed 20% or more improvement in the BPRS score (for difference between groups, p less than 0.01). By the end of the study, 94 (76%) patients in the clozapine group and 81 (64%) in the risperidone group no longer met the severity of psychopathology inclusion criteria (p less than 0.05). Extrapyramidal symptoms occurred significantly less frequently in the clozapine group than in the risperidone group (13% vs 28%, p=0.008). However, convulsions, dizziness, sialorrhea, tachycardia, and somnolence occurred significantly more frequently among those receiving clozapine. No case of agranulocytosis was observed during the study. Granulocytopenia occurred with low incidence in both groups (1% clozapine, 2% risperidone). Low neutrophil count was significantly more frequent among risperidone-treated patients (3% vs 11%, p less than 0.01). Hypotension occurred more frequently among

risperidone-treated patients (p less than 0.01). Weight gain was significantly greater for the clozapine group (2.4 kilograms vs 0.2 kilograms; p less than 0.002) (Azorin et al, 2001).

c) In the treatment of refractory schizophrenia, giving a risperidone trial before clozapine was more beneficial given its better side effect profile. A retrospective review study compared the relative efficacy profiles of clozapine and risperidone in a group of the most refractory, chronically institutionalized patients. The specific goal was to identify superiority (or lack thereof) of either agent on global clinical outcome as well as on specific symptom domains, including positive symptoms, negative symptoms, and aggressive behavior, compared with a baseline of conventional antipsychotic treatment in a total of 24 patients. Information obtained from systematic retrospective chart review was blindly rated by 2 psychiatrists using the 7-point Clinical Global Impressions Improvement (CGI-I) scale on overall clinical state and along specific symptom domains as above. The mean dose was 520 +/- 94 mg daily for clozapine and 7.5 +/- 2.2 mg daily for risperidone. Fourteen patients (58%) were classified as responders to clozapine, while 6 (25%) responded to risperidone. On specific symptom domains, response rates to clozapine were 38% (9/24) on positive symptoms, 29% (7/24) on negative symptoms, and 71% (12/17) on aggressive behavior. For risperidone, response rates were 17% (4/24) on positive symptoms, 8% (2/24) on negative symptoms, and 41% (7/17) on aggressive behavior. The results of this study would support the utility of first giving a risperidone trial in patients with treatment-refractory schizophrenia because of its better side effect profile compared with clozapine (Sharif et al, 2000).

d) Risperidone and clozapine had similar antipsychotic effects in 59 patients with paranoid schizophrenia. In a double-blind randomized study, patients were divided in three groups receiving either 4 milligrams risperidone, 8 milligrams risperidone, or 400 milligrams clozapine daily for 28 days. The antipsychotic effect was highly significant for both risperidone and clozapine. Patients on 4 milligrams of risperidone better tolerated therapy than those patients receiving clozapine. Withdrawals from clozapine treatment were mostly due to side effects, whereas withdrawals from risperidone treatment occurred from lack of therapeutic response (Heinrich et al, 1994).

e) Similar effectiveness of risperidone and clozapine was also observed in an 8-week, double-blind trial that allowed dose adjustment based on response in 86 patients with treatment-resistant chronic schizophrenia. The mean effective dose was 6.4 milligrams (mg) for risperidone and 291 mg for clozapine. The larger proportion of patients with clinical improvement after 7 and 14 days' treatment with risperidone suggested earlier onset of effect compared to clozapine treatment (Bondolfi et al, 1998)

f) In a prospective, open-label, 12-week trial, risperidone was found to be a poor substitute for clozapine in the treatment of chronic refractory schizophrenia. Six patients with schizophrenia and 4 with schizoaffective disorder were switched from a mean clozapine dose of 565 milligrams(mg)/day to a mean dose of risperidone 8 mg/day at 12 weeks. No subjects improved after being switched. Overall, patients who were switched from clozapine tended to worsen when taking risperidone. Statistically significant increases over baseline in the mean total of the Positive and Negative Syndrome Scale occurred at 9 and 12 weeks (P less than 0.05). The Brief Psychiatric Rating Scale scores also increased significantly over baseline at weeks 6, 9, and 12 (P less than 0.05). Five subjects failed to complete the entire 12 weeks. Of the 5 patients that completed the 12 weeks, the Clinical Global Impressions Scale indicated that 2 patients were unchanged, one was minimally worse, and 2 were much worse. The authors concluded that this study does not support replacing clozapine with risperidone for patients with treatment-resistant schizophrenia (Still et al, 1996).

4.6.D.5 Adverse Effects

a) Adverse effects and death were more commonly reported as the reasons for the discontinuation of clozapine while ineffectiveness was more often reported as the reason for discontinuation of risperidone (long-acting injection) in a retrospective, phase 3 study (n=322). Patients with a diagnosis of schizophrenia, schizoaffective disorder, bipolar disorder or other psychotic disorders who received clozapine (n=161), and had mean duration of therapy of 12.3 +/- 18.6 months (range, 0.25 to 100 months; median, 3 months) were matched by age (mean age, 40 +/- 12.6 years (yr); range, 18 to 83 yr) and gender at discontinuation to patients who discontinued risperidone long-acting injection (n=161). The risperidone patients (mean age, 39.9 +/- 13.1 yr , range 18 to 83 yr) were matched without knowledge of the reason for discontinuation of therapy (mean duration of therapy of 5.9 +/- 8.7 months; range, 0.5 to 46 months; median, 3 months). The reasons for discontinuation differed significantly between clozapine and risperidone injection; additionally, death as reason for discontinuation was significantly more common with clozapine (13%) vs risperidone injection (1.9%) (Taylor et al, 2009).

Reasons for Discontinuation: Clozapine vs Risperidone

Reason	Clozapine (n=161) n (%)	Risperidone (n=161) n (%)	OR (95% CI)	p value
Patient's decision	77 (47.8)	64 (39.7)	1.41 (0.89 to 2.21)	0.139
Adverse effects	57 (35.4)	32 (19.9)	2.19 (1.31 to 3.67)	0.0023
Ineffectiveness	3 (1.9)	59 (36.6)	0.034 (0.01 to 0.14)	less than 0.0001
Death	21 (13)	3 (1.9)	7 (2.09 to 23.5)	0.0003

Other	3 (1.9)	3 (1.9)	-	-

The cause of death reported in clozapine patients (mean age, 49.2 +/- 14.5 yr, range 30 to 83 yr) included: pneumonia (n=5), lung carcinoma (n=3), other carcinoma (n=2), myocardial infarction (n=2), cerebrovascular accident (n=2), clozapine overdose (n=2), gastrointestinal hemorrhage (n=1), cardiac arrest (n=1), left ventricular failure (n=1), asphyxia during restraint (n=1) and sepsis (n=1). There was no incidence of neutropenia or agranulocytosis at the time of death in any of the patients. The cause of death in the risperidone patients included: myocardial infarction (n=1), left ventricular failure (n=1) and sudden unexplained death (n=1). The mortality rate for clozapine patients was 8.5 per 1000 patient-years (95% CI, 5.53 to 13.07) vs 5.3 per 1000 patient-years (95% CI, 1.7 to 16.61) (Taylor et al, 2009).

b) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence of pancreatitis than patients receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of pancreatitis were identified in patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), risperidone, (mean dose, 4 mg/day) or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatment with the atypical antipsychotic medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which were related to the conventional neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of treatment (Koller et al, 2003b).

c) Clozapine was associated with fewer extrapyramidal side effects (EPS) than was risperidone (Miller et al, 1998). Outpatients receiving stable doses of clozapine (n=41), risperidone (n=23), or conventional antipsychotics (n=42) were screened for EPS. Utilizing the Barnes Akathisia Scale, akathisia was noted in 7.3% of clozapine patients, 13% of risperidone patients, and 23.8% of conventional antipsychotic users. From the Simpson-Angus scale, rigidity and cogwheeling were noted in 4.9% and 2.4% of clozapine patients, 17.4% and 17.4% of risperidone patients, and 35.7% and 26.2% of conventional antipsychotic users, respectively. However, salivation was noted in 36.6% of clozapine patients, 8.7% of risperidone patients, and 4.8% of conventional antipsychotic users.

d) Insomnia and extrapyramidal side effects were more common with risperidone, and sedation and weight gain were more common with clozapine in a single-blind, crossover pilot study of the side effect profiles of the 2 drugs (Daniel et al, 1996). Twenty outpatients with schizophrenia or schizoaffective disorder were randomized to each drug for 6 weeks separated by a 1-week tapering-off period before crossover. The mean doses at week 6 were 6.1 milligrams/day (range 1 to 10 mg/d) of risperidone and 375 milligrams/day (range 75 to 800 mg/d) of clozapine. Three patients dropped out of the study; there was no significant difference in therapeutic effect between the 2 treatment groups. Mean body weight was greater (p less than 0.005) and sleepiness and lack of alertness were reported more often after the clozapine treatment phase. Restlessness and insomnia were more frequent complaints after the risperidone phase. A longer, double-blind study with a large sample of patients is needed to further elucidate the therapeutic differences and side effect profiles of these 2 drugs.
