2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, haloperi quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM) oral tablets 1999z; O'Brien et al, 1999q; Prod Info INVEGA(TM) extended-release oral tablets, 2006; Owens, 2001ab; Du et al, 2001v; Lande et al, 1992z; Prod Info GEODON(R) intramuscular injection, oral capsule, 2005; Sweetma antiarrhythmic agents may also prolong the QT interval and increase the risk of arrhythmias, the concurrent a with a drug from this class is not recommended (Prod Info FANAPT(TM) oral tablets, 2009; Prod Info Quinag
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. The study de in the plasma concentrations of haloperidol when given concurrently with quinidine versus haloperidol tre under the concentration curve (AUC) was increased from 54.3 ng/h/mL on haloperidol alone to 103.2 ng/ peak concentration (Cmax) also showed an increase from 1.9 ng/mL on haloperidol to 3.8 ng/mL on com and time to peak concentration (Tmax) were not significantly changed, thereby suggesting to the authors is more likely responsible for the plasma level changes than an elimination alteration (Young et al, 1993)

3.5.1.BS Probucol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Even though no formal drug interaction studies have been done, the coadministration of drugs interval is not recommended. Probucol has been shown to prolong the QTc interval (Gohn & Simmons, 1992 Antipsychotics including haloperidol (Prod Info Haldol(R), 1998e), quetiapine (Owens, 2001s), risperidone (Pr 2000a), amisulpride (Prod Info Solian(R), 1999p), sertindole (Brown & Levin, 1998c); sultopride (Lande et al, (Sweetman, 2004) have been shown to prolong the QT interval at therapeutic doses.
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if probucol and antipsychotics are used concomitantly.
7) Probable Mechanism: additive effect on QT interval

3.5.1.BT Procainamide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, haloperi quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM) oral tablets 1999z; O'Brien et al, 1999q; Prod Info INVEGA(TM) extended-release oral tablets, 2006; Owens, 2001ab; Du et al, 2001v; Lande et al, 1992z; Prod Info GEODON(R) intramuscular injection, oral capsule, 2005; Sweetma antiarrhythmic agents may also prolong the QT interval and increase the risk of arrhythmias, the concurrent a with a drug from this class is not recommended (Prod Info FANAPT(TM) oral tablets, 2009; Prod Info Quinag
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. The study de in the plasma concentrations of haloperidol when given concurrently with quinidine versus haloperidol tre under the concentration curve (AUC) was increased from 54.3 ng/h/mL on haloperidol alone to 103.2 ng/ peak concentration (Cmax) also showed an increase from 1.9 ng/mL on haloperidol to 3.8 ng/mL on com and time to peak concentration (Tmax) were not significantly changed, thereby suggesting to the authors is more likely responsible for the plasma level changes than an elimination alteration (Young et al, 1993)

3.5.1.BU Prochlorperazine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concomitant use of phenothiazines and antipsychotic agents may cause additive effects on the recommended. Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Co

Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, though nc antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999j), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), quetiapine (Owens, 2001n), risper 1999n), sertindole (Agelink et al, 2001j), sultopride (Lande et al, 1992i), ziprasidone (Prod Info GEODON(R) i capsule, 2005), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as phen not recommended.
7) Probable Mechanism: additive QT prolongation

3.5.1.BV Propafenone
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of risperidone with other drugs that potentially prolong the QTc interval, such approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is a Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of propafenone and risperidone is not recommended life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring i
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BW Protriptyline
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999d), sertindole (Agelink et al, 2001a), c sultopride (Lande et al, 1992a), and zotepine (Sweetman, 2003). Even though no formal drug interaction stuc coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experiment deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanis prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999

3.5.1.BX Quetiapine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Risperidone can prolong the QT interval in some patients, which may result in ventricular tachy torsades de pointes, and its use with other agents that may prolong the QT interval, such as quetiapine, is no Risperdal(R), 2002c; Owens, 2001q). Coadministration of risperidone 3 mg twice daily with quetiapine 300 m steady-state pharmacokinetics of quetiapine (Prod Info Seroquel(R), 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Because of the potential additive effects on the QT interval, the concurrent administ risperidone is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking risper Laita et al, 1999u; Ravin & Levenson, 1997i; Gesell & Stephen, 1997e; Lo Vecchio et al, 1996e; Brown e

3.5.1.BY Ranitidine
1) Interaction Effect: increased risperidone bioavailability
2) Summary: Concurrent use of risperidone and ranitidine resulted in a 26% increase in the bioavailability of active metabolite, 9-hydroxyrisperidone, and risperidone combined was increased by 20% (Prod Info RISPER IM injection, 2009). Use caution if these agents are used concomitantly. Monitor patients for increased risperi akathisia, parkinsonism, dyspepsia, tachycardia, constipation, or dry mouth).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Concurrent treatment with ranitidine and risperidone has resulted in increased rispe

RISPERDAL(R) CONSTA(R) long-acting IM injection, 2009). Caution is advised if these agents are used con
for increased risperidone adverse events, including sedation, akathisia, parkinsonism, dyspepsia, tachycardia
7) Probable Mechanism: unknown

3.5.1.BZ Rifampin

1) Interaction Effect: decreased plasma concentrations of risperidone and the active metabolite 9-hydroxyris
2) Summary: Concomitant use of rifampin may reduce plasma concentrations of risperidone (Prod Info RISP
RISPERDAL(R) M-TAB(R) orally disintegrating tablets, 2008). Patients should be closely monitored if concon
may be placed on a lower dose of risperidone between 2 to 4 weeks before the planned discontinuation of rif
expected increase in plasma concentrations of risperidone plus 9-hydroxyrisperidone (Prod Info RISPERDAL
injection, 2008).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of risperidone following the addition of rifampin during t
higher risperidone doses may be needed. Patients may be placed on a lower dose of risperidone 2 to 4 week
rifampin therapy to adjust for the expected increase in plasma concentrations of risperidone plus 9-hydroxyris
maintained on the lowest available dose of risperidone long-acting injection (25 mg), it is recommended to co
interruption of treatment is necessary (Prod Info RISPERDAL(R) CONSTA(R) long-acting IM injection, 2008).
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of risperidone by rifampin

3.5.1.CA Ritonavir

1) Interaction Effect: increased risperidone serum concentrations and potential toxicity (hypotension, sedatio
arrhythmias)
2) Summary: Coadministered ritonavir may increase serum concentrations of risperidone, resulting in risperi
Kelly et al, 2002a)A risperdal dose decrease may be required when coadministered with ritonavir (Prod Info N
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor patients for signs and symptoms of neuroleptic toxicity (hypotension, sedati
arrhythmias). Reduce doses of risperidone as required.
7) Probable Mechanism: decreased risperidone metabolism
8) Literature Reports

a) Increases in risperidone serum concentration occurred in a patient taking concomitant ritonavir. A 48-
diagnosed with acquired immunodeficiency syndrome (AIDS) was admitted to a psychiatric hospital for n
medications included zidovudine 250 mg twice daily, didanosine 300 mg once daily, indinavir 400 mg twi
twice daily. He was given risperidone 3 mg twice daily upon admission. After receiving two doses of rispe
progressively drowsy and disoriented. He then became lethargic and comatose. Physical exam revealed
points with miotic pupils. Laboratory tests were normal. A toxic or metabolic etiology was suspected to be
medication was discontinued. Twenty-four hours later, his neurologic status returned to baseline and pro
reappeared. The author suggests that an interaction between risperidone, indinavir and ritonavir may hav
coma (Jover et al, 2002).

b) Extrapyramidal symptoms (EPS) occurred in a patient initiated on ritonavir and indinavir while taking
35-year-old white male with AIDS received risperidone 2 mg twice daily for treatment of Tourette's-like tic
month history of hand tremor, twitching and jerky involuntary movements of the face, shoulders, arms, an
were dapsone, pyrimethamine, azithromycin, and hydroxyzine. Risperidone was initiated at 1 mg twice d
increased to 2 mg twice daily. Indinavir 800 mg twice daily and ritonavir 200 mg twice daily was initiated
dosage was increased. One week later he experienced significantly impaired swallowing, speaking, and
existing tremors. Ritonavir and indinavir were discontinued. One month later the patient agreed to try ind
the same time he increased the risperidone dose to 3 mg twice daily. Symptoms worsened over the next
parameters were unremarkable and vital signs were stable. Risperidone was discontinued and clonazep
patients symptoms improved. Caution is warranted when risperidone is prescribed with ritonavir/indinavi

3.5.1.CB Ropinirole

1) Interaction Effect: diminished effectiveness of ropinirole
2) Summary: Theoretically, risperidone may oppose the dopaminergic effect of dopamine agonists, such as r
(R) oral tablets, 2007; Prod Info REQUIP(R) oral tablets, 2006). If concurrent use of ropinirole and a dopamin
warranted, monitor patients closely for loss of ropinirole efficacy.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution with the concurrent use of risperidone and ropinirole as this may result
ropinirole due to the antagonistic dopaminergic effect of risperidone (Prod Info REQUIP(R) oral tablets, 2006)
and a dopamine antagonist is clinically warranted, monitor patients closely for signs and symptoms of diminis
such as worsening of extrapyramidal movements, rigidity, tremor, or gait disturbances.
7) Probable Mechanism: pharmacological antagonism

3.5.1.CC Sematilide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of sematilide and risperidone is not recommended due to the risk of additive ef concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of sematilide and risperidone is not recommended du life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring i
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prolongation in Laita et al, 1999a). Concomitant use of Class III antiarrhythmic agents such as sematilide and risperidon the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CD Sertindole

1) Interaction Effect: cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of sertindole with other drugs that potentiallly prolong the QTc interval, such a approached with caution (Brown & Levin, 1998e; Prod Info Risperdal(R), 2002e).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as risper recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe Laita et al, 1999aj; Ravin & Levenson, 1997o; Gesell & Stephen, 1997g; Lo Vecchio et al, 1996g; Brown
b) Thirty, otherwise healthy, schizophrenic patients participated in an open, dose titration (4 to 16 mg/da cardiovascular effects of sertindole. At the end of the 3-week study it was concluded that resting heart ra times increased in a dose-related manner, while there was no change in PQ-conduction times, autonomi pressure. Conduction times increased an average 3.5% to 6.5% over the dosing range (Agelink et al, 20
c) The overall incidence of QT interval prolongation with sertindole is estimated at 1.9% to 4%, and the torsades de pointes has been estimated at 0.13% to 0.21% (Brown & Levin, 1998d). Periodic electrocard in the United Kingdom per sertindole's official labeling (Cardoni & Myer, 1997a).

3.5.1.CE Simvastatin

1) Interaction Effect: increased simvastatin serum concentrations with an increased risk of myopathy or rhab
2) Summary: Concomitant use of risperidone and simvastatin may increase the bioavailability of simvastatin. are both metabolized by cytochrome P450-3A4 (CYP3A4). Although risperidone is predominantly metabolize a slow metabolizer phenotype due to possession of a CYP2D6 polymorphic genotype may convert to CYP3A risperidone metabolism. As a result, risperidone may competitively inhibit simvastatin metabolism, thereby in rhabdomyolysis. In a case report, a patient developed rhabdomyolysis complicated by acute compartment sy simvastatin concomitantly with risperidone (Webber et al, 2004).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of risperidone with simvastatin is not recommended. If concurrent patient for signs and symptoms of myopathy or rhabdomyolysis (muscle pain, tenderness, or weakness). Mo and discontinue use if CK levels show a marked increase, or if myopathy or rhabdomyolysis is diagnosed or
7) Probable Mechanism: competitive inhibition of cytochrome P450-3A4-mediated simvastatin metabolism
8) Literature Reports
a) Rhabdomyolysis occurred in a 22-year-old man after simvastatin 10 milligrams (mg) daily was added comprising clonazepam 2 mg and risperidone 4 mg daily. Approximately 5 days after beginning simvasta presented with right ankle and heel pain. Over the next 24 hours, the pain advanced proximally and incre extremity showing signs of warmth, erythema, rash, and pronounced tenseness of the distal muscle com kinase (CK), aspartate and alanine aminotransferase concentrations were 12, 408 units/liter (L), 296 Inte IU/L, respectively. CK concentrations peaked at 25, 498 units/L. Simvastatin was withdrawn and the pati decompression fasciotomies due to acute compartment syndrome of the right lower extremity. Risperido continued without incident (Webber et al, 2004).

3.5.1.CF Sotalol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of sotalol and risperidone is not recommended due to the risk of additive effect use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003a).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of sotalol and risperidone is not recommended due t threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is ac
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prolongation in Laita et al, 1999a). Concomitant use of Class III antiarrhythmic agents such as sotalol and risperidone m QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CG Spiramycin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Spiramycin has been shown to prolong the QTc interval at the recommended therapeutic dose Even though no formal drug interaction studies have been done, the coadministration of antipsychotics and o QTc interval, including spiramycin, is not recommended. Several antipsychotic agents have demonstrated QT amisulpride (Prod Info Solian(R), 1999v), haloperidol (O'Brien et al, 1999n), quetiapine (Owens, 2001y), rispe 1999ab), sertindole (Agelink et al, 2001r), sultopride (Lande et al, 1992v), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of spiramycin and antipsychotics is not recommende
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CH Sulfamethoxazole
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cotrimoxazole has been shown to prolong the QTc interval at the recommended therapeutic do though no formal drug interaction studies have been done, the coadministration of antipsychotics and other d interval, including cotrimoxazole, is not recommended. Several antipsychotic agents have demonstrated QT p amisulpride (Prod Info Solian(R), 1999g), haloperidol (O'Brien et al, 1999d), quetiapine (Owens, 2001i), rispe 1999i), sertindole (Agelink et al, 2001f), sultopride (Lande et al, 1992e), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of cotrimoxazole and antipsychotics is not recommer
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CI Sultopride
1) Interaction Effect: cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of sultopride with other drugs that potentiallly prolong the QTc interval, such a approached with caution (Lande et al, 1992m; Montaz et al, 1992a; Harry, 1997b; Prod Info Risperdal(R), 20
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as risper recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Fatal QRS prolongation and QTc prolongation have been reported in patients taking risperidone thera 1999p; Ravin & Levenson, 1997e; Gesell & Stephen, 1997a; Lo Vecchio et al, 1996a; Brown et al, 1993a
b) Sultopride may induce prolongation of the QT interval and ventricular arrhythmias including torsades or toxic doses (Lande et al, 1992l; Montaz et al, 1992; Harry, 1997a).

3.5.1.CJ Tedisamil
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of tedisamil and risperidone is not recommended due to the risk of additive effe concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of tedisamil and risperidone is not recommended due threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is ac
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prolongation in Laita et al, 1999a). Concomitant use of Class III antiarrhythmic agents such as tedisamil and risperidone QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CK Telithromycin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated which lengthen the QT interval (Agelink et al, 2001g; Owens, 2001j; Prod Info Haldol(R), 1998b; Lande et al, drug interaction studies have been done, antipsychotic agents should not be coadministered with other drugs the QTc interval, including telithromycin (Owens, 2001j).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Due to the potential for additive effects on the QT interval, the concurrent administra antipsychotic is not recommended.
7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Fatal QRS prolongation and QTc prolongation have been reported in patients taking risperidone thera 1999j; Ravin & Levenson, 1997b).

3.5.1.CL Terfenadine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotics have been shown to prolong the QTc interval at the recommended therap (TM), 2002b; Owens, 2001ad; Prod Info Orap(R), 1999g). Even though no formal drug interaction studies hav coadministration of terfenadine and other drugs known to prolong the QTc interval, including antipsychotics, i
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of terfenadine with any drug that prolongs the QT int agents, is contraindicated.
7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experiment deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanis prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999

3.5.1.CM Tetrabenazine

1) Interaction Effect: increased risk of QT interval prolongation, neuroleptic malignant syndrome, extrapyram
2) Summary: Tetrabenazine causes a small increase in the correct QT interval. As the degree of prolongatio develop into torsade de pointes-type VT. The concomitant use of tetrabenazine with other drugs known for Q should be avoided. In a randomized, double-blind, placebo controlled crossover study of healthy subjects, the mg dose of tetrabenazine on the QT interval was studied with moxifloxacin as a positive control. The 50 mg d approximate 8 millisecond mean increase in QT (Prod Info XENAZINE(R) oral tablets, 2008) In addition to QT may also cause adverse reactions such as neuroleptic malignant syndrome and extrapyramidal disorders, wh coadministered with neuroleptic drugs (eg, risperidone) (Prod Info XENAZINE(R) oral tablets, 2008).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Coadministration of tetrabenazine with risperidone or other neuroleptic drugs may i reactions, such as QT interval prolongation and increased risk of torsade de pointes. Other adverse reactions syndrome and extrapyramidal disorders may be enhanced when given with a dopamine agonist such as rispe oral tablets, 2008).
7) Probable Mechanism: increased dopamine levels; additive effects on QT interval prolongation

3.5.1.CN Thioridazine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although citing no data, the manufacturer of thioridazine states that concomitant use with other interval is contraindicated (Prod Info Mellaril(R), 2001). Several antipsychotic agents have demonstrated QT amisulpride (Prod Info Solian(R), 1999q), haloperidol (O'Brien et al, 1999j), pimozide (Prod Info Orap(R), 200 paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), risperidone (Duenas-Laita et al, 1 2001n), sultopride (Lande et al, 1992q), ziprasidone (Prod Info GEODON(R) intramuscular injection, oral cap (Sweetman, 2004).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as antips contraindicated.
7) Probable Mechanism: additive QT prolongation

3.5.1.CO Topiramate

1) Interaction Effect: decreased risperidone exposure
2) Summary: Concurrent administration of topiramate (200 mg/day) with a single, 2 mg dose of risperidone i

in a 25% decrease in risperidone exposure. Patients receiving risperidone and topiramate together should be response to risperidone (Prod Info TOPAMAX(R) oral tablets, oral sprinkle capsules, 2008).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: established
6) Clinical Management: If risperidone and topiramate are administered concurrently, monitor patients closel risperidone (Prod Info TOPAMAX(R) oral tablets, oral sprinkle capsules, 2008).
7) Probable Mechanism: unknown

3.5.1.CP Tramadol
1) Interaction Effect: an increased risk of seizures
2) Summary: Seizures have been reported in patients using tramadol. The manufacturer of tramadol states t medications with tramadol may enhance the risk of seizures (Prod Info Ultram(R), 1998).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution should be used if tramadol is to be administered to patients receiving neuro this combination, especially in patients with underlying conditions that might predispose to seizures.
7) Probable Mechanism: unknown

3.5.1.CQ Trifluoperazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concomitant use of phenothiazines and antipsychotic agents may cause additive effects on the recommended. Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Co Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, though no antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999j), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), quetiapine (Owens, 2001n), risper 1999n), sertindole (Agelink et al, 2001j), sultopride (Lande et al, 1992i), ziprasidone (Prod Info GEODON(R) i capsule, 2005), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as phen not recommended.
7) Probable Mechanism: additive QT prolongation

3.5.1.CR Trimethoprim
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cotrimoxazole has been shown to prolong the QTc interval at the recommended therapeutic do though no formal drug interaction studies have been done, the coadministration of antipsychotics and other d interval, including cotrimoxazole, is not recommended. Several antipsychotic agents have demonstrated QT p amisulpride (Prod Info Solian(R), 1999g), haloperidol (O'Brien et al, 1999d), quetiapine (Owens, 2001i), rispe 1999i), sertindole (Agelink et al, 2001f), sultopride (Lande et al, 1992e), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of cotrimoxazole and antipsychotics is not recommer
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CS Trimipramine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999d), sertindole (Agelink et al, 2001a), o sultopride (Lande et al, 1992a), and zotepine (Sweetman, 2003). Even though no formal drug interaction stud coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experiment deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanis prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999

3.5.1.CT Valproic Acid

1) Interaction Effect: increased plasma valproic acid concentrations
2) Summary: The addition of risperidone to valproic acid produces a significant increase in the peak plasma acid (Prod Info Risperdal(R) Consta(TM), 2003c) as well as marked increases in ammonia levels (Carlson et capacity of risperidone could lead to a competition for protein-binding with the high protein-binding capacity o displacement of valproic acid from plasma protein-binding sites (van Wattum, 2001). However, Valproic acid treatment regimen consisting of risperidone (Spina et al, 2000c). Monitoring of ammonia levels may be warra new or increased manic behavior when taking valproic acid and risperidone, especially in patients vulnerable hyperammonemia, including the young, on valproate polytherapy, severely handicapped, or suffering from m decreased free serum carnitine (Carlson et al, 2007). In patients prescribed this combination of drugs, monitc OH-risperidone concentrations does not appear to be warranted.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Monitor for increased ammonia levels and plasma valproic acid concentrations with drug therapy or changes in risperidone dose.
7) Probable Mechanism: unknown
8) Literature Reports
a) In 2 case reports of 11 year-old boys, there were marked exacerbations in manic behavior and a 2 to ammonia levels when risperidone and valproic acid were concomitantly administered. The first patient, w disorder, attention-deficit/hyperactivity disorder (ADHD), psychosis, and manic symptoms, was admitted behavior. Chlorpromazine was added as needed and risperidone was added to replace his aripiprazole. acid 250 mg twice daily, the patient experienced a qualitative exacerbation of manic behavior. The risper adjusted to 2 mg/day and valproic acid to 625 mg/day. The patient's valproate level ranged from 87 to 9C When valproic acid was discontinued, and the ammonia level fell to 55, his manic behavior stopped. The absence epilepsy and ADHD, was on stable doses of valproic acid. Because of his psychotic symptoms, increased to 1.125 mg/day over 5 weeks. The patients exhibited markedly pronounced manic behavior a 113, despite a normal valproic acid level of 71. Upon discontinuation of risperidone and valproic acid, the and the manic behavior resolved. One month later when the patient was rechallenged with risperidone (i there was no return of either mania or hyperammonemia (Carlson et al, 2007).
b) A study was performed to evaluate the pharmacokinetic interaction between risperidone and valproic concentrations of risperidone and 9-hydroxyrisperidone (9-OH risperidone) were compared in patients tre patients comedicated with valproic acid. Thirty-three patients with a DSM-IV diagnosis of schizophrenia, bipolar disorder, were stabilized with risperidone alone or in combination with valproic acid. The results c given at doses up to 1200-1500 mg/day had clinically insignificant effects on plasma concentrations of ris metabolite. Valproic acid can be added safely to a treatment regimen consisting of risperidone. In patient drugs, monitoring of plasma risperidone or 9-OH-risperidone concentrations does not appear to be warra
c) The combination of valproic acid and risperidone led to significantly increased levels of valproic acid i suffered from mood swings and increasingly aggressive behavior. Valproic acid treatment was initiated a Valproate serum levels were in the therapeutic range. After 10 days of treatment, risperidone 2 mg/day w to 3 mg/day on day 4. On day 5 after risperidone was started, the patients symptoms improved but valpr therapeutic range at 191 mg/L. Valproic acid was decreased to 1000 mg/day and the level normalized to subsequently stabilized. The author concludes that the high-protein-binding capacity of risperidone coulc binding with the high protein-binding capacity of valproic acid, leading to displacement of valproic acid fr (Van Wattum, 2001).
d) In 21 patients, repeated oral doses of risperidone 4 mg daily did not affect the pre-dose or average pl (area under the concentration-time curve) of valproate 1000 mg daily compared to placebo. There was, h valproate maximum plasma concentration (Cmax) after risperidone coadministration (Prod Info Risperda

3.5.1.CU Vasopressin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Antipsychotics and vasopressin have been shown to prolong the QTc interval at the recommen 2001b; Prod Info Solian(R), 1999a; Duenas-Laita et al, 1999c; Brown & Levin, 1998; Harry, 1997; Prod Info N Friedman, 1993; Mauro et al, 1988). Even though no formal drug interaction studies have been done, the coa prolong the QTc interval is not recommended.
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of drugs that prolong the QT interval, such as antipsy recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CV Zolmitriptan
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Zolmitriptan has been shown to prolong the QTc interval at the recommended therapeutic dose Antipsychotics including haloperidol (Prod Info Haldol(R), 1998g), quetiapine (Owens, 2001aa), risperidone (I risperidone, 2000c), amisulpride (Prod Info Solian(R), 1999y), sertindole (Agelink et al, 2001u); sultopride (La (Sweetman, 2004) have been shown to prolong the QT interval at therapeutic doses. Even though no formal been done, the coadministration of drugs known to prolong the QT interval is not recommended.

3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of zolmitriptan and antipsychotics is not recommende
7) Probable Mechanism: additive effect on QT interval

3.5.1.CW Zotepine
1) Interaction Effect: increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Zotepine used concurrently with neuroleptics may increase the risk of seizures (Hori et al, 1992 drugs that potentiallly prolong the QTc interval, such as zotepine and risperidone, should be approached with Info Risperdal(R), 2002d).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitoring for seizures is particularly important in those patients who: (1) are taking have a history of seizure disorders; (3) are of young age; or (4) have a past history of brain injury. The concu prolong the QT interval, such as zotepine and risperdone, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Since zotepine can prolong the QT interval it is recommended that an ECG is performed before starti existing prolongation of the QT interval should not be given zotepine (Sweetman, 2004).
b) Fatal QRS prolongation and QTc prolongation have been reported in patients taking risperidone thera 1999w; Ravin & Levenson, 1997j; Gesell & Stephen, 1997f; Lo Vecchio et al, 1996f; Brown et al, 1993f).

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters
A) Therapeutic
1) Physical Findings
a) Bipolar Disorder
1) A prolonged time to relapse to any mood episode (depression, mania, hypomania, or mixed) is indica risperidone (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).
2) Closely monitor effectiveness during the first 4 to 8 weeks of starting carbamazepine or other known inducers. The dose of risperidone may need to be titrated upward (Prod Info RISPERDAL(R) CONSTA(R
b) Schizophrenia
1) Positive and Negative Syndrome Scale (PANSS), which measures positive symptoms, negative symp uncontrolled hostility/excitement, and anxiety/depression, evaluates response to therapy (Prod Info RISP acting injection, 2009).
a) Positive psychotic symptoms (delusions, auditory hallucinations, racing thoughts)
b) Negative psychotic symptoms (anhedonia, apathy, amotivation, ambivalence).
2) Closely monitor effectiveness during the first 4 to 8 weeks of starting carbamazepine or other known inducers. The dose of risperidone may need to be titrated upward (Prod Info RISPERDAL(R) CONSTA(R
B) Toxic
1) Laboratory Parameters
a) Fasting blood glucose testing should be measured prior treatment and periodically during treatment in pat obesity, family history of diabetes) for diabetes mellitus. Patients with known diabetes mellitus should be regu glucose control during risperidone treatment. When symptoms of hyperglycemia develop, fasting blood gluco (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).
b) Complete blood count should be monitored frequently during the first few months of risperidone. If there a a decrease in CBC, then risperidone should be discontinued at the first sign of decline in WBC. For absolute 1000/mm(3), discontinue risperidone and perform follow-up WBC until recovery. Patients with preexisting low induced leukopenia/neutropenia are potentially at greatest risk for leukopenia, neutropenia, and agranulocyto

CONSTA(R) long acting injection, 2009).

2) Physical Findings

a) Tardive dyskinesia should be observed for in patients on risperidone particularly the elderly (elderly wome patients on chronic risperidone (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).

b) Hyperglycemia symptoms including polydipsia, polyuria, polyphagia, and weakness should be monitored f (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).

c) Monitor ECG at baseline and periodically during treatment (Pacher & Kecskemeti, 2004).

d) Cerebrovascular events (eg, stroke, transient ischemic attack) should be observed for in elderly patients v (not an indication) because of the higher incidence of cerebrovascular events observed with oral risperidone

e) Neuroleptic malignant syndrome (NMS) (hyperpyrexia, muscle rigidity, altered mental status, and evidenc (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmia) should be monitored fc should be immediately discontinued in the presence of NMS. Carefully monitor for NMS recurrence if risperid RISPERDAL(R) CONSTA(R) long acting injection, 2009).

f) Orthostatic hypotension symptoms including heart rate and blood pressure should be monitored for in all p during the initial dose-titration phase of oral risperidone. A dose reduction may be necessary if hypotension o predisposed to hypotension include those with known cardiovascular disease (history of myocardial infarction conduction abnormalities), cerebrovascular disease, who are dehydrated and hypovolemic, and in the elderly hepatic impairment (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).

g) Fever and other symptoms or signs of infection should be monitored for in patients on risperidone becaus neutropenia or agranulocytosis (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).

h) Patients at high-risk for suicide should be closely supervised during therapy because of the increased risk with schizophrenia or bipolar disorder (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009).

i) Confusion, obtundation, postural instability with frequent falls, extrapyramidal symptoms, and clinical featu neuroleptic malignant syndrome are manifestation of increased sensitivity in patients with Parkinson's Diseas

4.2 Patient Instructions

A) Risperidone (By mouth)

Risperidone

Treats schizophrenia and certain problems caused by bipolar disorder.

When This Medicine Should Not Be Used:
You should not use this medicine if you have had an allergic reaction to risperidone.

How to Use This Medicine:
Tablet, Liquid, Dissolving Tablet

Your doctor will tell you how much of this medicine to use and how often. Your dose may need to be changed what works best for you. Do not use more medicine or use it more often than your doctor tells you to.

Measure the oral liquid medicine with a marked measuring spoon, oral syringe, or medicine cup. You may mi milk, coffee, or orange juice. Do not mix with cola or tea.

If you are using the disintegrating tablet, make sure your hands are dry before you handle the tablet. Do not c contains the tablet until you are ready to take it. Remove the tablet from the blister pack by peeling back the f not push the tablet through the foil. Place the tablet in your mouth. It should melt quickly. After the tablet has water.

If a Dose is Missed:

If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next c medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.

How to Store and Dispose of This Medicine:

Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light. Do Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after treatment. You will also need to throw away old medicine after the expiration date has passed.

Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:

Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, a

There are many other medicines that you should not use while you are taking risperidone. Taking risperidone may be dangerous, even life-threatening. Make sure your doctor and your pharmacist knows about all other r

Make sure your doctor knows if you are taking carbamazepine (Tegretol®), cimetidine, furosemide (Lasix®), paroxetine (Paxil®), phenobarbital, ranitidine, or valproate (Depakene®, Depakote®). Tell your doctor if you a quinidine, phenytoin (Dilantin®), or rifampin (Rifadin®). Make sure your doctor knows if you are also using m

Some blood pressure medicines are atenolol, hydrochlorothiazide (HCTZ), lisinopril, metoprolol, quinapril, Ac Lotrel®, Norvasc®, Toprol®, and Zestril®.

Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and a relievers, and sedatives.

Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:

Make sure your doctor knows if you are pregnant, plan to become pregnant, or if you are breast feeding. Tell
of liver disease, kidney disease, stroke, or breast cancer. Make sure your doctor knows if you have heart prol
seizures, or trouble swallowing.
Make sure your doctor knows if you have a family history of a heart condition called congenital long QT syndı
ever had Neuroleptic Malignant Syndrome (NMS) caused by other antipsychotic medicines.

Risperdal® M-Tab® contains aspartame (phenylalanine). If you have phenylketonuria (PKU), talk to your doc

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:

Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, c
Change in how much or how often you urinate.
Confusion, weakness, and muscle twitching.
Constant muscle movement that you cannot control (often in your lips, tongue, arms, or legs).
Dry mouth, increased thirst, muscle cramps, nausea or vomiting.
Fast, slow, irregular (uneven), or pounding heartbeat.
Fever, sweating, muscle stiffness.
In males: Painful, prolonged erection of your penis.
Lightheadedness, fainting, or seizures.
Severe diarrhea, vomiting, or stomach pain.
Skin rash.
Sudden or severe headache, problems with vision, speech, or walking.
Twitching or muscle movements you cannot control (often in your eyes, jaw, neck or upper body).
Unusual bleeding, bruising, or weakness.
Yellowing of your skin or the whites of your eyes.

If you notice these less serious side effects, talk with your doctor:

Anxiety, trouble sleeping, increased dreaming.
Constipation, diarrhea, nausea, or upset stomach.
Darkening of your skin.
Drooling, or stuffy nose.
In women: Unusually heavy bleeding during your menstrual period.
Severe tiredness.
Trouble having sex.
Weight gain.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

B) Risperidone (Injection)

Risperidone

Treats schizophrenia and certain problems caused by bipolar disorder.

When This Medicine Should Not Be Used:
You should not receive this medicine if you have had an allergic reaction to risperidone.

How to Use This Medicine:
Injectable

Your doctor will prescribe your exact dose and tell you how often it should be given. This medicine is given as
A nurse or other trained health professional will give you this medicine. This medicine is usually given every 2

If a Dose is Missed:

This medicine needs to be given on a fixed schedule. If you miss a dose or forget to use your medicine, call y
instructions.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, a

Possible Side Effects While Using This Medicine:

Call your doctor right away if you notice any of these side effects:

Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, o
Change in how much or how often you urinate.
Chills, cough, sore throat, and body aches.
Dry mouth, increased hunger or thirst, or muscle cramps.
Fast, slow, pounding, or uneven heartbeat.
Feeling depressed, agitated, or nervous.
Fever, sweating, confusion, or muscle stiffness.
Lightheadedness, dizziness, or fainting.
Mood or behavioral changes, or thoughts of hurting yourself or others.
Numbness or weakness in your arm or leg, or on one side of your body.
Painful, prolonged erection of your penis (in males).
Problems with balance or walking.
Seizures or tremors.
Swelling in your hands, ankles, or feet.
Trouble with speaking or swallowing.
Twitching or muscle movements you cannot control (often in your eyes, jaw, neck or upper body).
Unusual bleeding, bruising, or weakness.
Yellowing of your skin or the whites of your eyes.

If you notice these less serious side effects, talk with your doctor:
Blurred vision or change in vision.
Constipation, diarrhea, nausea, vomiting, or stomach pain or upset.
Dry mouth or drooling.
Headache.
Pain, swelling, or a lump under your skin where the shot is given.
Rash or itching skin.
Stuffy or runny nose.
Weight gain.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Current users of atypical antipsychotic drugs (including risperidone) and typical antipsychotic drugs had a similar d cardiac death, according to a retrospective cohort of 93,300 adult users of antipsychotic drugs and 186,600 matched c patients age 30 to 74 years (mean 45.7 +/- 11.8 years) with similar cardiovascular risk at baseline who had at least on outpatient visit in each of the 2 preceding years. Sudden cardiac death was defined as occurring in the community and admitted to the hospital, non-sudden deaths, deaths due to extrinsic causes, or causes not related to ventricular tachy defined as the interval between the time the prescription was filled and the end of the day's supply. Low and high dose less than 100 milligrams (mg) of chlorpromazine, and doses comparable to chlorpromazine 300 mg or greater, respec sudden cardiac death (incidence-rate ratio) in current users of atypical antipsychotic drugs in 79,589 person-years was less than 0.001) which was similar to the risk in current users of typical antipsychotic drugs in 86,735 person-years wh 2.34, p less than 0.001). The risk of sudden cardiac death in current risperidone users in 24,589 person-years was 2.9 than 0.001). The risk of sudden cardiac death significantly increased with increasing dose in both the typical and atypi atypical antipsychotic use, the incidence rate ratio increased from 1.59 (95% CI, 1.03 to 2.46) in low-dose use to 2.86 dose use. To limit the effects of confounding of the study results, there was a secondary analysis performed in a coho propensity score, which resulted in a similar risk of sudden death as the primary cohort analysis (Ray et al, 2009). In a Journal of Medicine, it has been suggested that antipsychotic drugs continue to be used in patients with clear evidence populations with cardiac risk profiles (eg, elderly patients), there should an age-dependent justification required prior to suggested (although not formally tested) that ECGs be performed before and shortly after initiation of antipsychotic the emergent QT interval prolongation (Schneeweiss & Avorn, 2009).

B) Schizophrenia

1) Risperidone is a benzisoxazole derivative. It is approved for the treatment of schizophrenia. It blocks both serc (2) receptors. It is effective in chronic schizophrenia for positive and negative symptoms with a response rate of 5 Rossi et al, 1997; Smith et al, 1996). At doses of 8 milligrams or less risperidone is associated with a lower risk of conventional antipsychotics (Foster & Goa, 1998). Comparative efficacy with haloperidol and other conventional n shown that risperidone has a significantly higher clinical response rate and allows for significantly less prescribing (Davies et al, 1998; Bech et al, 1998; Luebbe, 1996). Risperidone has also shown some efficacy in psychotic disc HIV, levodopa, and other medical conditions. Refractory obsessive-compulsive disorder and refractory depressior risperidone in select cases.

C) Bipolar Mania

1) Long-acting injection risperidone alone or in combination with lithium or valproate is approved for the maintena disorder (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 2009). Oral risperidone alone or in combina approved for the short-term treatment of acute manic or mixed episodes associated with Bipolar I Disorder (Prod I oral solution, orally-disintegrating tablets, 2006).

D) Irritability associated with Autistic Disorder

1) Risperidone is approved for the treatment of irritability associated with autistic disorder in children and adolesc aggression towards others, deliberate self-injuriousness, temper tantrums, and quickly changing moods (Prod Info oral solution, orally-disintegrating tablets, 2006).

See Drug Consult reference: FIRST- VS SECOND-GENERATION ANTIPSYCHOTIC AGENTS FOR SCHIZOPHREN

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) In vitro studies have shown that risperidone acts primarily as a serotonin (5-HT2) and dopamine (D2) antagoni serotonergic receptors. Risperidone also binds to alpha-1 and alpha-2 adrenergic and histamine H1 receptors, alt Dissociation from 5-HT2 and H1 receptors is slow; however, the drug rapidly dissociates from dopaminergic and a potency of risperidone as a dopamine D2 antagonist is less than that of haloperidol, and its 5-HT2 antagonist pote ritanserin. Risperidone interacts weakly or not at all with other receptor and neurotransmitter systems, including cl Anon, 1993a; Gerlach, 1991; Leysen et al, 1988; Niemegeers et al, 1988).

2) Studies have shown that there is an exponential dose-response relationship between the daily dose of risperid receptor occupancy (Dresel et al, 1998; Remington et al, 1998). The slope of the curve is between that of haloper closely resembles haloperidol. One study did find that extrapyramidal effects were linked to D(2) occupancy with t symptoms having the highest percentage of binding (Remington et al, 1998). The other study found no clear relati D(2) occupancy. They hypothesized that the decreased incidence of extrapyramidal effects seen with risperidone the D(2) receptor but to risperidone's high 5-HT(2) affinity providing a relative protection from symptoms (Dresel e

3) Animal studies have shown that risperidone inhibits tryptamine- and serotonin-induced cyanosis and 5-hydroxy twitching; it also blocks central and peripheral manifestations of dopaminergic stimulation, including apomorphine-

apomorphine- or amphetamine-induced stereotypy or hypermotility (Anon, 1991; Megens et al, 1988). Risperidon
than haloperidol in the inhibition of locomotion and induction of catalepsy; in addition, risperidone causes a signifi
corresponding to the effect of ritanserin (Gerlach, 1991).
4) Potent alpha-2 adrenoceptor blockade has been demonstrated with risperidone, as it reverses clonidine inhibit
norepinephrine release in occipital cortex. It also exhibits complete and potent lysergic acid diethylamide (LSD) a
1991; Leysen et al, 1988; Niemegeers et al, 1988).

B) REVIEW ARTICLES

4.5 Therapeutic Uses

Agitation, acute - Psychotic disorder

Anorexia nervosa

Autistic disorder - Irritability

Behavioral syndrome - Dementia

Behavioral syndrome - Mental retardation

Bipolar I disorder

Borderline personality disorder

Catatonia

Cocaine dependence

Cognitive function finding

Delusional disorder

Dementia

Dementia - Psychotic disorder

Depression, Refractory; Adjunct

Drug-induced psychosis - Levodopa adverse reaction

Gilles de la Tourette's syndrome

Huntington's disease

Inhalant abuse

Obsessive-compulsive disorder, Refractory

Organic psychotic condition

Parkinson's disease - Psychotic disorder

Pervasive developmental disorder

Pick's disease

Posttraumatic stress disorder

Schizophrenia

Schizotypal personality disorder

Stuttering

Tardive dyskinesia

Trichotillomania

Water intoxication syndrome

4.5.A Agitation, acute - Psychotic disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Olanzapine orally disintegrating tablets and risperidone oral solution yielded similar improvements on the and Negative Syndrome Scale and the Clinical Global Impression scale in 87 patients treated for acute p emergency setting, according to an open-label, flexible-dose study(Hatta et al, 2008)

3) Adult:

a) Olanzapine orally disintegrating tablets (ODT) and risperidone oral solution (OS) yielded similar improvem for Positive and Negative Syndrome Scale (PANSS-EC) and the Clinical Global Impression (CGI) scale in 87 psychotic agitation in a psychiatric emergency setting, according to an open-label, flexible-dose study. Patien score of 15 or higher who accepted oral medication were assigned to receive initial doses of either olanzapin or risperidone OS 3 mg (n=53). Treatment group assignments were based on previous effective treatments, olanzapine or risperidone according to the time of study trial entry. Patients who experienced continued agita time, and after 1 hour could receive adjunctive drug therapy. PANSS-EC scores in both groups decreased ov from baseline was similar between the olanzapine and risperidone group (2.8 vs 3.2; p=0.22). Repeated mea score over time ANOVA (at baseline and every 15 minutes for 1 hour) revealed no significant main effect of t treatment over time (p=0.09 and p=0.41, respectively). There was a significant mean change in heart rate in t compared with risperidone OS group (-9.2 vs 1.1 beats/minute, p=0.03). There were no significant differences for adverse effects including extrapyramidal symptoms (Hatta et al, 2008).

4.5.B Anorexia nervosa

See Drug Consult reference: ANOREXIA NERVOSA - DRUG THERAPY

4.5.C Autistic disorder - Irritability

FDA Labeled Indication

1) Overview

FDA Approval: Adult, no; Pediatric, yes (5 years and older)
Efficacy: Pediatric, Effective
Recommendation: Pediatric, Class IIa
Strength of Evidence: Pediatric, Category A

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone was more effective than placebo in improving the emotional and behavioral symptoms of au towards others, deliberate self-injuriousness, temper tantrums, and quickly changing moods in short-ter studies (Prod Info RISPERDAL(R) oral tablets, oral solution, orally-disintegrating tablets, 2006; McCrack

continued risperidone therapy maintained efficacy up to 6 months and led to lower relapse rates compar
2002).
Treatment with oral risperidone was well tolerated and more effective in improving autism symptoms con
randomized, double-blind study (n=40) (Nagaraj et al, 2006).

3) Pediatric:

a) Risperidone was more effective than placebo for the short-term treatment of severe behavioral problems i
randomized, double-blind, placebo-controlled study (n=101). Patients (ages 5 to 17 years) with autism accom
problems (tantrums, aggression, or self-injurious behavior) received placebo (n=49) or risperidone 0.5 to 3.5
dose during last week, 1.8 mg/day) for 8 weeks. Primary efficacy measures were the score at eight weeks on
Aberrant Behavior Checklist and the rating on the Clinical Global Impressions-Improvement (CGI-I) scale. A p
a 25% or greater reduction in the Irritability score and a rating of much improved or very much improved on th
Irritability score for the risperidone group decreased by 56.9% following 8 weeks of treatment as compared w
placebo group (p less than 0.001). The rate of positive response was significantly higher in risperidone-treate
placebo (69% vs 12%, respectively; p less than 0.001). Risperidone was generally well tolerated and most ac
transient. Due to the uncertainty of a clear benefit with regard to the core symptoms of autism the authors rec
reserved for the treatment of moderate-to-severe behavioral problems accompanying autism (McCracken et a
endpoints, risperidone significantly decreased the overall score on the Ritvo-Freeman scale, which was modi
measure to a parent rating scale and included subscales for assessing sensory motor behaviors, social relate
sensory responses, and language (subscales I, II, III, IV, and IV, respectively). Specifically, significant treatm

0.3; p=0.191). The clinical global impression (CGI) scores were also significantly improved in the risperidone
A subgroup analysis on dementia type (Alzheimer's disease, vascular dementia and mixed dementia) found t
total scores were significantly improved in the risperidone group in both Alzheimer's disease and vascular de
dementia subjects. Treatment-emergent adverse events were comparable between risperidone (84.3%) and
number of patients who discontinued therapy due to treatment-emergent adverse events was higher in the ris
versus placebo (11.2%). Common adverse events leading to discontinuation in the risperidone group were sc
extrapyramidal disorders, aggressive reaction, pneumonia, injury, cerebrovascular disorder, and fall (De Deyn

4.5.E Behavioral syndrome - Mental retardation

1) Overview

FDA Approval: Adult, no; Pediatric, no

Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Useful for the adjunctive therapy of behavioral disturbances in patients with mental retardation
Effectively reduced severe behavior problems in children with below average intelligence

3) Adult:

a) Seven patients with Prader-Willi Syndrome and behavioral disturbances responded favorably to risperidor average dose was 1.64 milligrams daily). Six patients were adults and 1 was an adolescent. The patients hac antipsychotic medications (Durst et al, 2000).

b) In one double-blind, placebo-controlled crossover study, 37 patients with behavioral abnormalities such as irritability, agitation, hyperactivity, automutilation, and autism despite current therapy improved on risperidone medications were given orally for 3 weeks, followed by 3 weeks of crossover treatment. Doses of risperidone day; at weekly evaluations, daily dosage was increased by 4 mg/day up to a maximum total dose of 12 mg/da Global Impression (CGI) scores occurred. Risperidone caused significant improvement in CGI parameters thr study; placebo was not effective. No extrapyramidal symptoms occurred. No significant cardiovascular, bioch were reported (Vanden Borre et al, 1993a).

4) Pediatric:

a) Risperidone was safe and effective as a short- and long-term therapy for the reduction of severe behavior moderate intellectual disabilities. In a 6-week, randomized, double- blind, placebo controlled study, patients (average intelligence (IQ, 36 to 84) and a diagnosis of conduct disorder, oppositional defiant disorder, or disru otherwise specified received placebo (n=63) or risperidone (n=55) 0.02 to 0.06 milligrams (mg)/kilogram/day Efficacy of risperidone was assessed according to the change in score from baseline to endpoint on the cond Nisonger Child Behavior Rating Form. Patients treated with risperidone showed a significantly larger reductio subscale scores from baseline to endpoint as compared with placebo (-15.2 vs -6.2, respectively; p less than patients also showed significantly better improvements than did placebo-treated patients on all other subscal Rating Form. Risperidone was generally well tolerated and most adverse effects were mild to moderate, inclu headache (29%). As a long-term, open-label extension, 107 patients from this controlled study received rispe titrated up to maximum of 0.06 mg/kg/day; mean dose 1.51 mg/day) for 48 weeks. Throughout the 48-week e was maintained in patients treated with risperidone during the controlled trial and significant symptom improv who had received placebo during the controlled trial. Risperidone was generally well tolerated throughout the Adverse events included headache (32.7%), somnolence (32.7%), rhinitis (28%), increased appetite (9.3%), increase from baseline, 5.5 kilograms), and transient, mild elevations in prolactin levels (mean maximum leve (ng/mL) in boys; 23.9 ng/mL in girls). Additional studies are needed to investigate the safety and efficacy of ri for the treatment of severe, disruptive behavior in pediatric patients (Findling et al, 2004; Aman et al, 2002).

4.5.F Bipolar I disorder

FDA Labeled Indication

1) Overview
FDA Approval: Adult, yes (oral and intramuscular); Pediatric, yes (10 years and older, oral only)
Efficacy: Adult, Effective; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIa; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Intramuscular long-acting risperidone is indicated as monotherapy or in combination with lithium or valpr treatment of bipolar I disorder in adults (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 200
Oral risperidone is indicated for the short-term treatment of acute manic or mixed episodes associated w aged 10 years of age and older and adults (Prod Info RISPERDAL(R) oral tablets, 2007; Prod Info RISPI disintegrating tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007).
Oral risperidone, at doses ranging from 0.5 to 6 milligrams per day for 3 weeks, was effective in the treat episodes of bipolar I disorder in children aged 10 to 17 years in a multicenter, randomized, double-blind, Info RISPERDAL(R) oral tablets, 2007; Prod Info RISPERDAL(R) M-TAB orally disintegrating tablets, 20 oral solution, 2007).

3) Adult:

a) Monotherapy

1) Intramuscular

a) In a multicenter, randomized, double-blind, placebo-controlled study of adult patients who met DS bipolar disorder type I and who were stable on medications or experiencing an acute manic or mixed intramuscular (IM) risperidone was effective for the maintenance treatment of bipolar I disorder. Dur a total of 501 patients were treated with IM risperidone at the starting dose of 25 mg and titrated up in patients not tolerating the starting dose). Of the 501 treated patients, 303 (60%) were deemed to h to double-blind treatment with either the same dose of IM risperidone or placebo. The results of the s compared to placebo, patients receiving monotherapy IM risperidone were delayed to reaching the s was the time to relapse to any mood episode (depression, mania, hypomania, or mixed). The majori rather than depressive symptoms and based on their history of bipolar disorder, these patients had, episodes than depressive episodes (Prod Info RISPERDAL(R) CONSTA(R) long acting injection, 20

2) Oral

a) Risperidone monotherapy was effective in the acute and continuation treatment of mania in patie
open- label, multicenter study, patients with acute mania and a score of at least 20 on the Young Ma
received six months of risperidone monotherapy at a mean dose of 4.2 milligrams (mg) daily (range
improvements in the YMRS score were observed from baseline to weeks 1, 2, 4, 6, 12, and 24 (p les

week 4 (p=0.015) (correlating with the highest mean doses of risperidone), but then decreased signi
(p=0.027). Other adverse events included impotence, drowsiness, weight gain (mean increase, 3.2 l
dizziness, hypotension, incontinence, and galactorrhea. Within the initial 4 weeks of treatment, incre
symptoms was seen in four patients (4.2%) and the appearance of a depressive episode was obser
Randomized, controlled studies are needed to confirm the safety and efficacy of risperidone monoth
of bipolar mania (Vieta et al, 2004).

b) In two placebo-controlled trials, risperidone monotherapy was more effective than placebo in red
patients with bipolar disorder. Patients meeting DSM-IV criteria for bipolar I disorder with manic or m
without psychotic features received risperidone (1 to 6 milligrams (mg)/day; mean modal dose, 4.1 t
weeks (n=246; n=286). In both trials, risperidone was more effective than placebo in the reduction o
(YMRS) scores of these patients (Prod Info RISPERDAL(R) oral tablets, 2007; Prod Info RISPERDA
tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007).

b) Combination Therapy

1) Intramuscular

a) In a multicenter, randomized, double-blind, placebo-controlled study of adult patients who met DS
bipolar disorder type I and who experienced at least 4 episodes of mood disorder requiring psychiat
previous 12 months and at least 2 episodes in the 6 months prior to starting the trial, long-acting intr
effective for bipolar I disorder when used as combination therapy with lithium or valproate. During a
total of 240 patients were treated with IM risperidone at the starting dose of 25 mg and titrated up if
patients not tolerating the starting dose) in addition to continuing their usual bipolar disorder therapy
discontinued after the first 3 weeks of the initial injection of IM risperidone. Of the 240 treated patien
be stable for at least the last 4 weeks and were randomized to double-blind treatment with either the
placebo in addition to their usual bipolar disorder therapy for 52 weeks. The results of the 52-week s
compared to placebo, patients receiving IM risperidone as combination therapy were delayed to rea
which was the time to relapse to any new mood episode (depression, mania, hypomania, or mixed)
RISPERDAL(R) CONSTA(R) long acting injection, 2009).

2) Oral

a) The efficacy of risperidone as a combination therapy for the treatment of manic or mixed episode
disorder was established in one controlled trial, while a second controlled trial failed to show efficacy
combination trial, patients (n=148) on lithium or valproate therapy (therapeutic range, 0.6 to 1.4 mEq
respectively) with bipolar I disorder with or without psychotic features and with inadequately controlle
received risperidone (1 to 6 mg/day; mean modal dose, 3.8 mg/day), an active comparator, or place
original therapy. Combination therapy with adjunctive risperidone was more effective than lithium or
of the YMRS total score. However, in a second combination trial in 142 patients on lithium, valproate
inadequately controlled manic or mixed symptoms, the addition of risperidone (1 to 6 mg/day; mean
not superior to lithium, valproate, or carbamazepine (therapeutic range, 0.6 to 1.4 mEq/L, 50 to 125
respectively) alone in the reduction of the YMRS total score. The failure of this trial could be due to i
hydroxyrisperidone clearance by carbamazepine, leading to subtherapeutic levels of risperidone and
RISPERDAL(R) oral tablets, 2007; Prod Info RISPERDAL(R) M-TAB orally disintegrating tablets, 20
oral solution, 2007).

b) Risperidone (median modal dose of 4 milligrams) may be more effective in the treatment of mani
bipolar disorder than placebo when combined with mood stabilizing drugs. Bipolar patients, aged 18
with a manic or mixed episode and a score of at least 20 on the Young Mania Rating Scale (YMRS)
double-blind, placebo-controlled study. To be eligible for this study the patient also had to be taking
divalproex or carbamazepine) for a minimum of 2 weeks prior to randomized assignment into treatm
measure was the change in YMRS score from baseline to endpoint. There was a decrease of 14.5 a
score for the risperidone and placebo groups, respectively, at the end of the 3 weeks (p=0.089). Ris
patients with or without psychotic features. When combined with carbamazepine, risperidone media
concentrations decreased by 40%. Due to a high number of dropouts in both groups the study was i
determine the true treatment effects. Additional studies are ongoing (Yatham et al, 2003).

c) Risperidone was associated with significantly greater improvement compared with placebo. A mu
group study investigated adding risperidone, haloperidol, or placebo to a mood stabilizer (lithium or
acute mania. After completing the 3 week, double-blind phase of the study, patients were offered op
an additional 10 weeks of follow-up. Improvement on the Young Mania Rating Scale and the Clinica
Improvement scale was greater with risperidone at 3 weeks. The investigators concluded that risper
addition to lithium or valproate for the treatment of bipolar mania (Ghaemi & Sachs, 1997).

d) An improvement was seen in all patients who completed another small, 6-week, open label study
(mean dose, 3 mg per day) and concurrent mood-stabilizing drugs in the treatment of acute psychot
enrolled and by week 6, all of the completers had a 50% improvement as assessed by the Young M
1996).

e) As an add-on therapy, risperidone brought significant improvement to patients with bipolar disorc

bipolar type. In a 6-month, open study, patients with a diagnosis of bipolar or schizoaffective disorde hypomanic, depressive, or mixed episode (n=541; 430 completed the study) were given risperidone anticonvulsants, and antidepressants to clinical response and tolerability. The average dose of rispe was 4 milligrams (mg) per day and at the end of the study, 3.9 mg/day. For all patients, scores on th (YMRS) were significantly reduced at week 1 and at every point thereafter (p less than 0.001 for all patients, for whom p was less than 0.05). Mean scores on the YMRS decreased from 25.6 at baseli scores on the Hamilton Rating Scale for Depression (HAM-D) were significantly reduced from baseli than 0.0001), with scores declining from 12.8 at baseline to 4.1 at 6 months. Scores on the Positive (PANSS) declined from 72 at baseline to 40 at 6 months (p less than 0.0001). According to the Clini (CGI), no patients were free from symptoms at baseline and only 5% were rated as "mildly ill." At st showed no symptoms of mania or depression and a further 30% were "mildly ill." During the study, 2 relapses into a mood state different from that at the start of the trial. Scores for extrapyramidal symp study than at baseline (p less than 0.0001). There were significant reductions in dystonia, rigidity, hy dyskinesia, tremor, and akathisia subscores. There were no cases of new-emergent tardive dyskine reactions included increase in weight (2.4% of patients), drowsiness (1.3%), impotence (0.7%), and very low incidence of exacerbation mania in the first 6 weeks (1.8%) (Vieta et al, 2001).

f) Long-term use of adjunctive risperidone for breakthrough episodes of mania or depression was re study. A group of outpatients (n=12) with bipolar disorder type I, who experienced breakthrough epis maintenance medication, were treated with a mean dose of 2.75 mg per day of risperidone. Scores Functioning scale improved from 10 to 25 points in 4 of the 8 patients who completed 6 months of tr worsening of mania (Sachs G, 1999).

g) In an open study, 10 patients with rapid cycling bipolar disorder (type I or type II) improved with r 1998). Patients were allowed to continue thyroid medications and benzodiazepines but had all antid discontinued. Risperidone was started at 1 milligram twice daily and titrated as needed. After 6 mon 5.5 affective episodes during the previous 6 months to 2 episodes while receiving risperidone (p less Rating Scale for Depression scores also decreased from 14 to 6.

h) Open studies using risperidone 1 to 6 milligrams as adjunct therapy in the treatment of refractory some efficacy. In one study, 9 out of 14 patients were rated as much improved on the Clinical Globa Among the other 5 patients, 3 stopped due to ataxia and dizziness or weight gain and 2 experienced al, 1997). In another study, 4 of 7 patients had a mild to moderate improvement on the CGI rating sc change after therapy (McIntyre et al, 1997). A controlled trial is needed to establish the benefits of ri

4) Pediatric:

a) Monotherapy

1) In a multicenter, randomized, double-blind, placebo-controlled trial, oral risperidone, at doses ranging day, was effective in the treatment of mania in children aged 10 to 17 years. Patients who were experien bipolar I disorder were randomized to receive either risperidone 0.5 to 2.5 mg/day (n=50; mean modal do mg/day (n=61; mean modal dose, 4.7 mg), or placebo (n=58) for 3 weeks. Risperidone was initiated at 0 target dose by day 7, with further increases to the maximum tolerated dose by day 10. Compared to plac groups showed a significant reduction from baseline in the total Young Mania Rating Scale (YMRS) scor seen in the 3 to 6 mg/day dose group were comparable to those seen in the 0.5 to 2.5 mg/day dose grou evident at doses higher than 2.5 mg/day. Adverse events reported at a higher incidence than placebo in fatigue (18%-30%), dizziness (13%-16%), dystonia (8%-13%), abdominal pain (15%-18%), nausea (13% somnolence (42%-56%), and abnormal vision (4%-7%) (Prod Info RISPERDAL(R) oral tablets, 2007; Pr orally disintegrating tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007).

b) Combination Therapy

1) In a case series including 11 children and adolescents aged 5 to 16 years with difficult to manage mo bipolar disorder) and aggressive behavior, 8 had therapeutic responses to risperidone 0.75 to 2.5 milligra symptoms were clinically very diverse and most were taking concurrent medications, such as mood stab psychometric instruments were used for assessment, so improvement was purely subjective. Seven pati marked improvement and one patient was considered moderately improved. Side effects reported includ anxiety (Schreier, 1998).

4.5.G Borderline personality disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Has reduced aggressive behavior and hostility in patients with borderline personality disorder

3) Adult:

a) Treatment with risperidone was associated with improvement in aggression, mood, and anergy in 13 patie disorder. In an 8-week open label study, patients were given risperidone, starting at 1 milligram (mg) per day basis to a maximum of 4 mg/day. The average final dose was 3.27 mg/day. Scores on the Brief Psychiatric R reduced by an average of 21% (p=0.003), with improvements specifically on the anergia scale (p=0.0033) an (p=0.0144). Depression was reduced (p=0.0025) and, according to the self-rated Aggression Questionnaire, by 18% (p=0.0057). Four patients experienced insomnia and 3 experienced agitation. Somnolence, anxiety,

reported by 2 patients (Rocca et al, 2002).

b) A 31-year-old woman with comorbid borderline personality disorder and dysthymia was successfully treat
(Szigethy & Schulz, 1997). She had been hospitalized 5 times and had failed therapy with fluoxetine, sertralir
perphenazine. She had been maintained on fluvoxamine but after an exacerbation of symptoms, risperidone
sustained improvement over the next 3 months. Risperidone was increased and a fluvoxamine taper was uns
resumption of fluvoxamine she was again able to return to her full-time job.

c) A 31-year-old woman was successfully treated with risperidone for her extreme impulsivity associated witl
personality disorder (Khouzam & Donnelly, 1997). After being refractory to multiple antipsychotics, antidepres
carbamazepine and valproate, she went into remission on risperidone 4 milligrams daily.

4.5.H Catatonia

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

One case report documents the successful use of risperidone for catatonia

3) Adult:

a) A 47-year-old man with persistent organic catatonia responded to risperidone 4 milligrams twice daily ther
with psychotherapy and pharmacologic therapy that included antidepressants, lithium carbonate, and various
1996).

4.5.I Cocaine dependence

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone is not effective in reducing cocaine use
Risperidone reduced craving and relapses in cocaine-dependent patients with schizophrenia

3) Adult:

a) Cocaine Dependence Only

1) There was no reduction in cocaine use associated with risperidone. A 12-week, randomized, double-l
evaluated using risperidone for the treatment of cocaine dependence. Cocaine-dependent subjects (n=1
or 8 mg of risperidone, with a subsequent change to active doses of 2 mg and 4 mg. Subjects attended t
provided urine samples, obtained medication, and underwent one behavioral therapy session per week.
interim analysis. Retention was worse for the 4 and 8 mg medication groups. Side effects were primarily
although neither the 2 nor 4 mg dose was well accepted by subjects. Risperidone is unlikely to find broa
cocaine dependence (Grabowski et al, 2000).

b) Schizophrenia With Concomitant Cocaine Dependence

1) The results of a pilot study suggest that risperidone therapy reduced craving and relapses in cocaine-
schizophrenia. In this 6-week, open label trial, patients with a dual diagnosis of schizophrenia and cocair
of cocaine/month) received risperidone (n=8; initial, 2 milligrams (mg)/day, titrated to maximum dose of 6
neuroleptic medication treatment (n=10; haloperidol, fluphenazine, or chlorpromazine). Patients in the ris
less cue reactivity in regard to the intensity (p=0.005) and depression (p=0.031) dimensions of craving a
therapy, but there was no statistical difference on the energy and feeling sick dimensions. Risperidone-tr
significantly lower rate of relapse (defined as any substance abuse) than did patients on typical neurolep
respectively; p=0.025). Although not significant, a tendency toward a greater reduction in negative and g
was seen in risperidone-treated patients. Larger, double-blind studies are needed to substantiate these f

4.5.J Cognitive function finding

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone-treated patients have shown some positive results in their neurocognitive abilities

3) Adult:

a) In a small randomized study (n=13), risperidone demonstrated an advantage over haloperidol for improvir
(Addington & Addington, 1997). Patients received either risperidone or haloperidol over a 6 week period. The
risperidone subjects on executive functioning (Wisconsin Card Sorting Test), on a measure of sustained atter
test), and on delayed verbal recall.

b) Risperidone therapy appeared to exert a more favorable effect on verbal working memory in treatment-res than did haloperidol therapy (Green et al, 1997a). In a randomized, double-blind comparison of treatment witl haloperidol (n=29), verbal working memory was measured at baseline and after 4 weeks of both a fixed dose Risperidone patients showed a significant improvement in memory using a Digit Span Distractibility Test from the fixed-dose (p less than 0.0001) and the flexible dose (p less than 0.0003) phases. The haloperidol-treated significantly. Results suggest that treatment of schizophrenia could be broadened to include the impact on ne
c) Risperidone improved neuropsychological impairment in withdrawn cocaine-dependent patients (Smelson patients received either risperidone 2 to 4 milligrams or no drug. Neuropsychological testing was done before group receiving risperidone showed improvement in the Digit Symbol test (p less than 0.01), the Trails Part A Grooved Peg Board dominant (p less than 0.003) and nondominant tests (p less than 0.06). No difference wa

4.5.K Delusional disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone has been effective in the treatment of delusional disorder in case reports and open trials
Risperidone was effective treatment of monosymptomatic hypochondriacal psychosis

3) Adult:

a) Risperidone reduced most delusional parameters in a 50-year-old female with persecutory delusions (Fea treatment with sulpiride, 200 to 800 milligrams (mg) daily, produced side effects and resulted in patient noncc patient was originally part of a 24-week, double-blind, randomized, placebo-controlled, crossover trial (1 to 4 placebo) with 4 participants; all other participants dropped out of the study. A collaborative approach was use in the study. In this approach the delusions are not challenged from the outset. The certainty with which the p change, but these beliefs were qualitatively different; the persecution had happened in the past, but was not tools used were the Brief Psychiatric Rating Scale (BPRS), Positive and Negative Syndrome Scale (PANSS) of Delusions Schedule (MADS). During the placebo phase (weeks 0 to 11) there was no change in delusiona (weeks 12 to 24), the patient received 2 weeks of 1 mg risperidone, which was then titrated to 2 mg accordin trial crossover, MADS results indicated improvement in delusional condition had begun; substantial improvem risperidone treatment. The final trial dose was 2 mg of risperidone at night. By the end of the 24-week trial, ef marked reduction or absence of delusions, suspicions, anxiety, tension, and depression.
b) Risperidone eliminated or reduced delusions of theft in 17 of 18 patients treated for 12 weeks in an open- burden on the caretaker was evaluated for 16 of the responding patients. The mean daily risperidone dose fo milligrams. There were significant reductions in Neuropsychiatric Inventory (NPI) scores for delusion (p less t (p=0.002), anxiety (p=0.017), irritability/lability (p=0.023), and aberrant motor behavior (p=0.011) with risperid Zarit Caregiver Burden Interview (ZBI) dropped from 41 at the start of the study to 23 at 12 weeks (p less tha
c) An 81-year-old male presented with tactile hallucinations and DELUSIONS OF INFESTATION at which tir initiated and started gradually. The patient was asymptomatic 3 months later. After 9 months he returned with haloperidol that had been prescribed by another physician. Haloperidol was discontinued and low dose risper later his symptoms recurred and the risperidone dose was increased. At the time of publication he was sympt
d) A 23-year-old male presented with ocular complaints. He was suffering from continuous pain and the feeli down his face. Risperidone 2 milligrams per day was started and increased to 4 milligrams per day 3 days lat after 2 weeks and discharged at 4 weeks (Cetin et al, 1999).

4.5.L Dementia

occurred in 2.5% and 0%, respectively. During the double-blind phase, the mean weight increase was 1.
risperidone group compared with a mean loss of 0.5 +/- 2.9 kg in the placebo group (Rapaport et al, 200
4) Adjunctive risperidone therapy was effective in the treatment of nonpsychotic depressive disorders in
a case series, five female patients (ages 48 to 61 years) with treatment-resistant depression and suicida
(maximum dose, 1 milligram/day) in addition to their current antidepressant medication for at least 5 mor
Impressions-Severity of illness scores were reported as "markedly ill" or "among the most extremely ill" a
adjunctive therapy, all patients were rated as "very much improved" on the Clinical Global Impressions-Ir
patients did not report further suicidal ideation. Risperidone was well tolerated. Larger, controlled studies
these findings (Viner et al, 2003).
5) Eight cases were described of risperidone therapy augmenting selective serotonin reuptake inhibitor
major depressive episodes without psychotic features (Ostroff & Nelson, 1999). All patients had incomple
therapy with Hamilton Rating Scale for Depression (HAM-D) scores of 16 to 27. Risperidone 0.5 to 1 mill
and HAM-D scores decreased to a range of 0 to 6 within 1 to 7 days.

4.5.O Drug-induced psychosis - Levodopa adverse reaction

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective for levodopa-induced psychotic symptoms

3) Adult:

a) In an open-label trial in 10 patients, low dose risperidone was useful for levodopa-induced psychotic symp
with advanced Parkinson's disease and cognitive decline (Meco et al, 1997b). Nine patients improved signific
Rating Scale and the Hallucinosis Questionnaire after 2 weeks and peaked after 6 weeks (p less than 0.01).
risperidone due to worsening Parkinson's disease.
b) In a 26 week-trial, 23 of 39 parkinsonism patients treated with risperidone demonstrated complete or near
hallucinations and delusions and an approximately 50% to 75% reduction was seen in another 4 patients. Six
improvement and an additional 6 had rapid and pronounced deterioration of parkinsonism which required risp
mean dose of risperidone was 1.10 milligrams (mg) with a mean duration of treatment of 16.2 weeks. Sixteen
trial (Leopold, 2000). Similar results were found in a 12-week open pilot study involving 17 patients receiving
day (Mohr et al, 2000).

4.5.P Gilles de la Tourette's syndrome

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIa; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

May be an effective alternative for treatment of Tourette's syndrome

3) Adult:

a) Risperidone was effective in treating patients with Tourette's Syndrome (TS). In a randomized, double-blir
patients with moderate to severe TS received either risperidone 0.5 to 6 milligrams/day or placebo for 8 week
0.25 mg once daily and increased to 0.5 mg twice daily. Thereafter, the dose could be altered for an individua
exceed 6 mg/day. Sixty-one percent of patients in the risperidone group and 26% in the placebo group impro
Tourette's Syndrome Severity Scale (TSSS) by 8 weeks (p=0.04). The severity of disease at baseline did not
risperidone group also showed significantly greater improvement in functioning than did the placebo group (p
occurring in patients with greater impairment in functioning at baseline. Patients treated with risperidone shov
parkinsonism than did patients treated with placebo (p=0.004. An increase in parkinsonism occurred only in p
average parkinsonism at baseline. Risperidone caused a greater incidence of fatigue than did placebo (57%
(35% vs 4%, p=0.02). Depression also occurred more frequently with risperidone, resulting in discontinuation
group (Dion et al, 2001).
b) Risperidone treatment resulted in improvement in the severity of Tourette's syndrome tics in an open trial
1996). All subjects (age range 8 to 53 years) had been treated with clonidine and neuroleptics and had exper
unacceptable side effects. The mean risperidone dose was 2.7 milligrams/day (range 0.5 to 9 mg/d). Twenty-
took neuroleptics during the study period. Eight patients dropped out because of side effects; of the original 3
experienced improvement. Reported side effects included sedation (18% of patients), akathisia/agitation (10%
weakness, insomnia, depression, anxiety, and aggressive behavior (3% each). Risperidone dose, other medi

diagnoses did not significantly affect response, and there was no correlation between those factors and the ty

4) Pediatric:

a) Tourette syndrome patients demonstrated a reduction in aggression in 78.5% of 28 patients and a decrea of tics in 61.7% of 28 patients. The average daily dose of risperidone was 2 milligrams daily. The tics and agg at baseline and 2 weeks to 4 months later (average 2 months) (Sandor & Stephens, 2000).

4.5.Q Huntington's disease

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective for the involuntary movements per case reports

3) Adult:

a) Four patients with involuntary movements secondary to Huntington Chorea (and no psychotic symptoms) therapy (Dallocchio et al, 1999). Patients received an initial dose of risperidone 1 milligram (mg) every 8 hour were increased in 0.5-mg increments per day to 3 mg every 8 hours. There was no significant improvement s higher doses produced a significant reduction in choreic disturbances as seen on the Marsden and Quinn Sc Symptoms worsened again as the patients were withdrawn from risperidone. Another patient with genetically but only with psychosis and no movement disorder also received risperidone 3 mg/day. Her psychiatric condi any side effects.

4.5.R Inhalant abuse

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone was effective in the treatment of inhalant abuse

3) Adult:

a) A 25-year-old male had a 5-year history of inhalant (gasoline and carburetor cleaning fluid) abuse. Risperi daily was started which effectively reduced hallucinations and paranoia and eliminated aggressive behavior c After an increase to 1 mg twice daily paranoid thoughts ceased and craving for inhalants was reduced. He ha follow-up (Misra et al, 1999).

4.5.S Obsessive-compulsive disorder, Refractory

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Adjunctive therapy may be effective for obsessive-compulsive disorder refractory to serotonin reuptake i 2008; McDougle et al, 2000; Agid & Lerer, 1999; Stein et al, 1997; Saxena et al, 1996).

3) Adult:

a) Adjunctive therapy of risperidone or olanzapine with serotonin-reuptake inhibitors (SRI) were equally effec compulsive symptoms in SRI monotherapy-resistant outpatients, according to an 8-week, single-blind, rando conclusion may be limited by the lack of a placebo arm, single-arm design, and underpowered nature of the t prospective, open-label phase of SRI monotherapy (n=96), patients who were treatment-resistant (defined as the total score of Yale-Brown Obsessive Compulsive Scale (Y-BOCS) and a Clinical Global Impression Seve entered an 8-week single-blind phase (n=50). Patients in the single-blind phase received SRI daily doses of c citalopram 50 to 80 mg, fluoxetine 60 mg, fluvoxamine 200 to 300 mg, paroxetine 50 to 60 mg, or sertraline 2 receive either risperidone 1 to 3 mg/day (n=25), or olanzapine 2.5 to 10 mg/day (n=25) in addition to the SRI personnel and assessor-blinding constituted the single-blind study design; patients were not blinded. In an int carried forward analysis of the primary endpoints, both treatments significantly improved Y-BOCS and CGI-S The magnitude of change in mean Y-BOCS total scores, CGI-S scores, and responder rates (35% or greater versus baseline, and a CGI-I score of 2 or less) was similar between groups.

Primary Efficacy Endpoints at 8 Weeks		
	Risperidone (n=25)	Olanzapine (n=25)

Responder rates*	44% (11/25)	48% (12/25)
Mean end-point Y-BOCS score	22.6 +/- 7.2	22.2 +/- 7.4
Change in mean Y-BOCS score from baseline	-7.5; p less than 0.001	-8.4; p less than 0.0
Mean end-point CGI-S score	3.2 +/- 1.7	3.1 +/- 1.8
Change in mean CGI-S score from baseline	-1.7; p less than 0.001	-1.9; p less than 0.0
* p=1; Y-BOCS=Yale-Brown Obsessive Compulsive Scale; CGI-S=Clinical Global Impression Severity s		

b) Adverse effects of risperidone compared with olanzapine-treated patients included tension/inner unrest (2 (16% vs 52%, p=0.016), and amenorrhea (66.7% vs 10%, p=0.02), respectively. The small sample size and t calculation may have contributed to the limitations of this study (Maina et al, 2008).
c) Obsessive compulsive disorder (OCD) patients with and without comorbid chronic tic disorders or schizoty respond to the addition of low-dose risperidone to ongoing serotonin reuptake inhibitor (SRI) therapy. A doub was designed to determine the short-term efficacy and tolerability of potent SRIs in combination with risperid refractory to SRIs alone. Seventy adult patients with a primary diagnosis of OCD received 12 weeks of treatm patients were refractory to 6 weeks of risperidone (n=20) or placebo (n=16) addition. Behavioral ratings, inclu Compulsive Scale, were obtained at baseline and throughout the trial. Placebo-treated patients subsequently trial of risperidone addition. For study completers, 9 (50%) of 18 risperidone-treated patients were responder mg per day) compared to 0 of 15 in the placebo addition (p less than 0.005). Seven (50%) of 14 patients who addition responded. Risperidone addition was superior to placebo in reducing OCD (p less than 0.001), depre anxiety (p=0.003) symptoms. Other than mild, transient sedation, risperidone was well tolerated (McDougle e
d) Risperidone (initial dose of 2 milligrams/day) was effective in a 24-year-old patient with methamphetamine compulsive disorder-like symptoms (Iyo et al, 1999).
e) Fourteen of 16 patients with obsessive-compulsive disorder had substantial reductions in obsessive-comp within 3 weeks of initiating risperidone. Result were usually seen within the first few days. Before the addition received a serotonin reuptake inhibitor (SRI) for at least 12 weeks either alone or in combination with mood s anxiolytics. In addition to the OCD, patients had horrific mental imagery, comorbid schizophrenia, schizoaffec disorder (Saxena et al, 1996).
f) In a case series, 3 of 8 patients with obsessive- compulsive disorder (DSM-IV criteria) showed significant i Global Impression Change Scale after receiving augmentation with risperidone 1 to 2 milligrams/day. Of the noted minimal to much improvement, 3 patients had no change in symptoms and 1 patient was unable to tole 1997).
g) A 25-year-old man with obsessive compulsive disorder refractory to multiple medications improved with ri paroxetine (Agid & Lerer, 1999). Risperidone 1.5 milligrams (mg)/day was added to paroxetine 60 mg/day. Hi Obsessive Compulsive Scale for obsessions went from 14 to 4 and for compulsions went from 20 to 2. After The depressed symptoms responded to a decreased dose of risperidone of 0.5 mg/day.

4.5.T Organic psychotic condition

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:
Has reduced symptoms of psychosis caused by medical conditions

3) Adult:
a) A case series reports the successful use of risperidone in five patients who fulfilled DSM-IV criteria for psy condition and two who met the criteria for mood disorder due to a general medical condition with severe psyc 1997). All seven responded to treatment including four patients who had previously failed initial treatment wit antipsychotic agent.
b) In a case series of 21 patients with HIV-related psychotic disorders, 20 patients treated with risperidone h (Singh et al, 1997). Most responded to low doses (mean 3.3 milligrams) and required only a short course (me adverse effects were reported and no hematological effects were observed.

4.5.U Parkinson's disease - Psychotic disorder

See Drug Consult reference: THERAPY OF PSYCHOTIC DISTURBANCES IN PARKINSONIAN PATIENTS

4.5.V Pervasive developmental disorder

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective for the treatment of symptoms related to pervasive developmental disorders and autism in adul
In children with autism spectrum disorder, responders to 24 weeks of open-label therapy with oral risperi
rates when randomized to continue additional 8 weeks of double-blind treatment with risperidone versus
Treatment with oral risperidone relieved several behavioral symptoms associated with pervasive develop
to 12 years in an 8-week, multicenter, randomized, double-blind, placebo-controlled study (n=79) (Shea

3) Adult:

a) Risperidone therapy was effective in 3 autistic disorder patients. All 3 patients tolerated risperidone well a
effects. Effective doses in each patient were 5 milligrams daily, 4 milligrams daily, and 1 milligram daily, resp
2 of the patients and both showed no increase in seizure frequency. Improved social relations and reduced a
observed in all patients and decreased repetitive behavior in 1 patient (McCartney et al, 1999).

b) In a double-blind, placebo controlled trial including adults with autistic disorder (n=17) or pervasive develo
patients treated with risperidone (mean dose 2.9 milligrams per day) were considered responsive to therapy
recipients (p less than 0.002). At the end of the 12 week trial, patients initially randomized to placebo were tre

b) Risperidone improved functionality on the Children's Global Assessment Scale in 13 out of 14 cases in an adolescents (ages 9 to 17 years) treated for pervasive developmental disorders. Starting doses of 0.25 milligi increased in 0.25 mg/day increments every 5 to 7 days to optimal doses ranging from 0.75 to 1.5 mg daily in occurred in attention, lessening of obsessional behaviors, decrease in agitation and anxiety and improvemen Steele, 1996).

c) Behavioral symptoms improved in a series of 6 children (ages 7 to 15) with pervasive developmental diso treatment for 5 months (range 1-8 months) at a mean optimal dose of 2.7 milligrams (mg) daily (range 1 to 6 patient rating scores decreased, which reflected improvements in aggression, temper tantrums, and mood ins followed for more than 2 years, of whom one discontinued risperidone due to increased liver enzymes; one p new agent, and the third patient continued risperidone with good response (Perry et al, 1997)

4.5.W Pick's disease

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective in one case report

3) Adult:

a) A 42-year-old woman with a presumptive diagnosis of Picks Disease was treated with risperidone (titrated demonstrated significant improvements and cognitive stabilization. The author suggested that controlled trials antipsychotics in treating Picks Disease need to be performed and might produce promising results (Curtis &

4.5.X Posttraumatic stress disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Possibly effective in treating patients with irritable aggression in posttraumatic stress disorder
Possibly effective in treating intrusive thoughts associated with posttraumatic stress disorder

3) Adult:

a) Risperidone was effective in a 48-year-old male war veteran demonstrating increased irritability and anger stress disorder. Fluoxetine and diazepam were ineffective. With the addition of risperidone 1 milligram daily t reported less intensity in his anger and more confidence in his ability not to act on it (Monnelly & Ciraulo, 199
b) Two patients with posttraumatic stress disorder responded favorably to risperidone 6 milligrams daily and Other agents were ineffective (Krashin & Oates, 1999).

4.5.Y Schizophrenia

FDA Labeled Indication

1) Overview

FDA Approval: Adult, yes (oral and intramuscular); Pediatric, yes (13 years and older, oral only)
Efficacy: Adult, Effective; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIa; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone is indicated for the treatment of schizophrenia in adults (Prod Info RISPERDAL(R) CONSTA Prod Info RISPERDAL(R) oral tablets, 2007; Prod Info RISPERDAL(R) M-TAB orally disintegrating table (R) oral solution, 2007)and pediatric patients 13 years of age and older (Prod Info RISPERDAL(R) oral ta RISPERDAL(R) M-TAB orally disintegrating tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007) Approved for maintenance treatment of schizophrenia in adults (Prod Info RISPERDAL(R) oral tablets, 2 M-TAB orally disintegrating tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007; Prod Info RISPE acting injection, 2009)
Oral risperidone, at doses ranging from 1 to 6 milligrams per day, was effective in the treatment of schizo to 17 years in 2 short-term (6 and 8 weeks), double-blind, controlled trials (Prod Info RISPERDAL(R) ora RISPERDAL(R) M-TAB orally disintegrating tablets, 2007; Prod Info RISPERDAL(R) oral solution, 2007)

3) Adult:

a) General Information

1) Risperidone is effective for the positive and negative symptoms associated with chronic schizophreni 75% (Foster & Goa, 1998b; Rossi et al, 1997a; Smith et al, 1996a). Dose ranges of risperidone 4 to 16 m greater improvement than placebo in Clinical Global Impression (CGI) and total Positive and Negative Sy The 4 to 6 milligram dose appears to be the most effective (Marder & Meibach, 1994a; Chouinard et al, 1 Spahn, 1992a). At doses of 8 milligrams or less risperidone is associated with a lower risk of extrapyram antipsychotics (Foster & Goa, 1998b). Comparative efficacy with haloperidol and other conventional neu risperidone has a significantly higher clinical response rate and allows for significantly less prescribing of (Davies et al, 1998)(Bech et al, 1998a; Luebbe, 1996a). Patients treated with risperidone have a lower re with haloperidol (Csernansky et al, 2002a). Patients have also been successfully switched from depot an et al, 1999).

b) Monotherapy

1) Intramuscular

a) Long-acting injectable risperidone was significantly more effective than placebo in the treatment a randomized, double-blind, placebo-controlled, multicenter study, patients (n=400) with schizophre injections of long-acting risperidone (25 milligrams (mg), 50 mg, or 75 mg) or placebo every two wee week run-in period, patients received oral risperidone (titrated to a dose of 4 mg/day) for at least 3 d risperidone (2 mg/day, 4 mg/day, or 6 mg/day) or placebo for the first three weeks of the double-blin Positive and Negative Syndrome Scale (PANSS) total scores were significantly more improved in pa risperidone 25 mg, 50 mg, or 75 mg as compared with those who received placebo (p=0.002, p less respectively). Improvements in positive and negative symptoms were also significantly greater in all groups as compared with the placebo group (p less then or equal to 0.05, all values). Clinical improv 20% reduction in PANSS total scores and was observed in only 17% of placebo patients as compar patients in the 25 mg, 50 mg and 75 mg long-acting risperidone groups, respectively (p less then 0.0 long-acting risperidone was efficacious, it offered no additional benefit over the 25 mg and 50 mg do well tolerated and extrapyramidal adverse events were mild throughout the study period. Small incre baseline to endpoint were observed in risperidone-treated patients and these changes appeared to 2003).

2) Oral

a) Olanzapine and risperidone were equally safe and effective therapies in the treatment of schizop international, multicenter, double-blind study, 175 elderly patients (mean age, 71 years) were rando risperidone (mean dose, 1.9 milligrams (mg)/day) or olanzapine (mean dose, 11.1 mg/day) for 8 wee period of all psychotropic medications. Mean duration of illness was 36.5 years and Positive and Ne scores were between 50 and 120 at baseline. Clinical improvement was defined as a decrease of at score. Both treatment groups showed significant reductions from baseline in the total PANSS score 0.005) and significant differences were not observed between groups. Fifty-eight percent of risperido olanzapine-treated patients achieved clinical improvement as defined by the study. Both groups also improvement in four of the five PANSS factor scores (p less than 0.001). The greatest mean change occurred in the 93 patients who had received conventional antipsychotic medications in the thirty da less than 0.001). The rate of extrapyramidal symptoms (EPS) was similar between the risperidone a (9.2% vs 15.9%, respectively, p=nonsignificant). The severity of EPS symptoms was reduced in both endpoint with no significant difference between groups. A 7% or higher increase in weight occurred

treated patients as compared with those who received risperidone (14.8% vs 5.1%, p=0.043). No ne
observed in this patient population and mean QTc changes were not considered clinically relevant (
b) Risperidone treatment resulted in mild to substantial improvement in psychotic symptoms in appr
elderly Chinese patients (age 65 years or greater) participating in an open, 4-week study. Doses of r
basis of clinical responses and adverse effects and ranged from 0.25 to 7 milligrams (mg) per day (r
dose for functional psychoses was greater than that for organic mental disorders (2.8 mg/day vs 1.6
schizophrenia received the highest mean dose (4.1 mg/day). With improvement defined as a reducti
scores on various rating instruments, improvement occurred in 61% to 78% of patients. Patients witl
better than Alzheimer's patients. Of the 110 patients, 81 had one or more adverse effects. Weaknes
dizziness, and peripheral edema were the most common side effects (Hwang et al, 2001a).
c) Risperidone is beneficial in the treatment of patients with chronic schizophrenia, compared with c
and these benefits may appear only after longer-term treatment. A randomized, open, parallel, multi
term (12 months) effectiveness of risperidone with that of CNs. One hundred eighty-four subjects we
risperidone or CN and 165 of them completed the follow-up. Outcome measures were taken at 3, 6,
the Positive and Negative Syndrome Scale (PANSS) and the Extrapyramidal Symptom Rating Scale
risperidone was found to be superior to CNs in terms of both the average change in score from base
and the proportion of good responders (as defined by a 20% decrease in total PANSS scores; p=0.0
effectiveness of the risperidone treatment tended to increase over time and at 12 months, the perce
risperidone group was twice as large as that in the CN group (30% vs 15%; p=0.03). A worsening of
subjects receiving risperidone than in those receiving CNs (p=0.02) (Bouchard et al, 2000).
d) In an open, multicenter trial, risperidone was found to be effective in outpatients (Chouinard et al
subchronic or chronic schizophrenia treated on an outpatient basis were screened initially while on t
Their current therapy was discontinued and risperidone started at 2 milligrams (mg) daily and increa
After 2 weeks the dose could be titrated to a maximum of 10 mg or a minimum of 4 mg. At the end o
risperidone dose was 6.1 mg daily in 244 patients completing the study. The mean total Positive and
(PANSS) for schizophrenia decreased significantly from 86.3 to 63.6 (p=0.0001). Clinical improveme
baseline in total PANSS score) was seen in 85% of patients. The most frequent adverse events repo
headache, somnolence, dizziness, fatigue, anxiety, vomiting, and ejaculation failure/disorder.
e) In an open multicenter trial, risperidone was viewed as an efficacious and well tolerated medicati
overall antipsychotic action and above standard improvement in negative symptomology in 254 chro
and without exacerbation who were treated with risperidone 1 to 5 milligrams twice daily for 8 weeks
discontinuation of previous psychotropic medications; significant improvement in the overall Brief Ps

which 51% dropped out within the first 2 weeks, probably due to adverse reactions stemming from tl
previous psychotropics; the research team now recommends initial overlapping of therapies, especia
medicated with sedatives (Phillip, 1997).

c) Combination Therapy

1) Addition of celecoxib to risperidone therapy for patients with an acute exacerbation of schizophrenia r
than did risperidone therapy alone. In a randomized, double-blind study, 25 patients were given risperido
plus celecoxib 400 mg/day and 25 patients were given risperidone plus placebo. Both groups showed im
over the 5- week study, mainly with reductions in scores on the positive symptoms subscale of the Positi
(PANSS) (p=0.006) and on the general psychopathology subscale (p=0.01). Negative symptoms were n
Celecoxib therapy resulted in an improvement in total PANSS score relative to that of the placebo group
significant effects of celecoxib on the group-by-time interaction on any of the subscales, although a trend
on all subscales. The main influence of celecoxib occurred in weeks 2 to 4, resulting in earlier improvem
treating side effects of risperidone was not significantly different for the 2 groups. The use of benzodiaze
agitation appeared less in the celecoxib group, but the difference for the 2 groups was not statistically sig
were not observed (Muller et al, 2002).
2) In an open trial, risperidone added to clozapine was well tolerated and produced significant reduction
measured by the Brief Psychiatric Rating Scale (42.2 to 30.3, p=0.0002). Patients enrolled had either pe
symptoms despite optimal doses of clozapine (n=10) or a maximal clozapine dose limited by significant s
doses were kept constant while risperidone doses were increased to a maximum of 6 milligrams (mg) pe
tolerated, however, complaints included mild akathisia, hypersalivation, and worsening fatigue (Henderso
cases of refractory schizophrenic patients responding to combination therapy have been reported (More
clozapine 300 mg with risperidone 4.5 mg, and clozapine 400 mg with risperidone 6 mg.
3) As an add-on therapy, risperidone brought significant improvement to patients with bipolar disorder a
bipolar type. In a 6-month, open study, patients with a diagnosis of bipolar or schizoaffective disorder wh
depressive, or mixed episode (n=541; 430 completed the study) were given risperidone in combination w
antidepressants to clinical response and tolerability. The average dose of risperidone at the start of the s
day and at the end of the study, 3.9 mg/day. For all patients, scores on the Young Mania Rating Scale (Y
at week 1 and at every point thereafter (p less than 0.001 for all but the subgroup of depressed patients,
Mean scores on the YMRS decreased from 25.6 at baseline to 2.4 at 6 months. Likewise, scores on the
Depression (HAM-D) were significantly reduced from baseline at all evaluation times (p less than 0.0001
at baseline to 4.1 at 6 months. Scores on the Positive and Negative Syndrome Scale (PANSS) declined
months (p less than 0.0001). According to the Clinical Global Impressions scale (CGI), no patients were

and only 5% were rated as "mildly ill." At study endpoint, 44% of patients showed no symptoms of mania were "mildly ill." During the study, 25% of the patients experienced relapses into a mood state different fr Scores for extrapyramidal symptoms were lower at the end of study than at baseline (p less than 0.0001 reductions in dystonia, rigidity, hypokinesia, hyperkinesia, dyskinesia, tremor, and akathisia subscores. T emergent tardive dyskinesia. Nonextrapyramidal adverse reactions included increase in weight (2.4% of impotence (0.7%), and dysarthria (0.7%). There was a very low incidence of exacerbation mania in the fi 2001).

d) Refractory

1) Among patients who had been hospitalized for schizophrenia for longer than 5 years and who were c approximately 45% showed sufficient clinical improvement after 3 months of treatment with olanzapine o from the hospital. The 79 patients were not suited to treatment with clozapine either because of medical unwillingness to submit to the weekly blood drawings. Patients were given olanzapine 10 to 30 milligram 10 mg/day. Treatments were titrated quickly to the maximum tolerated dose and continued for 3 months. Psychiatric Rating Scale decreased from 67 to 53 for the olanzapine group (n=32) and from 63 to 52 for less than 0.001 for both groups). Of the 34 patients who were discharged from the hospital, only 3 requir 90-day follow-up. No significant side effects (such as weight change) were observed during the 3 months

e) Schizophrenia With Concomitant Cocaine Dependence

1) The results of a pilot study suggest that risperidone therapy reduced craving and relapses in cocaine- schizophrenia. In this 6-week, open label trial, patients with a dual diagnosis of schizophrenia and cocair of cocaine/month) received risperidone (n=8; initial, 2 milligrams (mg)/day, titrated to maximum dose of 6 neuroleptic medication treatment (n=10; haloperidol, fluphenazine, or chlorpromazine). Patients in the ris less cue reactivity in regard to the intensity (p=0.005) and depression (p=0.031) dimensions of craving a therapy, but there was no statistical difference on the energy and feeling sick dimensions. Risperidone-tr significantly lower rate of relapse (defined as any substance abuse) than did patients on typical neurolep respectively; p=0.025). Although not significant, a tendency toward a greater reduction in negative and g was seen in risperidone-treated patients. Larger, double-blind studies are needed to substantiate these f

4) Pediatric:

a) In 2 short-term (6 and 8 weeks), double-blind, controlled trials, oral risperidone, at doses ranging from 1 to effective in the treatment of schizophrenia in adolescents aged 13 to 17 years. Patients met the DSM-IV diag and were experiencing an acute episode at the time of enrollment. In the first trial (trial 1), patients were rand risperidone 1 to 3 mg/day (n=55; mean modal dose, 2.6 mg), risperidone 4 to 6 mg/day (n=51; mean modal d for 6 weeks. In the second trial (trial 2), patients were randomized to receive either risperidone 0.15 to 0.6 mg 0.5 mg) or risperidone 1.5 to 6 mg/day (n=125; mean modal dose, 4 mg). In both studies, risperidone was init up to the target dose range by approximately day 7 (except for the risperidone 0.15 to 0.6 mg/day group in tri initiated at 0.05 mg/day). Eventually, the dosage was increased to the maximum tolerated dose by day 14. C reduction occurred in the Positive and Negative Syndrome Scale (PANSS) score in all risperidone dose group (primary efficacy endpoint). Reductions in the PANSS scores in the 1 to 3 mg/day group were comparable to and to the 1.5 to 6 mg/day group in trial 2. The 1.5 to 6 mg/day group showed statistically significantly greater mg/day group in trial 2, with no additional benefit evident beyond the 3 mg/day dose. Adverse events reported placebo in both the risperidone 1 to 3 mg/day and 4 to 6 mg/day dose groups in trial 1 included parkinsonism dystonia (9%-18%), dizziness (7%-14%), akathisia (7%-10%), somnolence (12%-24%), and anxiety (6%-7%) tablets, 2007; Prod Info RISPERDAL(R) M-TAB orally disintegrating tablets, 2007; Prod Info RISPERDAL(R)

b) The results of a small study suggest that risperidone may be effective in the treatment of schizophrenia in prospective, open-label trial, eleven patients (mean age, 17.27 years) with first-episode, early-onset schizoph 0.5 milligrams (mg)/day, titrated based on clinical response and adverse effects; mean dose, 3.14 mg/day) fo Positive and Negative Syndrome Scale (PANSS) total score and positive symptoms score were significantly r than 0.01 and p less than 0.0001, respectively), however, a significant reduction was not observed for the ne PANSS (p=ns). Total scores for the Brief Psychotic Rating Scale were significantly reduced from baseline to baseline to endpoint, Clinical Global Impression-Severity (CGI-S) scores decreased by 31.6% (p less than 0.(scores decreased by 45.5% (p less than 0.0001). The most common adverse events observed were weight g depression (63%), orthostatic hypertension (45%), emotional indifference (45%), akathisia (36%). Because th improved significantly at a dose of only 1 mg/day, the authors suggest that lower initial doses of risperidone s as compared with adults, in order to minimize the risk of extrapyramidal side effects. Larger, controlled studie the safety and efficacy of risperidone for the treatment of schizophrenia in pediatric patients (Zalsman et al, 2

c) A 15-year old boy, with a diagnosis of simple deteriorative disorder (DSM-IV criteria or simple schizophrer improvement following risperidone therapy. He was started on 2 mg daily and this dosage was increased to 3 He did not report any significant side effects and showed clinical improvement. The author advocates the furt risperidone in the treatment of simple schizophrenia (Hirose, 2000).

4.5.Z Schizotypal personality disorder

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Appeared to effective in the treatment of schizotypal personality disorder

3) Adult:

a) Risperidone treatment was more effective than placebo in reducing the symptoms of schizotypal personal randomized, double-blind, placebo-controlled study, patients (n=25) with schizotypal personality disorder rece (0.25 milligrams (mg)/day for 1 week, then titrated by 0.5 mg/day every 2 weeks for 8 weeks; final dose, 2 mg comorbid borderline personality disorder. Weekly measurements of symptoms were taken using the Positive (PANSS), the Hamilton Rating Scale for Depression (HAM-D), and the Clinical Global Impressions Scale (CG Questionnaire (SPQ) was administered biweekly. Total PANSS scores were significantly lower in risperidone with placebo at weeks 3, 5, 7, and 9 (p=0.021, p=0.003, p=0.003, and p=0.013, respectively). PANSS negativ patients in the risperidone group than in the placebo group at all time points, with the difference reaching sign (p=0.027, p=0.006, and p=0.01, respectively). Patients in the risperidone group had significantly lower PANS patients in the placebo group at weeks 3, 5, 7, and 9 (p=0.042, p=0.007, p=0.005, and p=0.013, respectively) had significantly lower PANSS positive symptom scores at weeks 7 and 9 as compared with placebo (p=0.02 the end of treatment, SPQ and CGI scores showed greater reductions in the risperidone group than in the pla difference was not significant. The change in HAM-D scores was non- significant in both groups. Adverse eve decreased sexual arousal, delayed ejaculation, mild dystonic reaction and dry mouth. Larger studies are nee (Koenigsberg et al, 2003).

4.5.AA Stuttering

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Risperidone may be beneficial

3) Adult:

a) Risperidone may be effective in the treatment of developmental stuttering. A small, randomized, double- b was conducted to assess the efficacy of risperidone in the treatment of developmental stuttering in 16 adults. and eight received risperidone at 0.5 mg once daily at night, increased to a maximum of 2 mg per day. After 6 in all measures of stuttering severity were greater in the risperidone group than in the placebo group; the betw significant (p less than 0.05) on the most important measure, the percentage of syllables stuttered. In the risp baseline in scores for the percentage of syllables stuttered, time stuttering as a percentage of total time spea severity were significant (p less than 0.01); changes in scores on the fourth measure of stuttering, duration, w differences occurred in the placebo group. Five of the eight patients in the risperidone group responded best stuttering recurring at higher doses. Risperidone was generally well-tolerated (Maguire et al, 2000).

b) In one small study (n=21), patients were randomized to receive risperidone (n=10) up to 2 milligrams daily Every 2 weeks stuttering severity, adverse events, compliance, and tolerability were assessed. Risperidone t the mean stuttering severity compared to placebo (3.93 and 5.23, respectively (p less than 0.05). However, e social alienation-personal disorganization did not (Maguire et al, 1999).

4.5.AB Tardive dyskinesia

1) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

2) Summary:

Effective in reducing tardive dyskinesia in some patients when substituted for conventional antipsychotic

See Drug Consult reference: TARDIVE DYSKINESIA - DRUG THERAPY

3) Adult:

a) Risperidone treatment was more effective than withdrawal of antipsychotic therapy in reducing symptoms randomized, double-blind, placebo-controlled study (n=42), schizophrenic patients with persistent, severe tar risperidone (initial, 2 milligrams (mg)/day titrated in 2 mg increments to 6 mg/day over 6 weeks) or placebo fo washout period from all original conventional antipsychotic medications. Response was defined as a decreas Involuntary Movement Scale (AIMS) total score. Risperidone- treated patients showed a significantly greater score from baseline to endpoint, as compared with placebo (5.5 vs 1.1, respectively; p=0.001). This significar AIMS score between groups was observed from week 8 to endpoint, and grew more distinct over time. In adc significantly higher in the risperidone group as compared with the placebo group (68%(15) vs 30%(6), respec dyskinesia improvement in the risperidone group was noted mainly in the buccolinguomasticatory area rather movement of the extremities. Additional studies are needed to evaluate the long-term efficacy of risperidone t dyskinesia and whether symptoms reemerge when the risperidone dosage is withdrawn or reduced (Bai et al

b) Five of nine patients with tardive dyskinesia showed a lessening of severity of tardive dyskinesia when ris conventional antipsychotic drug they had been taking. After a tapering of the previous antipsychotic and antip patients were prescribed risperidone 2 milligrams (mg) per day. The dose was gradually increased over 4 we adjusted to maintain the least severity of tardive dyskinesia. Over the year-long study, 5 patients showed imp in score on the Abnormal Involuntary Movement Scale (AIMS) (responders). The dose for maximum effect in

improvement in AIMS score was 7 for responders and 0.5 for nonresponders (Chen et al, 2001).
c) Tardive movements were resolved with the addition of risperidone and a reduction in doses of trihexypher
old schizophrenic patient (Chong et al, 1999).
d) Tardive dyskinesia was diminished in a 54-year-old schizophrenic woman after switching to risperidone th
Risperidone 2 milligrams daily resolved her schizophrenic symptoms. At 8 months, her tardive dyskinesia wa
months, her parkinsonism had also resolved.

4.5.AC Trichotillomania

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS
2) Summary:
Augmented therapy in patients with trichotillomania
3) Adult:
a) In a case series, 3 of 5 patients with trichotillomania disorder (DSM-IV criteria) showed significant improve
Impression Change Scale after receiving augmentation with risperidone 1 milligram/day (Stein et al, 1997).

4.5.AD Water intoxication syndrome

1) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Ineffective
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS
2) Summary:
No effect on self-induced water intoxication
3) Adult:
a) Risperidone had no significant effect in treating self-induced water intoxication. In a prospective, 11 month
in 8 men with chronic schizophrenia and a history of polydipsia and episodic water intoxication, fluid intake wa
4 times daily weights. Risperidone was increased in doses up to 16 milligrams per day. Though there was a t
intake, there was no significant change in body weight over the study period (Milson et al, 1996).

4.6 Comparative Efficacy / Evaluation With Other Therapies

Amisulpride

Chlorpromazine

Clozapine

Haloperidol

Lithium

Olanzapine

Paroxetine

Perphenazine

Quetiapine

Ziprasidone

4.6.A Amisulpride

4.6.A.1 Schizophrenia

a) Amisulpride and risperidone therapies were equally effective in the treatment of positive and negative sym
with schizophrenia. In a randomized, double-blind, multi-center study, schizophrenic patients with productive

amisulpride 400 to 800 milligrams (mg) per day (mean dose, 630 mg/day) or risperidone 4 to 8 mg per day (n
weeks following a 3-to-6-day washout period. At 6 weeks, patients in both treatment groups showed significa
and Negative Symptom Scale (PANSS) total score and the three PANSS sub- scale scores, but no significan
treatment groups. The occurrence of adverse events was also similar between groups. Akathisia (16%), trem
were most commonly reported with risperidone administration while insomnia (17.3%) and constipation (17.3
in the amisulpride group (Hwang et al, 2003).

4.6.B Chlorpromazine

4.6.B.1 Schizophrenia

a) Based upon comparisons of minimum effective dosages identified in placebo- controlled, fixed-dose and f
development trials, the minimum effective dose of risperidone was 4 milligrams/day (equivalent to chlorproma
SW, 2003).

4.6.C Clozapine

Bipolar disorder

Hostile behavior

Parkinson's disease - Psychotic disorder

Schizophrenia

4.6.C.1 Bipolar disorder

a) In a retrospective study of 50 consecutive patients treated for bipolar disorder with atypical antipsychotic r
olanzapine (n=20), and risperidone (n=25), along with standard mood stabilizers, showed similar efficacy. Ov
improvement of at least 1 point in their Clinical Global Impressions assessment over the 12-week study. Mea
(mg) per day for clozapine, 11.7 mg/day for olanzapine, and 1.7 mg day for risperidone. The only serious adv
study was a seizure in a patient taking clozapine. Extrapyramidal symptoms (EPS) were reported in 12 of 42
occurred in 4 of 25 patients taking risperidone, 1 of 20 taking olanzapine, and 1 of 5 taking clozapine. Weight
patients taking clozapine and olanzapine than in those taking risperidone. Weight gain, which was greater tha
have been affected by concurrent mood enhancing medications (Guille et al, 2000a).

4.6.C.2 Hostile behavior

a) Clozapine reduced hostility in patients with schizophrenia and was superior to haloperidol and risperidone
seven patients with a diagnosis of schizophrenia or schizoaffective disorder and a history of poor response to
assigned to receive clozapine, olanzapine, risperidone, or haloperidol in cross-titration with the antipsychotic
study. Concomitant mood stabilizers and antidepressants had been phased out earlier. Daily doses of olanza
haloperidol were escalated within the first week to the target doses of 20, 8, and 20 milligrams (mg), respecti
were scheduled to achieve the target daily dose of 500 mg on day 24. Doses remained fixed for the remainde
second (6-week) period, doses were allowed to vary: 200 to 800 mg for clozapine, 10 to 40 mg for olanzapine
10 to 30 mg for haloperidol. Hostility, measured by the hostility item of the Positive and Negative Syndrome S
significantly (in comparison to baseline) in the clozapine group only (p=0.019). This effect was independent o
(delusional thinking, hallucinations) or on sedation. The effect of clozapine on hostility was superior to that of
risperidone (p=0.012) but not to that of olanzapine (Citrome et al, 2001).

4.6.C.3 Parkinson's disease - Psychotic disorder

a) In subjects with Parkinson's Disease (PD), risperidone may be considered as an alternative to clozapine h
extrapyramidal symptoms more than clozapine and therefore must be used with caution. A small (n=10) doub
efficacy and safety of risperidone and clozapine for the treatment of psychosis in patients with PD. Five patie
clozapine and five patients received risperidone. Clozapine was started at 12.5 mg at bedtime and risperidon
and both were titrated to symptomatic improvement was achieved or intolerable side effects emerged. Each s
months and was assessed prior to initiation of treatment and after 2, 4, 8, and 12 weeks of treatment. Assess
the Brief Psychiatric Rating Scale and the Unified Parkinson's Disease Rating Scale. Mean improvement in th
psychosis score was similar in the clozapine and the risperidone groups (p=0.23). Although the mean motor U
Rating Scale scores worsened in the risperidone group and improved in the clozapine group, this difference d
significance. Risperidone may be a reasonable alternative to clozapine in the treatment of psychosis in patien
used with caution since it may worsen extrapyramidal side effects (Ellis et al, 2000).

4.6.C.4 Schizophrenia

a) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in pat
schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double-
clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26)

(n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risp
mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 wee
individually (generally increased if response was insufficient, but sometimes reduced because of adverse effe
global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual or
speed and attention, improvement was seen with olanzapine. In simple motor function, there was improveme
global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximate
large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive ga
impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits we
in negative symptoms (Bilder et al, 2002b).

b) Clozapine was superior to risperidone for improving positive and negative symptoms of schizophrenia in p
response to treatment. In a prospective, double-blind study, patients meeting DSM-IV criteria for schizophren
to previous treatment underwent a single-blind placebo run-in period when all psychotropic and anticholinergi
They were then randomly assigned to treatment with clozapine (n=138) or risperidone (n=135). Starting with
milligrams (mg) and risperidone 1 mg, dosages were titrated over a period of 4 weeks to a minimum of 300 m
respectively, and possibly to 600 mg/day and 6 mg/day. Patients unable to tolerate the minimum dose were v
the next 8 weeks, doses were adjusted at 2-week intervals within the range of 200 to 900 mg/day for clozapir
risperidone. For patients who completed the 12-week study (n=201), median final daily doses were 600 mg fo
risperidone. Changes in the Positive and Negative Syndrome Scale of the BPRS (Brief Psychiatric Rating Sc
Impression (CBI) scale were significantly greater in the clozapine group than in the risperidone group for the i
who received at least one dose of treatment medication and had one post-dose BPRS evaluation) and in the
who completed the 28-day dose-setting period) (p less than 0.008 for all comparisons). Eighty-six percent of
protocol population and 70% in the risperidone per-protocol population showed 20% or more improvement in
between groups, p less than 0.01). By the end of the study, 94 (76%) patients in the clozapine group and 81
longer met the severity of psychopathology inclusion criteria (p less than 0.05). Extrapyramidal symptoms oc
in the clozapine group than in the risperidone group (13% vs 28%, p=0.008). However, convulsions, dizziness
somnolence occurred significantly more frequently among those receiving clozapine. No case of agranulocyt
study. Granulocytopenia occurred with low incidence in both groups (1% clozapine, 2% risperidone). Low neu
more frequent among risperidone-treated patients (3% vs 11%, p less than 0.01). Hypotension occurred more
treated patients (p less than 0.01). Weight gain was significantly greater for the clozapine group (2.4 kilogram
0.002) (Azorin et al, 2001).

c) In the treatment of refractory schizophrenia, giving a risperidone trial before clozapine was more beneficia
profile. A retrospective review study compared the relative efficacy profiles of clozapine and risperidone in a g
chronically institutionalized patients. The specific goal was to identify superiority (or lack thereof) of either age
well as on specific symptom domains, including positive symptoms, negative symptoms, and aggressive beha
of conventional antipsychotic treatment in a total of 24 patients. Information obtained from systematic retrosp
rated by 2 psychiatrists using the 7-point Clinical Global Impressions Improvement (CGI-I) scale on overall cli
symptom domains as above. The mean dose was 520 +/- 94 mg daily for clozapine and 7.5 +/- 2.2 mg daily f
(58%) were classified as responders to clozapine, while 6 (25%) responded to risperidone. On specific sympt
clozapine were 38% (9/24) on positive symptoms, 29% (7/24) on negative symptoms, and 71% (12/17) on ag
risperidone, response rates were 17% (4/24) on positive symptoms, 8% (2/24) on negative symptoms, and 4
behavior. The results of this study would support the utility of first giving a risperidone trial in patients with trea
because of its better side effect profile compared with clozapine (Sharif et al, 2000).

d) Risperidone and clozapine had similar antipsychotic effects in 59 patients with paranoid schizophrenia. In
study, patients were divided in three groups receiving either 4 milligrams risperidone, 8 milligrams risperidone
daily for 28 days. The antipsychotic effect was highly significant for both risperidone and clozapine. Patients
better tolerated therapy than those patients receiving clozapine. Withdrawals from clozapine treatment were
whereas withdrawals from risperidone treatment occurred from lack of therapeutic response (Heinrich et al, 1

e) Similar effectiveness of risperidone and clozapine was also observed in an 8-week, double-blind trial that
on response in 86 patients with treatment-resistant chronic schizophrenia. The mean effective dose was 6.4
and 291 mg for clozapine. The larger proportion of patients with clinical improvement after 7 and 14 days' trea
suggested earlier onset of effect compared to clozapine treatment (Bondolfi et al, 1998)

f) In a prospective, open-label, 12-week trial, risperidone was found to be a poor substitute for clozapine in th
schizophrenia. Six patients with schizophrenia and 4 with schizoaffective disorder were switched from a mea
milligrams(mg)/day to a mean dose of risperidone 8 mg/day at 12 weeks. No subjects improved after being s
were switched from clozapine tended to worsen when taking risperidone. Statistically significant increases ov
the Positive and Negative Syndrome Scale occurred at 9 and 12 weeks (P less than 0.05). The Brief Psychia
increased significantly over baseline at weeks 6, 9, and 12 (P less than 0.05). Five subjects failed to complete
patients that completed the 12 weeks, the Clinical Global Impressions Scale indicated that 2 patients were ur
worse, and 2 were much worse. The authors concluded that this study does not support replacing clozapine v
treatment-resistant schizophrenia (Still et al, 1996).

4.6.C.5 Adverse Effects

a) Adverse effects and death were more commonly reported as the reasons for the discontinuation of clozap
more often reported as the reason for discontinuation of risperidone (long-acting injection) in a retrospective,
with a diagnosis of schizophrenia, schizoaffective disorder, bipolar disorder or other psychotic disorders who
had mean duration of therapy of 12.3 +/- 18.6 months (range, 0.25 to 100 months; median, 3 months) were m
12.6 years (yr); range, 18 to 83 yr) and gender at discontinuation to patients who discontinued risperidone lon
risperidone patients (mean age, 39.9 +/- 13.1 yr , range 18 to 83 yr) were matched without knowledge of the
therapy (mean duration of therapy of 5.9 +/- 8.7 months; range, 0.5 to 46 months; median, 3 months). The re

significantly between clozapine and risperidone injection; additionally, death as reason for discontinuation wa
clozapine (13%) vs risperidone injection (1.9%) (Taylor et al, 2009).

Reasons for Discontinuation: Clozapine vs Risperidone

Reason	Clozapine (n=161) n (%)	Risperidone (n=161) n (%)	OR (95% CI)	p value
Patient's decision	77 (47.8)	64 (39.7)	1.41 (0.89 to 2.21)	0.139
Adverse effects	57 (35.4)	32 (19.9)	2.19 (1.31 to 3.67)	0.0023
Ineffectiveness	3 (1.9)	59 (36.6)	0.034 (0.01 to 0.14)	less than 0.0001
Death	21 (13)	3 (1.9)	7 (2.09 to 23.5)	0.0003
Other	3 (1.9)	3 (1.9)	-	-

The cause of death reported in clozapine patients (mean age, 49.2 +/- 14.5 yr, range 30 to 83 yr) include
carcinoma (n=3), other carcinoma (n=2), myocardial infarction (n=2), cerebrovascular accident (n=2), clo
gastrointestinal hemorrhage (n=1), cardiac arrest (n=1), left ventricular failure (n=1), asphyxia during rest
There was no incidence of neutropenia or agranulocytosis at the time of death in any of the patients. The
risperidone patients included: myocardial infarction (n=1), left ventricular failure (n=1) and sudden unexp
rate for clozapine patients was 8.5 per 1000 patient-years (95% CI, 5.53 to 13.07) vs 5.3 per 1000 patier
(Taylor et al, 2009).

b) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence of
receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of
patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), rispe
or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatme
medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which w
neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of t

c) Clozapine was associated with fewer extrapyramidal side effects (EPS) than was risperidone (Miller et al,
stable doses of clozapine (n=41), risperidone (n=23), or conventional antipsychotics (n=42) were screened fo
Akathisia Scale, akathisia was noted in 7.3% of clozapine patients, 13% of risperidone patients, and 23.8% o
users. From the Simpson-Angus scale, rigidity and cogwheeling were noted in 4.9% and 2.4% of clozapine p
risperidone patients, and 35.7% and 26.2% of conventional antipsychotic users, respectively. However, saliva
clozapine patients, 8.7% of risperidone patients, and 4.8% of conventional antipsychotic users.

d) Insomnia and extrapyramidal side effects were more common with risperidone, and sedation and weight g
clozapine in a single-blind, crossover pilot study of the side effect profiles of the 2 drugs (Daniel et al, 1996).
schizophrenia or schizoaffective disorder were randomized to each drug for 6 weeks separated by a 1-week
crossover. The mean doses at week 6 were 6.1 milligrams/day (range 1 to 10 mg/d) of risperidone and 375 m
mg/d) of clozapine. Three patients dropped out of the study; there was no significant difference in therapeutic
groups. Mean body weight was greater (p less than 0.005) and sleepiness and lack of alertness were reporte
treatment phase. Restlessness and insomnia were more frequent complaints after the risperidone phase. A l
large sample of patients is needed to further elucidate the therapeutic differences and side effect profiles of t

4.6.D Haloperidol

Cognitive function finding

Dementia

Extrapyramidal disease

Mania

Schizophrenia

4.6.D.1 Cognitive function finding

a) Results of a multicenter, randomized, double blind trial assessing cognitive function in patients experienci
episode or a related psychosis demonstrated that overall improvement in cognitive functioning was superior v
haloperidol. Patients (n=533) were randomized to receive either risperidone or haloperidol on a one-to-one ra
2 years or more. There were no significant differences in sex, race or ethnicity, age, diagnosis, or previous ne
group. Dosing strategies were equivalent in both groups where patients were started on 1 milligram per day (
titrated up to 4 mg/day, or in some cases, to a maximum of 8 mg/day. Patients in the risperidone group recei

modal total dose 3.3 mg/day) for an average of 192 days while patients in the haloperidol group received trea
2.9 mg/day) for an average of 218 days. Cognitive assessments, performed at several different follow-up inte
verbal and visuospatial episodic memory, vigilance, executive functioning, processing speed, and verbal fluer
conducted with a focus on the 3-month assessment revealed that there was significant improvement from bas
(n=169) for all measures except category verbal fluency and letter verbal fluency (p less than 0.05). In the ha
statistically significant improvements from baseline were noted in episodic memory, vigilance, and visuomoto
functioning and verbal fluency. Comparison between the two groups showed that, after 3 months of treatmen
significantly more beneficial than the haloperidol group on the composite measure of cognitive functioning. In
as a result of treatment with risperidone was not affected by changes in symptoms. Risperidone therapy also
haloperidol in relapse prevention and extrapyramidal side effects (Harvey et al, 2005).

b) Risperidone therapy appeared to exert a more favorable effect on verbal working memory in treatment-res
than did haloperidol therapy (Green et al, 1997). In a randomized, double-blind comparison of treatment with
haloperidol (n = 29), verbal working memory was measured at baseline and after 4 weeks of both a fixed dos
Risperidone patients showed a significant improvement in memory using a Digit Span Distractibility Test from
the fixed-dose (p less than 0.0001) and the flexible dose (p less than 0.0003) phases. The haloperidol-treated
significantly. Results suggest that treatment of schizophrenia could be broadened to include the impact on ne

4.6.D.2 Dementia

a) Some Chinese patients with dementia, who were non-responders to haloperidol, responded to risperidone
disturbances and improved mood. Thirty-five Chinese patients who had shown insufficient response to an 8-
having a total score of more than 10 on the Brief Psychiatric Rating Scale (BPRS) at the end of 8 weeks) (typ
switched abruptly from haloperidol to risperidone 0.5 milligrams (mg) at bedtime for weeks 1 to 4 and then (if
weeks 5 to 12. At week 13, the regimen was shifted again to haloperidol at the dose used in the earlier trial. T
the trial. Sixteen patients responded by the end of the risperidone trial (response = a decrease of 25% in the
resumption, the mean BPRS score stayed the same, but the number of responders decreased to 15. Patients
almost 6 times more likely to respond to risperidone than patients with Alzheimer's disease. Mean scores on
Alzheimer's Disease Rating Scale decreased (6.1 at baseline to 1.9 at 12 weeks of risperidone treatment) an
to haloperidol (to 2.4 after 4 weeks of haloperidol). Thirty- four of the 35 patients tolerated both doses of rispe
One patient experienced moderate rigidity with risperidone 1 mg/day, which was relieved by reduction of the
experienced fewer extrapyramidal symptoms with risperidone than with haloperidol (Lane et al, 2002).

b) Both risperidone and haloperidol in low doses reduced the severity and frequency of behavioral and psycl
Chinese patients with dementia. Risperidone was associated with less severe exacerbation of extrapyramida
randomized, double-blind trial, 55 elderly Chinese patients (mean age 80 years) with Alzheimer's dementia o
behavioral disturbance, were given either risperidone or haloperidol for 12 weeks after a 2-week washout per
psychotropic and antiparkinsonian drugs. The starting dose for both treatment drugs was 0.5 milligrams (mg)
individually in increments of 0.5 mg no faster than every other day, to a maximum of 2 mg/day. At 12 weeks,
haloperidol was 0.9 mg, and that of risperidone, 0.85 mg. Significant improvements on the Cohen- Mansfield
evident in both groups (haloperidol, p less than 0.001; risperidone, p=0.002). Significant reduction was seen
group and at 4 weeks in the haloperidol group. With risperidone, there were significant improvements in score
disturbances, aggressiveness and diurnal rhythm disturbances, whereas with haloperidol, improvement in on
reached statistical significance. However, none of the measures showed a significant difference between the
haloperidol, there was a significant worsening of EPS (p less than 0.001), whereas, with risperidone, EPS sc
worsened. Final EPS scores were significantly higher for haloperidol (p=0.001) (Chan et al, 2001).

4.6.D.3 Extrapyramidal disease

a) Data from a multicenter comparative study of risperidone, placebo, and haloperidol revealed that risperidc
extrapyramidal symptoms (Simpson & Lindenmayer, 1997). Mean changes in Extrapyramidal Symptom Ratir
baseline to worst score were significantly lower in each risperidone group than the haloperidol group (P less t

4.6.D.4 Mania

a) A small, controlled study, compared the efficacy and safety of risperidone versus lithium and haloperidol i
results with risperidone. Patients (n=45) were assigned to take risperidone (as monotherapy), dosed at 6 mg
day, or 800 to 1000 mg daily of lithium. All 3 groups showed a similar improvement on Brief Psychiatric Ratin
Scale scores. The EPS of risperidone and haloperidol were not significantly different and mania did not worse
treated patients (Segal et al, 1998).

4.6.D.5 Schizophrenia

a) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in pat
schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double-
clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26)
(n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risp
mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 weel
individually (generally increased if response was insufficient, but sometimes reduced because of adverse effe
global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual or
speed and attention, improvement was seen with olanzapine. In simple motor function, there was improveme
global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximate
large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive ga
impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits we

in negative symptoms (Bilder et al, 2002a).

b) The risk of relapse of schizophrenia was significantly less with long-term treatment with risperidone than v
double-blind study, 365 patients meeting DSM-IV criteria for schizophrenia or schizoaffective disorder and in
flexible doses of either risperidone or haloperidol. The trial was continued until the last enrolled patient had c
Means of modal daily doses were 4.9 milligrams (mg) for risperidone and 11.7 mg for haloperidol. At the end
risperidone group and 40% of the haloperidol group had relapsed. The risk of relapse was significantly higher
haloperidol (risk ratio 1.93, p less than 0.001). The risk of premature discontinuation was greater for the halop
risperidone group (risk ratio 1.52), mainly because of relapse. Median duration of treatment for the risperidon
haloperidol group, 238 days (p=0.02). The subtypes of relapse (psychiatric hospitalization, clinical deteriorati
suicidal or homicidal ideation) were similar in the 2 groups. In the risperidone group, there were improvement
negative symptoms, disorganized thoughts, and anxiety- depression, whereas symptoms were not improved
extrapyramidal symptoms was reduced from baseline in the risperidone group and increased in the haloperid
the groups were significant (p less than 0.02 for total score on the Extrapyramidal Symptom Rating Scale). Th
were somnolence (14% with risperidone and 25% with haloperidol), agitation (10% and 18% respectively), ar
respectively). Those taking risperidone had a mean increase in body weight of 2.3 kilograms (kg) and those t
decrease of 0.73 kg (p less than 0.001) (Csernansky et al, 2002).

c) Risperidone was more efficacious and had fewer adverse effects than haloperidol when used to treat refra
patients. Chinese patients, meeting DSM-III-R criteria for schizophrenia and having a history of treatment fail
neuroleptics given at least 3 months at full dose, were randomly assigned to receive risperidone (n=41) or ha
double-blind trial. The dose of risperidone was increased during the first week to 6 milligrams (mg) per day, a
mg/day. By the end of the study, the average score on the Positive and Negative Syndrome Scale (PANSS) I
risperidone group and by 28.3% for the haloperidol group (p=0.03). The general psychopathology and negati
showed greater improvement with risperidone, but there was no difference between treatments in the positive
patients rated as responders was higher in the risperidone group (31 of 41 vs 20 of 37, p=0.046). Total score
Symptoms Scale (TESS) were significantly lower with risperidone than with haloperidol (2.9 vs 6.9, p=0.01). I
favoring risperidone were those showing symptoms of the nervous system (rigidity, tremor, dystonia, and aka
system (hypotension, dizziness, tachycardia, hypertension and electrocardiogram abnormalities) (p=0.02 and
in the risperidone group required less medication for extrapyramidal symptoms during the study than did patie
authors mentioned that the dose of haloperidol was higher than the dose recommended in the United States
accounted for some of the difference between treatments in efficacy and adverse effects (Zhang et al, 2001).

d) Results of a subanalysis of data from the multinational risperidone trial (double-blind, randomized, paralle
reduction in negative symptoms was significantly better in patients receiving risperidone 16 mg/day than halo
0.05) (Moller et al, 1997). Patients with chronic schizophrenia (n=169) were treated with risperidone 1 mg, 4 r
haloperidol 10 mg/day for 8 weeks. Improvement was noted in each group. Risperidone onset was faster tha
Positive and Negative Syndrome Scale cluster scores revealed significantly greater improvement in the rispe
the haloperidol group on 2 clusters: activity and anxiety/depression (p less than 0.05).

e) Risperidone was significantly better than haloperidol in the treatment of chronic schizophrenia using comb
(Chouinard et al, 1993a; Marder & Meibach, 1994) to evaluate five factors of the Positive and Negative Syndr
Data from 513 patients showed that after 6 to 8 weeks of therapy, patients receiving risperidone 6 to 16 millig
adjusted mean changes in total Positive and Negative Syndrome Scale than patients treated with haloperidol
symptom areas that risperidone was significantly superior to haloperidol included: negative symptoms (p less
less than 0.05), disorganized thought (p less than 0.05), uncontrolled hostility/excitement (p less than 0.01), a
than 0.01). One author, however, noted some positive symptoms that reemerged after an initial response to r
1997).

f) In a meta-analysis, risperidone (4 to 8 milligrams(mg)/day) was found to be more effective and produce fe
haloperidol (4 to 20 mg/day). Seven studies done in a double-blind, randomized fashion were included. The p
clinical improvement defined as a 20% reduction in the total scores on the Brief Psychiatric Rating Scale or th
Syndrome Scale. Results showed that patients identified as treatment failures were 50% of those taking rispe
83% on placebo. There was a highly significant need for anticholinergic medication in the haloperidol-treated
risperidone (P less than 0.00001) (de Oliveira et al, 1996).

g) Risperidone was more effective than haloperidol in a double-blind, placebo-controlled, multicenter study (
schizophrenic patients were randomly assigned to receive 4 fixed doses of risperidone (2, 6, 10, and 16 millig
haloperidol 20 milligrams daily or placebo for 8-weeks (Marder and Meibach, 1994). Patients receiving risperi
statistically greater improvement than placebo or haloperidol in Clinical Global Impression (CGI) and total Pos
Scale (PANSS) scores. Of the four doses studied, the 6, 10, and 16 milligram doses were all effective with th
most effective. Similar results have been reported (Chouinard et al, 1993a; Marder, 1992).

h) In an 8-week, double-blind study, 1362 schizophrenic patients were randomly assigned to receive either r
milligrams/day, on a BID schedule, or haloperidol 10 milligrams daily (Muller-Spahn, 1992). Significantly grea
Negative Syndrome Scale (PANSS) and Brief Psychiatric Rating Scale (BPRS) total score, the PANSS Gene
the BPRS Activity and Anxiety/Depression cluster, was observed in the risperidone 4 milligram and 8 milligra
treated patients. In addition, a greater percentage of patients treated with risperidone 4 and 8 milligrams achi
PANSS and BPRS as compared with the haloperidol group.

i) Risperidone was faster acting, more effective, and had fewer side effects than haloperidol in a study to det
negative symptoms of schizophrenia (Claus et al, 1992a). The multicenter double-blind study that took place
included a two-week run-in period and a one-week washout period. The patients (n=42) took one to 5 mg bid
weeks. The Positive and Negative Syndrome Scale for Schizophrenia was the key efficacy parameter. The S
and Schizophrenia Change Conversion was used as a diagnostic aid and symptom severity measure. The Cl
was complete as a global rating. In addition, the occurrence of extrapyramidal side effects was also monitore

was approximately three times greater in the risperidone group, both at week six and at endpoint. In addition, was quicker in the risperidone group. Finally, the risperidone group needed 10 times less anticholinergic med extrapyramidal side effects than did the haloperidol group. According to this study, risperidone showed a grea schizophrenic symptoms than haloperidol.

j) Risperidone was less effective as monotherapy when compared to combination therapy of haloperidol and coexisting psychotic and depressive disorders. In this double-blind multicenter study, 123 patients were rand risperidone (dose titrated to 8 milligrams (mg) by the end of week 1) or the combination of haloperidol and an mg and 200 mg by the end of week 1). For all patients, doses were then adjusted under double blind conditio on response. At endpoint, the mean effective daily dose was 6.9 mg risperidone, and 9 mg haloperidol in con amitriptyline. In the 98 patients who completed at least 3 weeks of treatment, Brief Psychiatric Rating Scale (treatment groups, but the reduction in the combination treatment group was significantly greater than the risp The proportion of patients achieving at least 50% improvement in BPRS scores was also significantly higher 0.002). Greater benefit by combination therapy was still observed in an intent-to-treat analyses of the 123 pat medication for extrapyramidal symptoms was higher in the risperidone group (Muller-Siecheneder et al, 1998

4.6.D.6 Adverse Effects

a) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence of receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), rispe or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatme medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which w neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of t

4.6.E Lithium

4.6.E.1 Mania

a) A small, controlled study, compared the efficacy and safety of risperidone versus lithium and haloperidol i results with risperidone. Patients (n=45) were assigned to take risperidone (as monotherapy), dosed at 6 mg day, or 800 to 1000 mg daily of lithium. All 3 groups showed a similar improvement on Brief Psychiatric Ratin Scale scores. The EPS of risperidone and haloperidol were not significantly different and mania did not worse treated patients (Segal et al, 1998a).

4.6.F Olanzapine

Agitation, acute - Psychotic disorder

Bipolar disorder

Chronic schizophrenia

Dementia - Problem behavior

Extrapyramidal disease

Obsessive-compulsive disorder, Refractory

Schizophrenia

4.6.F.1 Agitation, acute - Psychotic disorder

a) Olanzapine orally disintegrating tablets (ODT) and risperidone oral solution (OS) yielded similar improvem for Positive and Negative Syndrome Scale (PANSS-EC) and the Clinical Global Impression (CGI) scale in 87 psychotic agitation in a psychiatric emergency setting, according to an open-label, flexible-dose study. Patien score of 15 or higher who accepted oral medication were assigned to receive initial doses of either olanzapin or risperidone OS 3 mg (n=53). Treatment group assignments were based on previous effective treatments, olanzapine or risperidone according to the time of study trial entry. Patients who experienced continued agita time, and after 1 hour could receive adjunctive drug therapy. PANSS-EC scores in both groups decreased ov from baseline was similar between the olanzapine and risperidone group (2.8 vs 3.2; p=0.22). Repeated mea score over time ANOVA (at baseline and every 15 minutes for 1 hour) revealed no significant main effect of t treatment over time (F=2.94, p=0.09 and F=0.88, p=0.41, respectively). There was a significant mean change ODT group compared with risperidone OS group (-9.2 vs 1.1 beats/minute, p=0.03). There were no significar treatment groups for adverse effects including extrapyramidal symptoms (Hatta et al, 2008).

4.6.F.2 Bipolar disorder

a) In a retrospective study of 50 consecutive patients treated for bipolar disorder with atypical antipsychotic r

improvement of at least 1 point in their Clinical Global Impressions assessment over the 12-week study. Mea
(mg) per day for clozapine, 11.7 mg/day for olanzapine, and 1.7 mg day for risperidone. The only serious adv
study was a seizure in a patient taking clozapine. Extrapyramidal symptoms (EPS) were reported in 12 of 42
occurred in 4 of 25 patients taking risperidone, 1 of 20 taking olanzapine, and 1 of 5 taking clozapine. Weight
patients taking clozapine and olanzapine than in those taking risperidone. Weight gain, which was greater tha
have been affected by concurrent mood enhancing medications (Guille et al, 2000).

4.6.F.3 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp
antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychotic study me
Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 to 30 milligrams/da
mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or ziprasidone 40 to 160 mg/day for up
patients discontinued treatment for any cause before 18 months; discontinuation rates ranged from 64 to 82%
from 3.5 months for ziprasidone to 9.2 months with olanzapine. The time to discontinuation was significantly l
compared with the quetiapine (hazard ratio (HR), 0.63; 95% confidence interval (CI), 0.52 to 0.76; p less than
(HR, 0.75; 95% CI, 0.62 to 0.90; p=0.002). Time to discontinuation due to adverse events were similar betwe
ranged from 10% for risperidone to 19% for olanzapine (p=0.04). More patients discontinued olanzapine due
of 0.9 kilograms/month) and greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides

4.6.F.4 Dementia - Problem behavior

a) Risperidone and olanzapine were equally effective in the treatment of dementia-related behavioral disturb
term care facilities. In a double-blind, parallel study, patients (mean age, 83 years) with dementia received or
2.5 milligrams (mg)/day, titrated to maximum dose of 10 mg/day) or risperidone (n=19, initial dose 0.5 mg/da
mg/day) at bedtime for two weeks following a 3-day washout period of psychotropic drugs. Antidepressants a
at stable doses and lorazepam was used as a rescue medication at doses of 0.5 to 1 mg as needed for acute
for olanzapine and risperidone were 6.65 mg (range, 2.5 to 10 mg) and 1.47 mg (range, 0.5 to 2 mg), respect
median of 3.5 days (range 1-12 days) and the median dose was 2 mg (range, 0.2 to 21 mg). Primary outcom
Neuropsychiatric Inventory (NPI) and the Clinical Global Impressions Scale (CGI). Both treatments significant
NPI scores from baseline to endpoint (p less than 0.0001, both values), however, there was no difference be
events were frequent in this elderly population, with the most common including drowsiness, falls, and extrap
at, 2003).

4.6.F.5 Extrapyramidal disease

a) Results of a retrospective analysis showed that olanzapine treatment was associated with a lower rate of
than haloperidol, but was similar to rates occurring with risperidone and clozapine therapy. In a pooled analys
clinical trials in 4611 patients with schizophrenia, frequency and severity of EPS associated with olanzapine t
(mg)/day) was compared with that of haloperidol (1 to 20 mg/day), risperidone (4 to 12 mg/day), clozapine (2
Dystonic events (ie, dystonia, oculogyric crisis, opisthotonos, torticollis) occurred in significantly fewer patient
compared with haloperidol (0.5% vs 5.6%, respectively; p less than 0.001) or risperidone (1% vs 3.2%, respe
no significant difference was found between olanzapine- and clozapine-treated patients. As compared with ol
significantly higher percentage of haloperidol-treated patients experienced parkinsonian events (ie, akinesia,
syndrome, hypertonia, hypokinesia, masked facies, and tremor) (9.3% vs 28.3%, respectively; p less than 0.0
akathisia, hyperkinesia) (6.7% vs 20.4%, respectively; p less than 0.001) during therapy. However, no signific
between the olanzapine group as compared with the placebo, risperidone, or clozapine groups in regard to th
akathisia events. Overall, EPS occurred in significantly more patients treated with haloperidol as compared w
respectively; p less than 0.001) and in fewer patients treated with clozapine as compared with olanzapine (2.
p=0.047). The overall rate of EPS was similar between the placebo and risperidone groups as compared with
patients received anticholinergic medications in the olanzapine group as compared with the haloperidol (p les
(p=0.018) groups. No difference was found between olanzapine-treated patients as compared with placebo o
percentage of patients given anticholinergic drugs during therapy (Carlson et al, 2003).

4.6.F.6 Obsessive-compulsive disorder, Refractory

a) Adjunctive therapy of risperidone or olanzapine with serotonin-reuptake inhibitors (SRI) were equally effec
compulsive symptoms in SRI monotherapy-resistant outpatients, according to an 8-week, single-blind, randor
conclusion may be limited by the lack of a placebo arm, single-arm design, and underpowered nature of the t
prospective, open-label phase of SRI monotherapy (n=96), patients who were treatment-resistant (defined as
the total score of Yale-Brown Obsessive Compulsive Scale (Y-BOCS) and a Clinical Global Impression Seve
entered an 8-week single-blind phase (n=50). Patients in the single-blind phase received SRI daily doses of c
citalopram 50 to 80 mg, fluoxetine 60 mg, fluvoxamine 200 to 300 mg, paroxetine 50 to 60 mg, or sertraline 2
receive either risperidone 1 to 3 mg/day (n=25), or olanzapine 2.5 to 10 mg/day (n=25) in addition to the SRI
personnel and assessor-blinding constituted the single-blind study design; patients were not blinded. In an int
carried forward analysis of the primary endpoints, both treatments significantly improved Y-BOCS and CGI-S
The magnitude of change in mean Y-BOCS total scores, CGI-S scores, and responder rates (35% or greater
versus baseline, and a CGI-I score of 2 or less) was similar between groups.

Primary Efficacy Endpoints at 8 Weeks		

	Risperidone (n=25)	Olanzapine (n=25)
Responder rates*	44% (11/25)	48% (12/25)
Mean end-point Y-BOCS score	22.6 +/- 7.2	22.2 +/- 7.4
Change in mean Y-BOCS score from baseline	-7.5; t=7.588, df=21, p less than 0.001	-8.4; t=7.456, df=20 0.001
Mean end-point CGI-S score	3.2 +/- 1.7	3.1 +/- 1.8
Change in mean CGI-S score from baseline	-1.7; t=7.022, df=21, p less than 0.001	-1.9; t=7.707, df=20 0.001
* p=1; Y-BOCS=Yale-Brown Obsessive Compulsive Scale; CGI-S=Clinical Global Impression Severity s		

b) Adverse effects of risperidone compared with olanzapine-treated patients included tension/inner unrest (2 (16% vs 52%, p=0.016), and amenorrhea (66.7% vs 10%, p=0.02), respectively. The small sample size and t calculation may have contributed to the limitations of this study (Maina et al, 2008).

4.6.F.7 Schizophrenia

a) Olanzapine and risperidone were equally safe and effective therapies in the treatment of schizophrenia in international, multicenter, double-blind study, 175 elderly patients (mean age, 71 years) were randomized to dose, 1.9 milligrams (mg)/day) or olanzapine (mean dose, 11.1 mg/day) for 8 weeks following a 1 week wash medications. Mean duration of illness was 36.5 years and Positive and Negative Syndrome Scale (PANSS) s at baseline. Clinical improvement was defined as a decrease of at least 20% in the total PANSS score. Both significant reductions from baseline in the total PANSS score at all time points (p less than 0.005) and signific observed between groups. Fifty-eight percent of risperidone-treated patients and 59% of olanzapine-treated improvement as defined by the study. Both groups also exhibited significant improvement in four of the five P 0.001). The greatest mean change in the total PANSS score occurred in the 93 patients who had received co medications in the thirty days prior to entering the study (p less than 0.001). The rate of extrapyramidal symp the risperidone and olanzapine treatment groups (9.2% vs 15.9%, respectively, p=ns). The severity of EPS sy groups from baseline to endpoint with no significant difference between groups. A 7% or higher increase in w more olanzapine-treated patients as compared with those who received risperidone (14.8% vs 5.1%, p=0.043 were observed in this patient population and mean QT-c changes were not considered clinically relevant (Jes

b) Olanzapine and risperidone improved neurocognitive deficits more than did haloperidol or clozapine in pa schizoaffective disorder that was refractory to treatment with typical antipsychotics. In a randomized, double- clozapine (n=24) 200 to 800 milligrams (mg) per day, olanzapine (n=26) 10 to 40 mg/day, risperidone (n=26) (n=25) 10 to 30 mg/day. Dose escalation and fixed-dose treatment (target doses: olanzapine 20 mg/day, risp mg/day, clozapine 500 mg/day) occurred during the first 8 weeks of the 14-week study; during the last 6 wee individually (generally increased if response was insufficient, but sometimes reduced because of adverse effe global neurocognitive score was seen for olanzapine and risperidone. In general executive and perceptual or speed and attention, improvement was seen with olanzapine. In simple motor function, there was improveme global neurocognitive performance with olanzapine and risperidone were of medium magnitude (approximate large enough to be clinically significant. Beneficial changes with clozapine were modest. Despite cognitive ga impairments of cognitive ability and social/vocational functioning. Improvements in neurocognitive deficits we in negative symptoms (Bilder et al, 2002).

c) In a prospective, multicenter, double-blind trial, olanzapine was more cost-effective than risperidone in pa schizoaffective disorder, or schizophreniform disorder. One hundred fifty patients were randomized to either per day (mg/d) (n=75) or risperidone (4 to 12 mg/d) (n=75) treatment for a period of 28 weeks. During the stu were significantly more likely to maintain a therapeutic response throughout the course of therapy than risper However, the proportion of patients who responded to treatment was not significantly different between group effects was similar between groups, but significantly more risperidone-treated patients required an anticholine emergent extrapyramidal effects than did those receiving olanzapine (45% versus 25%, p=0.016). Medicatior for olanzapine-treated patients than those treated with risperidone ($2513 versus $1581 US), but this differer in inpatient and outpatient service costs ($3516 vs $7291 US) (Edgell et al, 2000).

d) In an open-label study of patients with DSM-IV schizophrenia, olanzapine (n=21) was shown to be as effe acute treatments. At 6 months, risperidone was more effective for treatment of psychotic symptoms. Howeve less akathisia at the end of 6 months. At discharge the average doses of olanzapine and risperidone were 14 respectively. The reduction of psychotic symptoms with risperidone was significantly greater than with olanaz uncontrolled and adjusted by the treating psychiatrist based on the patient's response, tolerability of side effe recommendations. Measures of effectiveness included the SANS, SAPS, Brief Psychiatric Rating Scale (BPF (GAS) and quality of life measures. (Ho et al, 1999). Larger studies are needed comparing olanzapine and ris

e) Olanzapine (10 to 20 milligrams (mg) daily) was superior to risperidone (4 to 12 mg daily) in the treatment In an international, multicenter, double-blind, parallel-group 28-week prospective study of 339 patients with D schizophreniform disorder, or schizoaffective disorder, the olanzapine group had a significantly better overall decrease in the Positive and Negative syndrome Scale) and was significantly superior to risperidone in the tr

symptomatology. Based on the Kaplan-Meier survival curves, a significantly greater number of the olanzapine response at 28 weeks compared to the risperidone group. Overall adverse reactions were significantly less w extrapyramidal side effects, hyperprolactinemia and sexual dysfunction, with the exception of weight gain; su significantly less in the olanzapine group (Tran et al, 1997). The use of possibly unequivalent doses in this st criticized (Schooler, 1998; Gheuens & Grebb, 1998).

4.6.F.8 Adverse Effects

a) The results of one study suggest that patients receiving atypical antipsychotics have a higher incidence of receiving a conventional antipsychotic medication. In a retrospective, pharmacovigilance study, 192 cases of patients taking clozapine (mean dose, 306.7 milligrams (mg)/day), olanzapine (mean dose, 15 mg/day), rispe or haloperidol (mean dose, 8.2 mg/day). Of the identified cases, 40%, 33%, and 16% were related to treatme medications clozapine, olanzapine, or risperidone, respectively, as compared with 12% of the cases which w neuroleptic, haloperidol. In most patients, time to onset of pancreatitis was within 6 months after initiation of t

4.6.G Paroxetine

4.6.G.1 Panic attack

a) In an 8-week, randomized, single-blind, comparative trial (n=56) of low-dose risperidone and paroxetine ir both treatments were effective in reducing the occurrence and severity of panic attacks but there was no diffe improve anxiety associated with panic disorders. Thirty-three (8 men, 25 women) subjects were randomized t women) to paroxetine. The average age of the group was 40.36 +/- 12.37 years. Risperidone was initiated at necessary for lack of response or sedation (maximum dose of 16 mg/day). Paroxetine was initiated at 30 mg/ 60 mg/day if needed. The average risperidone dose was 0.53 mg (range 0.125 mg to 1 mg). All subjects in th mg/day except for one who required a dose of 40 mg. Subject assessments were conducted by a clinical rate using the 17-item Hamilton Depression Rating Scales (Ham-D-17), the Hamilton Anxiety Rating Scale (Ham- Scale (PDSS), the Sheehan Panic Anxiety Scale-Patient (SPAS-P) and the Clinical Global Impressions Scale risperidone group and 9 in the paroxetine group completed all study visits. A significant decrease in CGI scor subjects (p less than 0.001), but there was no significant difference between the groups. The CGI score impr to 2.84 +/- 1.02 at final assessment in the risperidone arm. Similarly, paroxetine resulted in a CGI score impr 2.67 +/- 0.71 at final assessment. All subjects, regardless of treatment, demonstrated a significant decrease i total score, PDSS item 1, PDSS item 2, Ham-A and Ham-D. There was no statistical difference between trea study, and there was no significant change in SPAS-p scores over time (Prosser et al, 2009).

4.6.H Perphenazine

Chronic schizophrenia

Schizophrenia

4.6.H.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychotic study me Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 to 30 milligrams/da mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or ziprasidone 40 to 160 mg/day for up patients discontinued treatment for any cause before 18 months; discontinuation rates ranged from 64 to 82% from 3.5 months for ziprasidone to 9.2 months with olanzapine. The time to discontinuation was significantly l compared with the quetiapine (hazard ratio (HR), 0.63; 95% confidence interval (CI), 0.52 to 0.76; p less than (HR, 0.75; 95% CI, 0.62 to 0.90; p=0.002). Time to discontinuation due to adverse events were similar betwe ranged from 10% for risperidone to 19% for olanzapine (p=0.04). More patients discontinued olanzapine due of 0.9 kilograms/month) and greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides

4.6.H.2 Schizophrenia

a) Risperidone and perphenazine were equally efficacious in a double-blind, multicenter, parallel-group study schizophrenics with acute exacerbation were enrolled (Hoyberg et al, 1993a). No statistically significant differ (defined as a 20% reduction in total Positive and Negative Syndrome Scale score at endpoint) were found be Clinical Global Impression severity scores were also comparable. Patients with predominantly negative symp significantly lower Brief Psychiatric Rating Scale hostility scores compared to patients taking perphenazine.

4.6.I Quetiapine

Chronic schizophrenia

Psychotic disorder

4.6.I.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp
antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychotic study me
Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 to 30 milligrams/da
mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or ziprasidone 40 to 160 mg/day for up
patients discontinued treatment for any cause before 18 months; discontinuation rates ranged from 64 to 82%
from 3.5 months for ziprasidone to 9.2 months with olanzapine. The time to discontinuation was significantly l
compared with the quetiapine (hazard ratio (HR), 0.63; 95% confidence interval (CI), 0.52 to 0.76; p less than
(HR, 0.75; 95% CI, 0.62 to 0.90; p=0.002). Time to discontinuation due to adverse events were similar betwe
ranged from 10% for risperidone to 19% for olanzapine (p=0.04). More patients discontinued olanzapine due
of 0.9 kilograms/month) and greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides

4.6.I.2 Psychotic disorder

a) Quetiapine and risperidone were similarly efficacious in treating psychotic symptoms and had similar over
treatment resulted in fewer extrapyramidal symptoms (EPS) and was more effective in reducing depression.
patients with schizophrenia, schizoaffective disorder, or other psychotic disorders (including bipolar disorder,
various forms of dementia) were randomized in a ratio of 3:1 to receive quetiapine (n=553) or risperidone (n=
quetiapine was 50 milligrams/day (mg/day), which was increased in 50- or 100- mg increments every 1 to 2 d
mg/day, given in divided doses. Risperidone was started at 1 mg twice daily, with upward titration to a target
3. Dosages were individually titrated to maximize efficacy while minimizing adverse reactions (mean prescrib
risperidone 4.4 mg). At the beginning of the study, approximately half of each group had EPS. There was a s
patients reporting EPS in both groups as the study progressed. The incidence of EPS in the quetiapine group
risperidone group at one month (41.1 vs 47.3) but not at the end of the study (38.6 vs 39.2). The percentage
treatment due to EPS or requiring anti-EPS medication was lower in the quetiapine group than in the risperid
Approximately one third of patients in each group withdrew before completion of the study. A higher percenta
treatment for lack of efficacy (10.3% vs 5.8%) and a higher percentage withdrew from quetiapine treatment b
vs 5.1%). Somnolence was the most common adverse event in both groups, followed by dry mouth and dizzi
significantly more often with quetiapine treatment (p less than 0.05). Occurrence of weight gain was low in bo

4.6.J Ziprasidone

4.6.J.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp
antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychotic study me
Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 to 30 milligrams/da
mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or ziprasidone 40 to 160 mg/day for up
patients discontinued treatment for any cause before 18 months; discontinuation rates ranged from 64 to 82%
from 3.5 months for ziprasidone to 9.2 months with olanzapine. The time to discontinuation was significantly l
compared with the quetiapine (hazard ratio (HR), 0.63; 95% confidence interval (CI), 0.52 to 0.76; p less than
(HR, 0.75; 95% CI, 0.62 to 0.90; p=0.002). Time to discontinuation due to adverse events were similar betwe
ranged from 10% for risperidone to 19% for olanzapine (p=0.04). More patients discontinued olanzapine due
of 0.9 kilograms/month) and greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides

DRUGDEX® Evaluations

QUETIAPINE

0.0 Overview

1) Class

a) This drug is a member of the following class(es):
Antipsychotic
Dibenzothiazepine

2) Dosing Information

a) Quetiapine Fumarate

1) Adult

a) Bipolar disorder, depressed phase

1) regular-release tablets, 50 mg ORALLY once a day on day 1, then 100 mg once daily on day 2, then day 3, then 300 mg once daily on day 4 (all doses given at bedtime); patients requiring higher doses sho day 5, increased to 600 mg on day 8 (week 1) (Prod Info SEROQUEL(R) oral tablets, 2008a)

2) re-initiation of therapy: if less than 1 week off of quetiapine, titration of dose is not required and maint re-initiated; if greater than 1 week off of quetiapine, initial titration schedule should be followed (Prod Info tablets, 2008a)

b) Bipolar disorder, Maintenance

1) regular-release tablets, 400 mg to 800 mg per day ORALLY divided twice daily; generally continuatio or lowest dose to maintain remission; periodically reassess for need and appropriate dose for maintenan Info SEROQUEL(R) oral tablets, 2008a)

c) Manic bipolar I disorder

1) regular-release tablets, initial, 50 mg ORALLY twice daily, may increase dosage by increments up to the second and third day, to a target dose 400 mg per day by the fourth day given in 2 divided doses (Pr (R) oral tablets, 2007b)

2) regular-release tablets, maintenance, dosage adjustments in increments of not more than 200 mg/da day 6; usual effective dosage range is 400 to 800 mg/day; MAX dosage 800 mg/day (Prod Info SEROQU 2007b)

3) re-initiation of therapy: if less than 1 week off of quetiapine, titration of dose is not required and maint re-initiated; if greater than 1 week off of quetiapine, initial titration schedule should be followed (Prod Info tablets, 2007b)

d) Schizophrenia

1) regular-release tablets, initial, 25 mg ORALLY twice daily, may increase dosage by 25 to 50 mg 2 to second and third day, as tolerated, to a target dose range of 300 to 400 mg daily by the fourth day, given doses (Prod Info SEROQUEL(R) oral tablets, 2007b)

2) regular-release tablets, maintenance, dosage adjustments, if indicated, should generally occur at inte days in dose increments/decrements of 25 to 50 mg twice a day; usual effective dosage range is 150 to divided doses), MAX dosage 800 mg/day (Prod Info SEROQUEL(R) oral tablets, 2007b)

3) extended-release tablets, initial, 300 mg ORALLY once daily, preferably in the evening; titrate to a tar to 800 mg daily; dose increases may occur at intervals of at least 1 day in increments of up to 300 mg/da mg/day (Prod Info SEROQUEL XR(TM) extended-release oral tablets, 2007)

4) re-initiation of therapy: if less than 1 week off of quetiapine, titration of dose is not required and maint re-initiated; if greater than 1 week off of quetiapine, initial titration schedule should be followed (Prod Info extended-release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007b)

e) Schizophrenia, Maintenance

1) extended-release tablets, 400 to 800 mg ORALLY once daily, preferable in the evening; periodically r appropriate dose for maintenance treatment (Prod Info SEROQUEL(R)XR extended-release oral tablets,

2) Pediatric

a) safety and effectiveness in pediatric patients have not been established (Prod Info SEROQUEL XR(TM) e tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2008a)

3) Contraindications

a) Quetiapine Fumarate

1) hypersensitivity to quetiapine fumarate or any component of the product (Prod Info SEROQUEL(R) oral tablets

4) Serious Adverse Effects

a) Quetiapine Fumarate

1) Agranulocytosis
2) Anaphylaxis
3) Death
4) Leukopenia
5) Neuroleptic malignant syndrome
6) Neutropenia
7) Priapism
8) Seizure

9) Sudden cardiac death
10) Suicidal thoughts
11) Syncope
12) Tardive dyskinesia

5) Clinical Applications
a) Quetiapine Fumarate
1) FDA Approved Indications
a) Bipolar disorder, depressed phase
b) Bipolar disorder, Maintenance
c) Manic bipolar I disorder
d) Schizophrenia
e) Schizophrenia, Maintenance

1.0 Dosing Information

Drug Properties

Storage and Stability

Adult Dosage

Pediatric Dosage

1.1 Drug Properties

A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product In
B) Synonyms
Quetiapine
Quetiapine Fum
Quetiapine Fumarate
C) Physicochemical Properties
1) Molecular Weight
a) Quetiapine fumarate: 883.11 (Prod Info Seroquel, 97)
2) Solubility
a) Systemic: Quetiapine fumarate is moderately soluble in water (Prod Info Seroquel, 97).

1.2 Storage and Stability

A) Quetiapine Fumarate
1) Preparation
a) Oral route
1) Administration
a) Quetiapine extended-release tablets should not be chewed, crushed or split and should be swall
SEROQUEL XR(TM) extended-release oral tablets, 2007).
b) The absorption of extended-release quetiapine tablets is affected by food; give without food or w
approximately 300 calories (Prod Info SEROQUEL XR(TM) extended-release oral tablets, 2007). Re
are only marginally affected by food, and may be given without regards to food (Prod Info SEROQU
2008a).

1.3 Adult Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage in Geriatric Patients

Dosage in Other Disease States

1.3.1 Normal Dosage

1.3.1.A Quetiapine Fumarate

1.3.1.A.1 Oral route

Bipolar disorder, depressed phase

Manic bipolar I disorder

Schizophrenia

Schizophrenia, Maintenance

1.3.1.A.1.a Bipolar disorder, depressed phase

1) The recommended quetiapine dosing schedule for the treatment of depressive episodes associa disorder is 50 milligrams (mg), 100 mg, 200 mg, and 300 mg given once a day at bedtime on days 1 respectively. If a higher dose is required, the dose may be increased to 400 mg on day 5 and 600 m In clinical trials, both 300 mg and 600 mg doses demonstrated antidepressant efficacy; however, no seen in the 600 mg group (Prod Info SEROQUEL(R) oral tablets, 2008a).

2) When restarting treatment in patients who have had an interval of less than 1 week off of quetiap dose is not required and the maintenance dose may be re-initiated. The initial titration schedule sho re-initiating therapy in patients who have not taken quetiapine for more than 1 week (Prod Info SER tablets, 2008a).

1.3.1.A.1.b Manic bipolar I disorder

1) As monotherapy or adjunct therapy (with lithium or divalproex) in the treatment of acute bipolar m recommended initial dose of quetiapine is 100 milligrams per day (mg/day) (in two divided doses) or 400 mg/day on day 4 in increments of up to 100 mg/day (in two divided doses). Additional dosage a mg/day by day 6 should be in increments of no more than 200 mg/day. Most patients respond to dos 800 mg/day. The safety of doses greater than 800 mg/day has not been evaluated (Prod Info SERO 2007b).

2) When restarting treatment in patients who have had an interval of less than 1 week off of quetiap dose is not required and the maintenance dose may be re-initiated. The initial titration schedule sho re-initiating therapy in patients who have not taken quetiapine for more than 1 week (Prod Info SER tablets, 2007b).

1.3.1.A.1.c Schizophrenia

1) Regular-Release Tablets

a) For the treatment of schizophrenia, the recommended initial dose of quetiapine regular-relea milligrams (mg) twice daily. On the second or third day, the dose may be increased in incremen or three times daily. By the fourth day a target dose of 300 to 400 mg daily divided in two or thre recommended. Further increases can be made in increments of 25 to 50 mg twice daily at inter days. Antipsychotic efficacy has been demonstrated in the range of 150 to 750 mg usually given The safety of doses greater than 800 mg has not been determined (Prod Info SEROQUEL(R) o

b) For the treatment of schizophrenia, average effective doses of quetiapine in clinical trials ha and 400 milligrams daily, with the dose given in 2 or 3 divided doses; maximum doses have bee (Goren & Levin, 1998; Fulton & Goa, 1995b; Anon, 1995b; Borison et al, 1996b).

c) When restarting treatment in patients who have had an interval of less than 1 week off of qu dose is not required and the maintenance dose may be re-initiated. The initial titration schedule when re-initiating therapy in patients who have not taken quetiapine for more than 1 week (Proc oral tablets, 2008a).

2) Extended-Release Tablets

a) For the treatment of schizophrenia, the recommended initial dose of quetiapine extended-rel milligrams (mg) once daily, preferably given in the evening. Titrate the dose based upon patient tolerance within a range of 400 to 800 mg/day. Doses may be increased in increments of up to intervals as short as 1 day. Doses greater than 800 mg/day have not been evaluated for safety Info SEROQUEL XR(TM) extended-release oral tablets, 2007).

b) When restarting treatment in patients who have had an interval of less than 1 week off of qu the dose is not required and the maintenance dose may be re-initiated. The initial titration sched followed when re-initiating therapy in patients who have not taken quetiapine for more than 1 we

SEROQUEL XR(TM) extended-release oral tablets, 2007).

3) Switching from Regular-Release to Extended-Release

a) Schizophrenic patients currently receiving 2 to 3 divided doses of oral quetiapine fumarate (i formulation) may be switched to the extended-release formulation at the equivalent total daily d orally once daily (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

1.3.1.A.1.d Schizophrenia, Maintenance

1) Doses of 400 to 800 milligrams (mg) per day of extended-release quetiapine were successful in compared to placebo in the double-blind extension phase of a clinical trial in schizophrenic patients open-label treatment for 16 weeks. The dose should be administered once daily in the evening eithe a light meal. The maximum dose evaluated in clinical trials was 800 mg. Periodic reassessments are evaluate the need and appropriate dose for maintenance treatment (Prod Info SEROQUEL(R)XR ex tablets, 2007).

2) When restarting treatment in patients who have had an interval of less than 1 week off of quetiap dose is not required and the maintenance dose may be re-initiated. The initial titration schedule for a be followed when re-initiating therapy in patients who have not taken quetiapine for more than 1 wee SEROQUEL(R)XR extended-release oral tablets, 2007).

1.3.1.A.1.e IMPORTANT NOTE

1) The FDA Safety Information and Adverse Event Reporting Program has reported that there have errors due to the similarity of the names, dosage forms, strengths, and dosing intervals for Seroquel (Anon, 2002).

1.3.2 Dosage in Renal Failure

A) Quetiapine Fumarate

1) Dosage adjustment does not appear necessary in patients with renal insufficiency (Prod Info SEROQUEL release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2008a).

1.3.3 Dosage in Hepatic Insufficiency

A) Quetiapine Fumarate

1) Patients with hepatic impairment should be started on quetiapine therapy using the regular-release tablets (mg)/day then increased daily in increments of 25 to 50 mg/day to an effective dose. In these patients, the me quetiapine is 30% lower than subjects with normal hepatic clearance (Prod Info SEROQUEL XR(TM) extende 2007; Prod Info SEROQUEL(R) oral tablets, 2008a; Green, 1999a).

2) Patients may be switched to an equivalent total daily dose using extended-release tablets once an effectiv reached with the regular-release tablets (Prod Info SEROQUEL XR(TM) extended-release oral tablets, 2007)

1.3.4 Dosage in Geriatric Patients

A) Quetiapine Fumarate

1) Elderly patients should be started on quetiapine therapy using the regular-release tablets at 25 milligrams increased daily in increments of 25 to 50 mg/day to an effective dose. Oral clearance of quetiapine was reduc older than 65 years (Prod Info SEROQUEL XR(TM) extended-release oral tablets, 2007).

2) Patients may be switched to an equivalent total daily dose using extended-release tablets once an effectiv reached with the regular-release tablets (Prod Info SEROQUEL XR(TM) extended-release oral tablets, 2007)

1.3.6 Dosage in Other Disease States

A) Quetiapine Fumarate

1) Debilitated Patients

a) The manufacturer recommends that patients who are debilitated or have a predisposition to hypotens slower dose escalation and lower target dose (Prod Info SEROQUEL(R) oral tablets, 2008a; Prod Info S extended-release oral tablets, 2007).

1.4 Pediatric Dosage

1.4.1 Normal Dosage

1.4.1.A Quetiapine Fumarate

1.4.1.A.1 Oral route

a) Safety and effectiveness for use in pediatric patients have not been established (Prod Info SEROQUI release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2008a).

b) In a small trial (n=10) of adolescents (mean age of 13.6 years) with selected psychotic disorders, que in a dosage range of 50 to 800 milligrams daily led to satisfactory clinical results and similar pharmacoki profiles to that of adults (McConville et al, 2000).

2.0 Pharmacokinetics

Onset and Duration

Drug Concentration Levels

ADME

2.1 Onset and Duration
A) Onset
1) Quetiapine Fumarate
a) Initial Response
1) Schizophrenia, oral: 7 to 14 days (Borison et al, 1996; Fulton & Goa, 1995)

2.2 Drug Concentration Levels
A) Quetiapine Fumarate
1) Therapeutic Drug Concentration
a) Schizophrenia, undefined (Fabre et al, 1995)
2) Time to Peak Concentration
a) Oral, regular-release tablets: 1.5 hours (Prod Info SEROQUEL(R) oral tablets, 2007; Fabre et al, 1995; Sh
1) Steady-state concentrations of quetiapine fumarate regular-release tablets occur within 2 days of dos
SEROQUEL(R) oral tablets, 2007).
2) A mean peak level of 278 ng/mL (range, 140 to 365 ng/mL) was observed after a 75-mg oral midday
quetiapine therapy; at this time, patients were receiving total daily doses of up to 250 mg. After a single d
quetiapine in schizophrenic patients, peak serum levels ranged from 18 to 136 ng/mL (mean, 60 ng/mL)
b) Oral, extended-release tablets: 6 h (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)
1) Steady-state concentrations of quetiapine fumarate extended-release tablets occur within 2 days of d
SEROQUEL(R)XR extended-release oral tablets, 2007).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

2.3.1 Absorption
A) Quetiapine Fumarate
1) Bioavailability
a) Oral: 9% (Goren & Levin, 1998).
1) The bioavailability of the extended-release quetiapine fumarate tablets, dosed once daily at stea
comparable to an equivalent dose of the regular-release tablets, dosed twice daily (Prod Info SERO
extended-release oral tablets, 2007).
2) Effects of Food
a) Regular-release tablets: marginally affected (Prod Info SEROQUEL(R) oral tablets, 2007)
1) When regular-release quetiapine fumarate tablets were administered with food, the Cmax and AU
and 15%, respectively (Prod Info SEROQUEL(R) oral tablets, 2007b).
2) Food increases the absorption of quetiapine (Goren & Levin, 1998). In healthy volunteers, admin
with food resulted in an increase in the peak serum concentration and area under the time-concentra
(each by approximately 1.5-fold) compared to the fasting state (Shimada et al, 1994).
b) Extended-release tablets: significant (Prod Info SEROQUEL(R)XR extended-release oral tablets, 200
1) Statistically significant increases in the Cmax and AUC of 44% to 52% and 20% to 22%, respecti
the 50-mg and 300-mg quetiapine fumarate extended-release tablets when given with a high-fat me
to 1000 calories). There was no significant effect on the Cmax or AUC when given with a light meal
calories) (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info SEROQUEL(R

2.3.2 Distribution
A) Distribution Sites
1) Quetiapine Fumarate
a) Protein Binding
1) 83% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-releas

B) Distribution Kinetics
1) Quetiapine Fumarate
a) Volume of Distribution
1) 10 L/kg +/- 4 L/kg (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR ext tablets, 2007)

2.3.3 Metabolism
A) Metabolism Sites and Kinetics
1) Quetiapine Fumarate
a) LIVER, extensive (Goren & Levin, 1998; Green, 1999)
1) Extensive first-pass metabolism occurs with quetiapine (Wetzel et al, 1995a).
2) Quetiapine fumarate is primarily metabolized by sulfoxidation and oxidation via the P450 CYP3A Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2
3) After a single oral dose, less than 1% of quetiapine is excreted unchanged (Prod Info SEROQUE 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).
B) Metabolites
1) Quetiapine Fumarate
a) N-desalkyl quetiapine, (active) (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)
1) Twenty metabolites of quetiapine have been identified; the 7-hydroxylated metabolite and the N- are pharmacologically active (Goren & Levin, 1998).

2.3.4 Excretion
A) Kidney
1) Quetiapine Fumarate
a) Renal Excretion (%)
1) 70% to 73% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended 2007; Green, 1999; Fulton & Goa, 1995)
a) Following administration of a single oral dose of carbon-labeled quetiapine, approximately 7 recovered in the urine (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)X oral tablets, 2007).
B) Feces
1) Quetiapine Fumarate
a) approximately 20% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extend tablets, 2007)
1) Following administration of a single oral dose of carbon-labeled quetiapine, approximately 20% c recovered in the feces (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR ex tablets, 2007).

2.3.5 Elimination Half-life
A) Parent Compound
1) Quetiapine Fumarate
a) Regular-release tablet, 6 hours (Prod Info SEROQUEL(R) oral tablets, 2007)
b) Extended-release tablet, 7 hours (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING
1) Quetiapine Fumarate
a) Oral (Tablet)
Increased Mortality in Elderly Patients with Dementia-Related Psychosis
Elderly patients with dementia-related psychosis treated with antipsychotic drugs are at an increased risk seventeen placebo-controlled trials (modal duration of 10 weeks) largely in patients taking atypical antips revealed a risk of death in drug-treated patients of between 1.6 times to 1.7 times the risk of death in pla Over the course of a typical 10 week controlled trial, the rate of death in drug-treated patients was about rate of about 2.6% in the placebo group. Although the causes of death were varied, most of the deaths a

cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature. Observationa similar to atypical antipsychotic drugs, treatment with conventional antipsychotic drugs may increase mo which the findings of increased mortality in observational studies may be attributed to the antipsychotic d some characteristic(s) of the patients is not clear. Quetiapine fumarate is not approved for the treatment dementia-related psychosis (Prod Info SEROQUEL(R) oral tablets, 2008).

Suicidality and Antidepressant Drugs

Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorde considering the use of quetiapine fumarate or any other antidepressant in a child, adolescent, or young a risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antid to placebo in adults beyond age 24; there was a reduction in risk with antidepressants compared to place and older. Depression and certain other psychiatric disorders are themselves associated with increases Patients of all ages who are started on antidepressant therapy should be monitored appropriately and ob clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advise observation and communication with the prescriber. Quetiapine fumarate is not approved for use in pedia Info SEROQUEL(R) oral tablets, 2008).

b) Oral (Tablet, Extended Release)

Increased Mortality in Elderly Patients with Dementia-related Psychosis

Elderly patients with dementia-related psychosis treated with antipsychotic drugs are at an increased risk seventeen placebo-controlled trials (modal duration of 10 weeks) largely in patients taking atypical antips revealed a risk of death in the drug-treated patients of between 1.6 times to 1.7 times the risk of death in patients. Over the course of a typical 10 week controlled trial, the rate of death in drug-treated patients w compared to a rate of about 2.6% in the placebo group. Although the causes of death were varied, most appeared to be either cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in studies suggest that, similar to atypical antipsychotic drugs may increase mortality. The extent to which t increased mortality in observational studies may be attributed to the antipsychotic drug as opposed to so the patients is not clear. Quetiapine fumarate extended-release is not approved for the treatment of patie related psychosis (Prod Info SEROQUEL XR(R) extended-release oral tablets, 2008).

Suicidality and Antidepressant Drugs

Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorde considering the use of quetiapine fumarate or any other antidepressant in a child, adolescent, or young a risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antid to placebo in adults beyond age 24; there was a reduction in risk with antidepressants compared to place and older. Depression and certain other psychiatric disorders are themselves associated with increases Patients of all ages who are started on antidepressant therapy should be monitored appropriately and ob clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advise observation and communication with the prescriber. Quetiapine fumarate extended-release tablets are n pediatric patients. Quetiapine fumarate is not approved for use in the treatment of depression, however, form of quetiapine fumarate is approved for the treatment of bipolar depression (Prod Info SEROQUEL X release oral tablets, 2008).

3.1 Contraindications

A) Quetiapine Fumarate

1) hypersensitivity to quetiapine fumarate or any component of the product (Prod Info SEROQUEL(R) oral tablets

3.2 Precautions

A) Quetiapine Fumarate

1) elderly patients with dementia-related psychosis (unapproved use); increased risk of death reported when atyp were used to treat behavorial disorders associated with dementia (Prod Info SEROQUEL XR(R) extended-release Prod Info SEROQUEL(R) oral tablets, 2008)

2) suicidal ideation and behavior or worsening depression; increased risk, particularly in children and adolescents first few months of therapy or during changes in dosing (decreases or increases) (Prod Info SEROQUEL XR(R) e tablets, 2008; Prod Info SEROQUEL(R) oral tablets, 2008)

3) agranulocytosis, including fatal cases, has been reported (Prod Info SEROQUEL(R)XR extended-release oral Info SEROQUEL(R) oral tablets, 2007)

4) aspiration pneumonia, patients at risk for; may cause esophageal dysmotility and aspiration (Prod Info SEROQ release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007)

5) cardiovascular disease, known; risk of orthostatic hypotension (Prod Info SEROQUEL(R)XR extended-release Prod Info SEROQUEL(R) oral tablets, 2007)

6) cerebrovascular disease; risk of orthostatic hypotension (Prod Info SEROQUEL(R)XR extended-release oral ta SEROQUEL(R) oral tablets, 2007)

7) concomitant use of antihypertensive medications; risk of orthostatic hypotension (Prod Info SEROQUEL(R)XR tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007)

8) dehydration; risk of orthostatic hypotension (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUE 2007)

9) diabetes mellitus or at risk of diabetes mellitus; occurrence of hyperglycemia, some cases associated with keto hyperosmolar coma or death (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info SEROQ

2007)
10) elderly patients (especially elderly women); increased risk of tardive dyskinesia (Prod Info SEROQUEL(R)XR tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007)
11) elevated cholesterol and triglyceride levels have been reported (Prod Info SEROQUEL(R)XR extended-relea Prod Info SEROQUEL(R) oral tablets, 2007a)
12) elevated serum transaminases (asymptomatic, transient and reversible) have been reported(Prod Info SERO extended-release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007)
13) hypovolemia; risk of orthostatic hypotension (Prod Info SEROQUEL(R)XR extended-release oral tablets, 200 SEROQUEL(R) oral tablets, 2007)
14) leukopenia/neutropenia has been reported; increased risk with history of drug-induced leukopenia/neutropeni WBC; if develops, discontinue therapy (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod In tablets, 2007)
15) neuroleptic malignant syndrome (NMS) has occurred (Prod Info SEROQUEL(R)XR extended-release oral tab SEROQUEL(R) oral tablets, 2007)
16) orthostatic hypotension, with or without syncope, may occur; increased risk during initial dose-titration period, titration, return to previous dose (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info SER tablets, 2007)
17) seizures, history of or predisposing factors for developing (Prod Info SEROQUEL(R)XR extended-release ora Info SEROQUEL(R) oral tablets, 2007)
18) tardive dyskinesia may occur; increased risk with increased duration of treatment and increased total cumula SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info SEROQUEL(R) oral tablets, 2007)

3.3.1 Cardiovascular Effects

3.3.1.A Quetiapine Fumarate

Orthostatic hypotension

Sudden cardiac death

Syncope

Tachycardia

3.3.1.A.1 Orthostatic hypotension

a) Incidence: 4% to 7% (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info SE tablets, 2007)

b) In monotherapy, placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, orthostatic hypotension was reported in 4% of patients receiving quetiapine fuma compared to 1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUE 2007).

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, hypotension was reported in 7% of patients receiving quetiapine fumarate tablets (n=196) compared to 2 (n=203); doses ranged from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

d) During acute therapy (up to 6 weeks) placebo-controlled clinical trials of adult patients with schizophr hypotension was reported in 7% of patients receiving quetiapine fumarate extended-release tablets (n=9 for placebo (n=319). Use quetiapine fumarate cautiously in patients with cerebrovascular disease, cardio conditions that predispose them to hypotension (i.e., hypovolemia, dehydration, and concomitant antihyp (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

e) The risk of hypotension is greater during dose-titration periods. Should hypotension develop during tit pre-titration dose is appropriate (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)X oral tablets, 2007).

3.3.1.A.2 Sudden cardiac death

a) In a large, retrospective, cohort study that included a primary cohort of 93,300 users of antipsychotic non-users of antipsychotic drugs, there was an increased risk of sudden cardiac death in adult participan age (mean age of 45.7 years) who were using quetiapine compared to those who were not using antipsy (incidence-rate ratio, 1.88; 95% confidence interval (CI), 1.3 to 2.71; p less than 0.001). In participants be atypical antidepressants (clozapine, olanzapine, quetiapine, risperidone), the incidence-rate ratio for sud increased from 1.59 (95% CI, 1.03 to 2.46) for those using low doses to 2.86 (95% CI, 2.25 to 3.65) for th (p=0.01) (Ray et al, 2009).

3.3.1.A.3 Syncope

a) Incidence: tablets, 1% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, 0.3% SEROQUEL(R)XR extended-release oral tablets, 2007)

b) During clinical trials, syncope was reported in 1% of patients receiving quetiapine fumarate tablets (n= 0.2% for placebo (n=954) and 0.4% for active control (n=527) (Prod Info SEROQUEL(R) oral tablets, 20

c) During clinical trials, syncope was reported in 0.3% of patients receiving quetiapine fumarate extende (n=951) and in 0.3% receiving placebo (n=319) (Prod Info SEROQUEL(R)XR extended-release oral tabl

3.3.1.A.4 Tachycardia

a) Incidence: 0.5% to 6% (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007; Prod Info S tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, tachycardia was reported in 6% of patients receiving quetiapine fumarate tablets 4% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

c) During clinical trials, tachycardia was reported in 3% of patients receiving quetiapine fumarate extend compared to 1% for placebo. Tachycardia (greater than 120 bpm) was reported in 0.8% of patients recei compared to 0% for placebo at any time during the clinical trials for quetiapine fumarate extended-releas SEROQUEL(R)XR extended-release oral tablets, 2007).

d) In four pooled, placebo controlled clinical trials for the treatment of schizophrenia (3 to 6 weeks in dur tachycardia was reported in 1% of patients receiving quetiapine fumarate tablets (n=399) compared to 0. (n=156) (Prod Info SEROQUEL(R) oral tablets, 2007).

e) In pooled, placebo-controlled clinical trials for the treatment (monotherapy) of acute bipolar mania in a was reported in 0.5% of patients receiving quetiapine fumarate tablets (n=192) compared to 0% for place SEROQUEL(R) oral tablets, 2007).

f) In pooled, placebo-controlled clinical trials for the adjunctive treatment of acute bipolar mania in adults reported in 0.6% of patients receiving quetiapine fumarate tablets (n=166) compared to 0% for placebo (SEROQUEL(R) oral tablets, 2007).

g) Evaluation of ECG's associated a mean increase in heart rate of 7 beats per minute (bpm) for quetiap compared to a mean increase of 1 bpm for placebo (Prod Info SEROQUEL(R) oral tablets, 2007; Prod In extended-release oral tablets, 2007).

h) An increase in heart rate (approximately 9 beats/minute) has been detected during 6 weeks of therap 1996a). Greater than 20 percent of patients receiving 100 to 200 milligrams daily have shown an increas beats per minute or greater or have experienced a decrease in systolic blood pressure of 30 millimeters (Garver, 2000a). The drug has not induced clinically significant arrhythmias in placebo-controlled studies

3.3.2 Dermatologic Effects

3.3.2.A Quetiapine Fumarate

3.3.2.A.1 Rash

a) Incidence: tablets, 4% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, less th
SEROQUEL(R)XR extended-release oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a
to 12 weeks) in adults, rash was reported in 4% of patients receiving quetiapine fumarate tablets (n=719
placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 20

c) During clinical trials for the treatment of schizophrenia in adults, rash was reported in less than 5% of
quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release oral tablet

3.3.3 Endocrine/Metabolic Effects

Quetiapine

Quetiapine Fumarate

3.3.3.A Quetiapine

Diabetes mellitus

Metabolic syndrome

3.3.3.A.1 Diabetes mellitus

See Drug Consult reference: ATYPICAL ANTIPSYCHOTIC AGENTS - EFFECT ON GLUCOSE AND RI

3.3.3.A.2 Metabolic syndrome

See Drug Consult reference: ANTIPSYCHOTIC AGENTS - METABOLIC SYNDROME

3.3.3.B Quetiapine Fumarate

Decreased prolactin level

Hyperglycemia

Hypothyroidism

Serum cholesterol raised

Serum triglycerides raised

Weight gain

3.3.3.B.1 Decreased prolactin level

a) In studies of patients with high prolactin levels, serum prolactin was reduced further in patients treate
in those receiving chlorpromazine. Prolactin levels were similar with placebo and quetiapine after 21 and
Quetiapine has minimal effect on the serum prolactin levels of schizophrenic patients. Decreases in prola
cases, were most likely related to discontinuation of the patient's antipsychotic therapy (Borison et al, 19
Fulton & Goa, 1995b).

3.3.3.B.2 Hyperglycemia

a) Incidence: 0.1% to 1% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) Hyperglycemia, including cases associated with ketoacidosis, hyperosmolar coma, or death, has bee
receiving atypical antipsychotics, including quetiapine fumarate. Hyperglycemia has resolved in some ca
discontinuation of the drug, while in other cases, continuation of antidiabetic treatment was required afte
(Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets

c) In two long-term, placebo-controlled clinical trials, blood glucose increases of 126 mg/dL or greater fo than 8 hours since a meal were reported in 10.7% of patients taking quetiapine fumarate tablets (n=646; exposure, 213 days) compared to 4.6% for placebo (n=680; mean duration of exposure, 152 days) (Proc oral tablets, 2007).
d) In placebo-controlled clinical trials of up to 12 weeks, fasting blood glucose levels of 126 mg/dL or gre blood glucose levels of 200 mg/dL or greater were reported for 3.5% of patients taking quetiapine fumara compared to 2.1% for placebo (n=1490) (Prod Info SEROQUEL(R) oral tablets, 2007).
e) In a 24-week trial (n=115), a fasting blood glucose of 126 mg/dL or greater was reported in 2.6% of p nonfasting blood glucose of 200 mg/dL or greater was reported in 1.7% of patients taking quetiapine fum Info SEROQUEL(R) oral tablets, 2007).
f) A 42-year-old man, after one month of quetiapine use, was diagnosed with new-onset diabetes mellitu admitted to the hospital after several days of nausea, vomiting, polyuria, and confusion. His blood glucos admission was 607 milligram/deciliter (mg/dL). Random blood glucose concentrations 4 months prior to t were 126 and 107 mg/dL. He had no prior history of glucose intolerance, hyperglycemia, and no familial The patient's history of bipolar disorder was concurrently treated with lithium carbonate, gabapentin, clor venlafaxine in addition to his quetiapine titration of 200 milligrams at night. He was eventually discharged regimen, and quetiapine was discontinued over the course of 9 days. The patient's insulin dose was wea 5 months after admission (Sobel et al, 1999).

3.3.3.B.3 Hypothyroidism

a) Summary

1) Cases of hypothyroidism have been reported with quetiapine use. Thyroid monitoring is recomm therapy, at least in patients with a history of or a propensity for thyroid disease (Liappas et al, 2006;

b) In placebo-controlled clinical trials, 0.5% and 2.7% of patients receiving quetiapine fumarate extende experienced decreased free thyroxine and increased TSH, respectively, compared to 0% and 1.2% for p (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).
c) In clinical trials using quetiapine fumarate tablets as monotherapy treatment, 0.7% of patients receivi experienced increased TSH levels with six patients requiring thyroid replacement therapy (Prod Info SEF tablets, 2007).
d) In placebo-controlled clinical trials for the adjunctive treatment of mania in adults, elevated TSH level 12% of patients receiving quetiapine fumarate tablets (n=196) compared to 7% for placebo (n=203). Thr treated patients also had concurrent low free T4 levels (Prod Info SEROQUEL(R) oral tablets, 2007).
e) In clinical trials, decreases in total and free thyroxine (T4) appear to be dose-related, with levels drop 20% at the higher end of the therapeutic dose range; maximal decreases were seen during the first two t therapy (Prod Info SEROQUEL(R) oral tablets, 2007).
f) A case of quetiapine-induced hypothyroidism was described in a 49-year-old woman. The patient had dysthymia, with 2 major depressive episodes in the past 14 years, and had been treated over the years v antidepressant and anxiolytic medications to varying degrees of success. Over the last 4 years, she was taking up to 150 mg/day. Six months prior to current presentation, in an attempt to discontinue zolpidem mood, treatment with venlafaxine (300 mg/day), paroxetine (30 mg/day), and quetiapine (800 mg/day) w significant improvement. A routine thyroid screening at the time of current presentation revealed decreas (4.17 mcg/dL; normal range, 6.09 to 12.23 mcg/dL) and free T4 values (0.53 ng/dL; normal range, 0.58 t elevated TSH level (6.78 micro-International Units/mL; normal range, 0.34 to 5.6 micro-International Unit symptoms included a modest weight gain, decrease in appetite, hoarseness of voice, slowing of motor a constipation. Although the patient's past medical record was negative for a thyroid disorder, she had a p for hypothyroidism. Subsequently, quetiapine was tapered and discontinued over a week, while the rest were continued at the same doses. Within the next 2 months, laboratory thyroid tests were within normal displayed a steady mood improvement. It is believed that thyroid autoimmunity may be responsible for th function monitoring is recommended in quetiapine-treated patients with a history of or a propensity for th et al, 2006).
g) A 46-year-old woman developed hypothyroidism 2 months after the addition of quetiapine to her exist Reaching a final titrated total dose of 425 milligrams of quetiapine daily, the patient developed an elevate hormone concentration of 8.45 microunits per liter. Prior medical history included successful radioactive hyperthyroidism but without detection of thyroid abnormalities until 4 years later when quetiapine was init function monitoring is recommended during quetiapine therapy (Feret & Caley, 2000).
h) Decreases in mean total thyroxine and occasionally decreased triiodothyronine levels have occurred schizophrenia with quetiapine (Anon, 1995a; Borison et al, 1996a).

3.3.3.B.4 Serum cholesterol raised

a) Incidence: tablets, 9% to 16% (Prod Info SEROQUEL(R) oral tablets, 2007)
b) During clinical trials for the treatment of schizophrenia in adults, elevations in cholesterol to levels of were reported in 16% of patients receiving quetiapine fumarate tablets compared to 7% for placebo (Pro oral tablets, 2007).
c) During adult bipolar depression clinical trials, elevations in cholesterol to levels of 240 mg/dL or great of patients receiving quetiapine fumarate tablets compared to 6% for placebo (Prod Info SEROQUEL(R)
d) During clinical trials for the treatment of schizophrenia in adults, an increase in mean cholesterol leve were reported in patients receiving quetiapine fumarate extended-release tablets compared to a decreas for placebo (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.3.B.5 Serum triglycerides raised

a) Incidence: tablets, 14% to 23% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) During clinical trials for the treatment of schizophrenia in adults, elevations in triglycerides to levels of were reported in 23% of patients receiving quetiapine fumarate tablets compared to 16% for placebo (Pr (R) oral tablets, 2007).

c) During adult bipolar depression clinical trials, elevations in triglycerides to levels of 200 mg/dL or grea 14% of patients receiving quetiapine fumarate tablets compared to 9% for placebo (Prod Info SEROQUE 2007).

d) During clinical trials for the treatment of schizophrenia in adults, an increase in mean triglyceride leve 15% was reported in patients receiving quetiapine fumarate extended-release tablets compared to a dec 6% for placebo (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.3.B.6 Weight gain

a) Incidence: 5% to 23% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR exte tablets, 2007)

b) Patients receiving quetiapine fumarate tablets demonstrated a greater incidence of weight increase (weight) than placebo in placebo-controlled schizophrenia trials (23% and 6%, respectively); in mania mo and 7%, respectively); in mania adjunct therapy trials (13% and 4%, respectively); and in bipolar depress respectively) (Prod Info SEROQUEL(R) oral tablets, 2007).

c) During adult schizophrenia clinical trials, weight gain of 7% or greater of body weight was reported in receiving quetiapine fumarate extended-release tablets compared to 5% for placebo (Prod Info SEROQU release oral tablets, 2007).

d) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, weight gain was reported in 5% of patients receiving quetiapine fumarate tablets 1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

e) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 6% of patients receiving quetiapine fumarate tablets (n=196) compared to 3% for placebo (n= from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

f) A logistic regression analysis of placebo-controlled clinical study of five fixed-doses of quetiapine fuma patients with schizophrenia revealed a positive correlation between dose and the occurrence of weight g Doses included in these studies included 75 milligrams (mg)/day, 150 mg/day, 300 mg/day, 600 mg/day, (Prod Info SEROQUEL(R) oral tablets, 2007).

g) Adolescent patients taking olanzapine experienced greater weight gain and increased in body mass i patients taking quetiapine in a retrospective study involving 103 patients younger than 18 years of age. F olanzapine (n=50, mean daily dose 13.9 milligrams (mg)) or quetiapine (n=53, mean daily dose 510.9 mg Weight and height were measured at baseline and 14 or more days after baseline. Average weight gain olanzapine group was 3.8 kilograms (kg) (p less than 0.001) compared to 0.03 kg in the quetiapine group and quetiapine groups showed slight, but significant, increases in height from baseline (0.006 meters, p= meters, p less than 0.001, respectively). After controlling for baseline differences, the mean weight chang was significant (3.4 kg, p less than 0.001). BMI increased by an average of 1.3 kg per square meter (m(2 group (p less than 0.001) compared to a decreased of 0.2 kg/m(2) in the quetiapine group. After controlli differences, the mean difference in change in BMI was significant (0.9 kg/m(2), p=0.008) (Patel et al, 200

3.3.4 Gastrointestinal Effects

3.3.4.A Quetiapine Fumarate

Abdominal pain

Constipation

Increased appetite

Indigestion

Vomiting

Xerostomia

3.3.4.A.1 Abdominal pain

a) Incidence: 4% to 7% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, abdominal pain was reported in 4% of patients receiving quetiapine fumarate tabl

to 1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral t
c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 7% of patients receiving quetiapine fumarate tablets (n=196) compared to 3% for placebo (n= from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).
d) A logistic regression analysis of placebo-controlled clinical study of five fixed-doses of quetiapine fum patients with schizophrenia revealed a positive correlation between dose and the occurrence of abdomin 0.05). Doses included in these studies included 75 milligrams (mg)/day, 150 mg/day, 300 mg/day, 600 m mg/day (Prod Info SEROQUEL(R) oral tablets, 2007).
e) Anticholinergic adverse effects of quetiapine therapy are dose-related. Dry mouth occurred in 8% to 1 patients in clinical trials. Constipation was also reported. Abdominal pain, dyspepsia, and anorexia occur (Borison et al, 1996a; Wetzel et al, 1995; Fulton & Goa, 1995b).

3.3.4.A.2 Constipation
a) Incidence: tablets, 8% to 10% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets SEROQUEL(R)XR extended-release oral tablets, 2007)
b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, constipation was reported in 8% of patients receiving quetiapine fumarate tablets 3% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tab
c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 10% of patients receiving quetiapine fumarate tablets (n=196) compared to 5% for placebo (r from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).
d) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, co reported in 10% of patients receiving quetiapine fumarate tablets (n=698) compared to 4% for placebo (r from 300 to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).
e) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, constip 6% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 5% for place ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).
f) Anticholinergic adverse effects of quetiapine therapy are dose-related. Dry mouth occurred in 8% to 1 patients in clinical trials. Constipation was also reported. Abdominal pain, dyspepsia, and anorexia occur (Borison et al, 1996a; Wetzel et al, 1995; Fulton & Goa, 1995b).

3.3.4.A.3 Increased appetite
a) Incidence: tablets, 5% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, less th SEROQUEL(R)XR extended-release oral tablets, 2007)
b) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, in reported in 5% of patients receiving quetiapine fumarate tablets (n=698) compared to 3% for placebo (n= from 300 to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).
c) During clinical trials for the treatment of schizophrenia in adults, increased appetite was reported in le taking quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release ora

3.3.4.A.4 Indigestion
a) Incidence: 5% to 7% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR exter tablets, 2007)
b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, dyspepsia was reported in 5% of patients receiving quetiapine fumarate tablets (r 1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl
c) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, dy in 7% of patients receiving quetiapine fumarate tablets (n=698) compared to 4% for placebo (n=347); do to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).
d) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, dyspe 5% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 2% for place ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).
e) A logistic regression analysis of placebo-controlled clinical study of five fixed-doses of quetiapine fum patients with schizophrenia revealed a positive correlation between dose and the occurrence of dyspeps Doses included in these studies included 75 milligrams (mg)/day, 150 mg/day, 300 mg/day, 600 mg/day, (Prod Info SEROQUEL(R) oral tablets, 2007).
f) Anticholinergic adverse effects of quetiapine therapy are dose-related. Dry mouth occurred in 8% to 1 patients in clinical trials. Constipation was also reported. Abdominal pain, dyspepsia, and anorexia occur (Borison et al, 1996a; Wetzel et al, 1995; Fulton & Goa, 1995b).

3.3.4.A.5 Vomiting
a) Incidence: 5% to 6% (Prod Info SEROQUEL(R) oral tablets, 2007)
b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, vomiting was reported in 6% of patients receiving quetiapine fumarate tablets (n= for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets,
c) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, vo 5% of patients receiving quetiapine fumarate tablets (n=698) compared to 4% for placebo (n=347); dose 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.4.A.6 Xerostomia

a) Incidence: 9% to 44% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR exte tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, dry mouth was reported in 9% of patients receiving quetiapine fumarate tablets (r 3% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 19% of patients receiving quetiapine fumarate tablets (n=196) compared to 3% for placebo (r from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

d) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, dı in 44% of patients receiving quetiapine fumarate tablets (n=698) compared to 13% for placebo (n=347); 300 to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

e) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, dry mo 12% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 1% for pla ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

f) Anticholinergic adverse effects of quetiapine therapy are dose-related. Dry mouth occurred in 8% to 1 patients in clinical trials. Constipation was also reported. Abdominal pain, dyspepsia, and anorexia occur (Borison et al, 1996a; Wetzel et al, 1995; Fulton & Goa, 1995b).

3.3.5 Hematologic Effects

3.3.5.A Quetiapine Fumarate

Agranulocytosis

Leukopenia

Neutropenia

Pancytopenia

3.3.5.A.1 Agranulocytosis

a) Agranulocytosis, including fatal incidences, has been reported during clinical trials and post-marketing fumarate (Prod Info SEROQUEL(R) oral tablets, 2008; Prod Info SEROQUEL XR(R) extended-release o

3.3.5.A.2 Leukopenia

a) Incidence: tablets, at least 1% (Prod Info SEROQUEL(R) oral tablets, 2008); extended-release tablet Info SEROQUEL XR(R) extended-release oral tablets, 2008; Prod Info SEROQUEL(R) oral tablets, 200

b) During quetiapine fumarate clinical trials, leukopenia was reported in at least 1% of patients receiving less than 5% of patients receiving extended-release tablets. Leukopenia has also been reported during p quetiapine fumarate. Patients possibly at risk for developing leukopenia include those with a preexisting of drug-induced leukopenia. Should leukopenia develop during quetiapine fumarate therapy, discontinue SEROQUEL(R) oral tablets, 2008; Prod Info SEROQUEL(R) oral tablets, 2008).

3.3.5.A.3 Neutropenia

a) Incidence: 0.3% (Prod Info SEROQUEL(R) oral tablets, 2008; Prod Info SEROQUEL XR(R) extended 2008)

b) During placebo-controlled clinical trials with quetiapine fumarate, neutropenia was reported in 0.3% o quetiapine fumarate monotherapy (n=2967) compared to 0.1% for placebo (n=1349). Neutropenia has al during post-marketing use of quetiapine fumarate. Patients possibly at risk for developing neutropenia in preexisting low WBC or a history of drug-induced neutropenia. Should neutropenia develop, discontinue SEROQUEL(R) oral tablets, 2008; Prod Info SEROQUEL XR(R) extended-release oral tablets, 2008).

3.3.5.A.4 Pancytopenia

a) Pancytopenia developed in a 71-year-old Caucasian male with a history of Parkinson's disease 3 wee quetiapine therapy at a dose of 25 milligrams twice daily for the treatment of drug-induced hallucinations counts improved within 48 hours of withdrawal of the drug and returned to normal in 7 days (Iraqi, 2003).

3.3.6 Hepatic Effects

3.3.6.A Quetiapine Fumarate

3.3.6.A.1 Increased liver enzymes

a) Incidence: tablets, 6% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, 1% (P
(R)XR extended-release oral tablets, 2007)
b) Transient, asymptomatic and reversible elevations in serum transaminase, primarily alanine aminotra
been reported. Peak elevations are usually seen within the first three weeks of treatment and most retur
with continued therapy (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extenc
tablets, 2007).
c) In pooled, placebo-controlled clinical trials for the treatment of schizophrenia (3 to 6 weeks in duratior
in serum transaminases of greater than 3 times the upper limits of normal was reported in 6% of patients
fumarate tablets compared to 1% for placebo (Prod Info SEROQUEL(R) oral tablets, 2007).
d) In pooled, placebo-controlled 6-week clinical trials for the treatment of schizophrenia in adults, elevati
transaminases of greater than 3 times the upper limits of normal was reported in 1% of patients receiving
extended-release tablets compared to 2% for placebo (Prod Info SEROQUEL(R)XR extended-release or

3.3.7 Immunologic Effects

3.3.7.A Quetiapine Fumarate

3.3.7.A.1 Anaphylaxis
a) Anaphylactic reactions, temporally related to quetiapine therapy, have been reported during post-mar
SEROQUEL(R) oral tablets, 2008a).

3.3.8 Musculoskeletal Effects

3.3.8.A Quetiapine Fumarate

3.3.8.A.1 Backache
a) Incidence: 3% to 5% (Prod Info SEROQUEL(R) oral tablets, 2007)
b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a
to 12 weeks) in adults, back pain was reported in 3% of patients receiving quetiapine fumarate tablets (n
1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl
c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults,
reported in 5% of patients receiving quetiapine fumarate tablets (n=196) compared to 3% for placebo (n=
from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.9 Neurologic Effects

3.3.9.A Quetiapine Fumarate

Akathisia

Altered mental status

Asthenia

Dizziness

Dystonia

Extrapyramidal disease

Headache

Insomnia

Lethargy

Parkinsonism

Restless legs syndrome

Sedated

Seizure

Somnolence

Tardive dyskinesia

Tremor

3.3.9.A.1 Akathisia

a) Incidence: less than 5% (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)

b) During clinical trials for the treatment of schizophrenia in adults, akathisia was reported in less than 5 quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release oral tablet

c) Akathisia developed in a male patient with Parkinson's disease following the administration of quetiap of dopamimetic psychosis. The 62-year-old man was taking levodopa at a daily dose of 400 milligrams (r a dose of 12.5 to 25 mg daily for approximately 5 days, when he developed severe motor restlessness, a pacing. His score on the Barnes Akathisia Scale (range, 0= no symptoms to 14=severe akathisia) reache withdrawn and symptoms of akathisia completely resolved within 2 days (Prueter et al, 2003).

3.3.9.A.2 Altered mental status

a) A 62-year-old man experienced acute mental status changes within 3 days of increasing his quetiapir milligrams daily while symptoms resolved within 48 hours of discontinuing quetiapine. There was no clini serotonin syndrome, or alcohol intoxication or withdrawal. Quetiapine is believed to be associated with th changes due to the close temporal relationship between the onset and resolution of symptoms (Sim et al

3.3.9.A.3 Asthenia

a) Incidence: 5% to 10% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, asthenia was reported in 5% of patients receiving quetiapine fumarate tablets (n= for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets,

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, in 10% of patients receiving quetiapine fumarate tablets (n=196) compared to 4% for placebo (n=203); d to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.9.A.4 Dizziness

a) Incidence: 9% to 18% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR exte tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, dizziness was reported in 11% of patients receiving quetiapine fumarate tablets (r 5% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 9% of patients receiving quetiapine fumarate tablets (n=196) compared to 6% for placebo (n= from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

d) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, di in 18% of patients receiving quetiapine fumarate tablets (n=698) compared to 7% for placebo (n=347); d to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

e) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, dizzine 10% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 4% for pla ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.9.A.5 Dystonia

a) Incidence: less than 5% (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)

b) During the first few days after initiating treatment with an antipsychotic medication, symptoms of dyst susceptible individuals. Symptoms may include spasm of neck muscles, which may progress to tightenin swallowing difficulty, breathing difficulty, and/or protrusion of the tongue. These symptoms can occur at l often occur (and occur with a greater severity) with high potency and at higher doses of first generation a medications. Males and younger age groups appear to be at greater risk for developing acute dystonia (I (R) oral tablets, 2008a).

c) During clinical trials for the treatment of schizophrenia in adults, dystonia was reported in less than 5% quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release oral tablet

d) A 43-year-old Caucasian woman developed acute dystonia after receiving four weeks of quetiapine tl dose of 400 milligrams (mg) daily. The woman experienced slow movement of her head to the right side, increased incidence of involuntary movement when under stress. Dystonic movement of her head to the observed. The patient was cross-tapered to ziprasidone (80 mg/day) and symptoms of dystonia resolved dose was reduced to 100 mg/day (Kropp et al, 2004).

3.3.9.A.6 Extrapyramidal disease

a) Incidence: 4% to 12% (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR exte tablets, 2007)

b) In two placebo-controlled clinical trials of adult bipolar depression patients, extrapyramidal symptoms included akathisia, tremor, dyskinesia, dystonia, extrapyramidal disorder, involuntary muscle contraction muscle rigidity and psychomotor hyperactivity) were reported in 12% of patients receiving quetiapine fum or 600 mg) compared to 6% for placebo. Individual adverse events in these studies did not exceed 4% fo (Prod Info SEROQUEL(R) oral tablets, 2007).

c) There were no differences in the incidence of extrapyramidal symptoms between groups receiving qu tablets and placebo in three adult acute mania and three adult schizophrenia placebo-controlled clinical t SEROQUEL(R) oral tablets, 2007)

d) In a 6-week, fixed-dose clinical trial of adult schizophrenia patients, extrapyramidal symptoms (which akathisia, akinesia, extrapyramidal syndrome, hypertonia, neck rigidity, hypokinesia, tremor and cogwhe reported in 6%, 6%, 4%, 8% and 6% of patients receiving quetiapine fumarate tablets (75 milligrams (mg 300 mg/day, 600 mg/day, and 750 mg/day, respectively) compared to 16% for placebo (Prod Info SERO 2007).

e) In placebo-controlled clinical trials of adult schizophrenic patients, adverse reactions potentially relate symptoms (akathisia, extrapyramidal disorder, dyskinesia, restlessness, dystonia, muscle rigidity, and tre for 8% of patients receiving quetiapine fumarate extended-release tablets, 8% for patients receiving quet tablets, and 5% for placebo; quetiapine doses ranged from 300 to 800 milligrams. Individual adverse eve did not exceed 3% for any treatment group (Prod Info SEROQUEL(R)XR extended-release oral tablets,

f) The severity of extrapyramidal symptoms (EPS) with quetiapine therapy has not differed from that of p trials (Garver, 2000a; Green, 1999a; Borison et al, 1996a; Fulton & Goa, 1995b; Anon, 1995a; Fabre et a

3.3.9.A.7 Headache

a) Incidence: tablets, 17% to 21% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release table SEROQUEL(R)XR extended-release oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, headache was reported in 21% of patients receiving quetiapine fumarate tablets (14% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tal

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 17% of patients receiving quetiapine fumarate tablets (n=196) compared to 13% for placebo from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

d) Headache was reported 7.4% of adult schizophrenic patients taking quetiapine fumarate extended-re a randomized, placebo-controlled, long-term trial (up to 12 months). After completion of an initial open la with quetiapine fumarate extended-release tablets, stabilized patients were randomized to either continu or switch to placebo (n=103) to determine the possibility of relapse (Prod Info SEROQUEL(R)XR extend tablets, 2007).

3.3.9.A.8 Insomnia

a) Incidence: tablets, 12% (Masand, 2000a; Green, 1999a; Borison et al, 1996a; Anon, 1995a; Fulton & al, 1995a); extended-release tablets, 8.5% (Prod Info SEROQUEL(R)XR extended-release oral tablets,

b) Insomnia was reported 8.5% of adult schizophrenic patients taking quetiapine fumarate extended-rel a randomized, placebo-controlled, long-term trial (up to 12 months). At the completion of the initial open patients who were stabilized on quetiapine fumarate extended-release tablets were randomized to either therapy or switch to placebo (n=103) to determine the possibility of relapse (Prod Info SEROQUEL(R)XR oral tablets, 2007).

c) The adverse effect of insomnia has a 12% frequency with quetiapine use (Masand, 2000a; Green, 19 1996a; Anon, 1995a; Fulton & Goa, 1995b; Fabre et al, 1995a).

3.3.9.A.9 Lethargy

a) Incidence: 5% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, le 5% of patients receiving quetiapine fumarate tablets (n=698) compared to 2% for placebo (n=347); dose 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.9.A.10 Parkinsonism

a) The results of a cohort study indicate that high-dose atypical antipsychotic therapy carries a similar ris of parkinsonism as does typical antipsychotic therapy. In a population-based, retrospective cohort study, and older) with evidence of dementia were followed for up to 1 year for the development of parkinsonism with typical or atypical antipsychotic use. As compared with older adults receiving atypical antipsychotic olanzapine, risperidone, quetiapine), incident parkinsonism was 30% more likely to occur in those taking (i.e., chlorpromazine, haloperidol, perphenazine) (adjusted HR, 1.3; 95% CI, 1.04 to 1.58), and 60% less patient who did not receive either therapy (HR, 0.4; 95% CI, 0.29 to 0.43). Older adults using higher pote antipsychotics had almost a 50% greater risk of experiencing parkinsonism as compared with patients pr antipsychotics (all were considered lower potency) (HR, 1.44; 95% CI, 1.13 to 1.84); however, in patients potency typical antipsychotics, the risk of developing parkinsonism was no different from that in adults ta antipsychotics (HR, 0.75; 95% CI. 0.48 to 1.15). In addition, a positive dose-related relationship was obs

occurrence of incident parkinsonism and the use of atypical antipsychotics. The risk for developing parki
than twice as great in patients using a high-dose atypical antipsychotic agent as compared with those pr
atypical antipsychotic agent (HR, 2.07; 95% CI, 1.42 to 3.02). Furthermore, patients taking a typical antip
to have a similar risk for the development of parkinsonism as patients receiving high-dose atypical antips
(p=ns). The authors conclude that atypical antipsychotics may not be safer than typical antipsychotics wh
are considered (Rochon et al, 2005).

3.3.9.A.11 Restless legs syndrome

a) Restless legs, temporally related to quetiapine therapy, have been reported during post-marketing us
SEROQUEL(R) oral tablets, 2008a).

3.3.9.A.12 Sedated

a) Incidence: tablets, 30% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, 13%
SEROQUEL(R)XR extended-release oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, se
in 30% of patients receiving quetiapine fumarate tablets (n=698) compared to 8% for placebo (n=347); d
to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

c) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, sedati
13% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 7% for pla
ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.9.A.13 Seizure

a) Incidence: tablets, 0.5% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, 0.1%
SEROQUEL(R)XR extended-release oral tablets, 2007)

b) Seizures were reported in 0.5% of patients treated with quetiapine fumarate tablets (n=3490) compar
with active control drugs (n=527) and 0.2% for placebo (n=954) in clinical trials (Prod Info SEROQUEL(R

c) During clinical trials, seizures were reported in 0.1% of patients treated with quetiapine fumarate exte
(n=951) compared to 0.9% for placebo (n=319) (Prod Info SEROQUEL(R)XR extended-release oral tabl

d) Quetiapine fumarate should be used cautiously in patients with a history of seizures (Prod Info SERO
2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.9.A.14 Somnolence

a) Summary

1) Somnolence was commonly reported during quetiapine fumarate clinical trials, especially during
periods (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release

b) Incidence: tablets, 16% to 34% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release table
SEROQUEL(R)XR extended-release oral tablets, 2007)

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults,
reported in 34% of patients receiving quetiapine fumarate tablets (n=196) compared to 9% for placebo (r
from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

d) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, so
reported in 28% of patients receiving quetiapine fumarate tablets (n=698) compared to 7% for placebo (r
from 300 to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

e) Somnolence was reported in 18% of patients treated with quetiapine fumarate tablets compared to 11
schizophrenia trials (Prod Info SEROQUEL(R) oral tablets, 2007).

f) In clinical trials for the treatment of acute bipolar mania using quetiapine fumarate as monotherapy, so
reported in 16% of patients taking quetiapine fumarate tablets compared to 4% for placebo (Prod Info SE
tablets, 2007).

g) In placebo-controlled clinical trials for the treatment of schizophrenia (up to 6 weeks) in adults, somno
12% of patients receiving quetiapine fumarate extended-release tablets (n=951) compared to 4% for pla
ranged from 300 to 800 mg (Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.9.A.15 Tardive dyskinesia

a) Incidence: tablets, 0.1% to 1% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablet
Info SEROQUEL(R)XR extended-release oral tablets, 2007)

b) A potentially irreversible tardive dyskinesia may develop in patients receiving antipsychotic drugs; this
duration of treatment and the cumulative dose. Less commonly, the syndrome can develop after brief tre
doses. Antipsychotics may mask the underlying process by suppressing the signs and symptoms of the s
prevalence of the syndrome appears to be highest among the elderly, especially elderly women; howeve
rely upon prevalence to estimate which patients are likely to develop the syndrome. The syndrome may
completely upon discontinuation of the antipsychotic medication (Prod Info SEROQUEL(R) oral tablets, 2
SEROQUEL(R)XR extended-release oral tablets, 2007).

c) During clinical trials for the treatment of schizophrenia in adults, tardive dyskinesia was reported 0.1%
taking quetiapine fumarate tablets (Prod Info SEROQUEL(R) oral tablets, 2007).

d) During clinical trials for the treatment of schizophrenia in adults, tardive dyskinesia was reported in le
taking quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release ora

e) A 44-year-old woman with schizophrenia resistant to typical neuroleptic agents developed tardive dys
of quetiapine therapy. While receiving 150 milligrams of quetiapine daily she developed involuntary chor

the tongue and jaw. Later, she also developed finger involvement. Quetiapine was discontinued and she therapy which improved the tardive dyskinesia symptoms (Ghelber & Belmaker, 1999).

3.3.9.A.16 Tremor

a) Incidence: tablets, 8% (Prod Info SEROQUEL(R) oral tablets, 2007); extended-release tablets, less th SEROQUEL(R)XR extended-release oral tablets, 2007)

b) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, 8% of patients receiving quetiapine fumarate tablets (n=196) compared to 7% for placebo (n=203); dose 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

c) During clinical trials for the treatment of schizophrenia in adults, tremor was reported in less than 5% quetiapine fumarate extended-release tablets (Prod Info SEROQUEL(R)XR extended-release oral tablet

3.3.10 Ophthalmic Effects

3.3.10.A Quetiapine Fumarate

Amblyopia

Disorder of lens

3.3.10.A.1 Amblyopia

a) Incidence: 2% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, amblyopia was reported in 2% of patients receiving quetiapine fumarate tablets (r 1% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

3.3.10.A.2 Disorder of lens

a) Although a causal relationship has not been substantiated, lens changes in patients during long-term fumarate have been reported. Examination to detect cataract formation is recommended at initiation of tr after beginning treatment, and every 6 months during the course of treatment (Prod Info SEROQUEL(R) Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3.3.12 Psychiatric Effects

3.3.12.A Quetiapine Fumarate

Agitation

Anxiety

Suicidal thoughts

3.3.12.A.1 Agitation

a) Incidence: 6% to 20% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, agitation was reported in 20% of patients receiving quetiapine fumarate tablets (n 17% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tal

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, in 6% of patients receiving quetiapine fumarate tablets (n=196) compared to 4% for placebo (n=203); do to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.12.A.2 Anxiety

a) Incidence: 4% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, anxiety was reported in 4% of patients receiving quetiapine fumarate tablets (n=7 for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets,

3.3.12.A.3 Suicidal thoughts

a) In two clinical studies involving patients with bipolar depression, the incidence of treatment emergent attempt during eight weeks of treatment was 1.7% and 2.6% in patients treated with quetiapine fumarate (mg)/day (n=350) and 600 mg/day (n=348), respectively, and 2.0% in patients receiving placebo (Prod Ir oral tablets, 2007).

3.3.14 Reproductive Effects

3.3.14.A Quetiapine Fumarate

3.3.14.A.1 Priapism

a) Priapism was reported in one patient taking quetiapine fumarate tablets; a causal relationship has not (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.15 Respiratory Effects

3.3.15.A Quetiapine Fumarate

Cough

Hyperventilation

Nasal congestion

Pharyngitis

Rhinitis

3.3.15.A.1 Cough

a) Incidence: at least 1% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) During clinical trials for the treatment of schizophrenia in adults, increased cough was reported in at l taking quetiapine fumarate tablets (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.15.A.2 Hyperventilation

a) A 69-year-old African-American female, admitted for major depression with psychotic features, develo acute respiratory alkalosis 3 days after being discharged from the hospital. At the time of the occurrence dose of quetiapine was 50 milligrams twice daily with concurrent treatments with metronidazole and micc etiologies include a comorbid hypersensitivity to quetiapine or to the concomitant administration of metro inhibit metabolism of quetiapine. Symptoms improved after discontinuation of quetiapine (Shelton et al, 2

3.3.15.A.3 Nasal congestion

a) Incidence: 5% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, na reported in 5% of patients receiving quetiapine fumarate tablets (n=698) compared to 3% for placebo (n= from 300 to 600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.15.A.4 Pharyngitis

a) Incidence: 4% to 6% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, pharyngitis was reported in 4% of patients receiving quetiapine fumarate tablets (3% for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tabl

c) In placebo-controlled clinical trials for the adjunct treatment of acute mania (up to 3 weeks) in adults, reported in 6% of patients receiving quetiapine fumarate tablets (n=196) compared to 3% for placebo (n= from 100 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.15.A.5 Rhinitis

a) Incidence: 3% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a to 12 weeks) in adults, rhinitis was reported in 3% of patients receiving quetiapine fumarate tablets (n=71 for placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets,

Death

Fatigue

Fever

Neuroleptic malignant syndrome

Pain

3.3.16.B.1 Death

a) Results of a population-based, retrospective cohort study demonstrated that the use of conventional a
associated with an even greater risk for death than atypical antipsychotics when administered to elderly p
years and older) with dementia. Atypical versus no antipsychotic use and conventional versus atypical ar
wise comparisons were made. A total of 27,259 matched pairs were identified and the dementia cohort w
place of residence (community versus long-term care facilities). In order to adjust for difference in baselir
propensity score matching was used. The primary outcome of the study was all-cause mortality. The risk
evaluated at 30, 60, 120, and 180 days after the antipsychotic medications were initially dispensed. Ther
significant increase in the risk for death at 30 days associated with new use of atypical antipsychotic med
with nonuse in both the community-dwelling cohort (adjusted hazard ratio (HR), 1.31 (95% confidence in
1.70); absolute risk difference, 0.2 percentage point) and long-term care cohort (adjusted HR, 1.55 (95%
absolute risk difference, 1.2 percentage points). For both cohorts, the risk associated with atypical antips
persist to 180 days. The risk for death associated with conventional antipsychotics was even greater thar
with atypical antipsychotics. At 30 days, the adjusted HR for the community-dwelling cohort was 1.55 (95
and 1.26 (95% CI, 1.04 to 1.53) for the long-term care cohort (adjusted risk difference for both was 1.1 p
risk appeared to persist to 180 days for both groups. Some important limitations to the study include unk
confounders may influence the results and cause of death could not be examined (Gill et al, 2007).

b) Results of a population-based, retrospective cohort study demonstrated comparable to possibly great
associated with the use of conventional antipsychotic medications in the elderly (aged 65 years and olde
atypical antipsychotic medications. The analysis excluded patients with cancer and included only new us
medications. The primary study outcome was 180-day all-cause mortality. A set of potential confounders
on healthcare utilization data within 6 months before the initiation of antipsychotic medications. Of the 37
identified, 12,882 and 24,359 received conventional and atypical antipsychotic medications, respectively
the conventional drug group within the first 180 days was 14.1% compared with 9.6% in the atypical drug
mortality ratio, 1.47; 95% confidence interval (CI), 1.39 to 1.56). In the multi-variable analysis which cont
confounders, the adjusted mortality ratio for the risk of death within 180 days for conventional versus aty
1.32 (95% CI, 1.23 to 1.42). When the most frequently prescribed conventional antipsychotic drugs were
risperidone, the mortality ratio associated with haloperidol was 2.14 (95% CI, 1.86 to 2.45) and loxapine
1.19 to 1.40), while there was no difference associated with olanzapine. The increased mortality risk for c
atypical drug therapy was greatest when doses higher (above median) doses were used (mortality ratio 1
1.86) and also during the first 40 days of therapy (mortality ratio 1.6; 95% CI, 1.42 to 1.8). Confirmatory a
multi-variable Cox regression, propensity score, and instrumental variable estimation confirmed the resu
(Schneeweiss et al, 2007).

c) The findings of one meta-analysis suggest that there may be a small increased risk of death associat
atypical antipsychotic agents for the treatment of dementia in elderly patients. The study analysis (n=511
randomized, double-blind, placebo-controlled, parallel group trials of antipsychotic use (i.e., aripiprazole
(n=5), quetiapine (n=3), risperidone (n=5)) in elderly patients (weighted mean age, 81.2 years) with dem
occurred more often in patients receiving atypical antipsychotic therapy as compared with placebo (118 (
respectively). The overall odds ratio, as assessed by meta-analysis, for death in elderly patients receivin
antipsychotics as compared with placebo was 1.54 (95% CI, 1.06 to 2.23; p=0.02), and the risk differenc
0.004 to 0.02; p=0.01). Overall, the relative risk associated with atypical antipsychotic use was 1.65 (95%
p=0.003); however this increased risk was only identified when all drugs were pooled for analysis; meta-
drugs did not show a statistically significant increased risk. A similar dropout rate was observed between
placebo-treated patients (32.2% vs 31.4%, respectively), with no significant difference in dropouts found
(Schneider et al, 2005).

d) The results of a retrospective cohort study indicate that conventional antipsychotic agents are at leas
antipsychotic agents to increase the risk of death among elderly patients 65 years of age or older. The st
new users of conventional agents (mean age, 83.2 years) and 13,748 new users of atypical agents (mea

higher adjusted relative risk of death was associated with the use of conventional antipsychotics as comp
antipsychotics at all time points studied after beginning therapy (within 180 days: RR, 1.37; 95% CI, 1.27
days: RR, 1.56; 95% CI, 1.37 to 1.78; 40 to 79 days: RR, 1.37; 95% CI, 1.19 to 1.59; 80 to 180 days: RR
1.41). In addition, the adjusted risks of death observed in patients with dementia (RR, 1.29; 95% CI, 1.15
dementia (RR, 1.45; 95% CI, 1.30 to 1.63), in a nursing home (RR, 1.26; 95% CI, 1.08 to 1.47), or not in
1.42; 95% CI, 1.29 to 1.56) were also higher with the use of conventional antipsychotic therapy as comp
antipsychotic use. This risk appeared to be dose-related and was greater with the use of higher dose (i.e
median) conventional antipsychotics (RR, 1.73; 95% CI, 1.57 to 1.90). Additional studies which specifica
optimum care of elderly patients requiring antipsychotic therapy are needed so that appropriate guidance
intervention can be provided (Wang et al, 2005).

3.3.16.B.2 Fatigue

a) Incidence: 10% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment of bipolar depression (up to 8 weeks) in adults, fa
10% of patients receiving quetiapine fumarate tablets (n=698) compared to 8% for placebo (n=347); dos
600 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 2007).

3.3.16.B.3 Fever

a) Incidence: 2% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a
to 12 weeks) in adults, fever was reported in 2% of patients receiving quetiapine fumarate tablets (n=719
placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 20

3.3.16.B.4 Neuroleptic malignant syndrome

a) Incidence: rare (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-r
2007)

b) A 20-year-old man developed neuroleptic malignant syndrome (NMS) within 8 to 9 weeks of starting
treatment of unprovoked aggression. The patient's medical history included severe mental retardation (IQ
of frequent unprovoked episodes of aggression, and treatment with haloperidol 5 mg/day for 14 months
symptoms. Quetiapine (100 mg/day) was added to the haloperidol therapy to help control the aggression
developed increased salivation, profuse perspiration, daytime drowsiness, decreased psychomotor activ
emotional reactivity within 4 to 5 days of starting the quetiapine. The symptoms persisted for 5 weeks an
haloperidol was decreased to 2.5 mg/day and the quetiapine was increased to 200 mg/day. Additionally,
started on lorazepam up to 5 mg/day. Within 3 weeks, the symptoms worsened and the patient develope
grade fever and later developed difficulty in walking with stiffness of the entire body, coarse tremors, high
sensorium, and difficulty in swallowing with regurgitation of both liquids and solids. Upon physical examir
muscular rigidity, profuse perspiration and elevated blood pressure. Laboratory analyses revealed leuko
creatinine phosphokinase (greater than ten fold increase), myoglobinuria, and mild renal impairment. The
a recent history of strenuous physical exercise, exposure to high ambient temperatures or any concomita
counter medications. Computed tomography of the brain and cerebrospinal fluid analysis did not reveal a
patient was diagnosed with NMS and all psychotropic medications were discontinued. Bromocriptine 7.5
consequently started along with supportive management. Within 48 hours the patient experienced a dec
perspiration, and his blood pressure stabilized. By the 4th day of treatment with bromocriptine his muscu
however, he developed patchy pneumonitis and was treated with antibiotics. Despite the treatment with a
respiratory status continued to decline and he died on the 10th day. Authors concluded a temporal relatio
initiation of quetiapine and the onset of NMS symptoms (Dan et al, 2009).

c) Based on a retrospective medication review, quetiapine was a probable cause of neuroleptic maligna
a 34-year-old male. His past medical history included a childhood accident resulting in severe brain dam
mental retardation, and seizures was hospitalized for mental status changes, tremors, temperature of 39
(C), and was subsequently diagnosed with (NMS) accompanied by extrapyramidal effects (EPS). During
patient experienced lead pipe rigidity, tachycardia, and high creatine kinase (CK) level. His medications i
200 mg three times per day, guanfacine 2 mg/day, carbamazepine 400 mg every 12 hours, valproic acid
and lorazepam 2 mg (frequency unknown). Quetiapine was discontinued on hospital day 2, and the patie
traditional treatment for NMS, which included bromocriptine 2.5 mg via a gastric feeding tube every 8 ho
dantrolene 1 mg/kg. On day 3, the patient continues to have high fever (41 degrees C), became hypoxic
intubated. Midazolam drip was started and titrated per hospital protocol to sedate the patient, bromocript
mg every 8 hours, and an infusion of 0.45% NaCl with sodium bicarbonate was started due to a high CK
international units per liter (L) and serum creatine levels up to 1.4 mcg/mL. Further, IV norepinephrine dr
because the patient was not hemodynamically stable. On day 6, his blood cell counts remained stable, t
NaCl with sodium bicarbonate was discontinued and bromocriptine was decreased to 2.5 mg every 6 ho
level and temperature have decreased (4450 international units/L and 39.3 degrees C, respectively). On
of NMS had resolved. The Naranjo probability scale suggested that quetiapine was the probable cause o
is not common for atypical antipsychotic drugs to cause NMS with associated EPS as reported in this ca
cases of NMS due to quetiapine identified in the literature and 75% of these cases had reactions that inc
et al, 2009).

d) Neuroleptic malignant syndrome (NMS), which can manifest clinically with hyperpyrexia, muscle rigid
instability, altered mental status, elevated CPK levels, myoglobinuria, and acute renal failure has been re
antipsychotic substances, including quetiapine fumarate. If neuroleptic malignant syndrome does occur,

medications and other drugs not essential to concurrent therapy should be discontinued, intensive sympt
monitoring should be initiated, and treatment of any concomitant serious medical problems should occur
of reintroduction of antipsychotics after a patient has experienced NMS should be taken; recurrences ha

e) A 44-year-old woman with a history of schizoaffective disorder and 3 earlier episodes of neuroleptic n
(NMS) presented with fever, decreased level of consciousness, rigidity, and urinary incontinence. Her me
quetiapine 200 milligrams/day (mg/day), clozapine 400 mg/day, divalproex sodium 750 mg/day, lamotrig
clonazepam 4 mg/day. She was found to have bilateral pneumonia and highly elevated creatine phospho
Antibiotics and oral bromocriptine 1.25 mg twice daily were started; antipsychotics were withheld. When
day 3, she showed paranoid delusions. Clozapine, divalproex sodium, lamotrigine, and clonazepam were
hospital day 4, her temperature was normal and her CPK level reduced. Ten days later her CPK level wa
returned to her baseline mental status. Although some of the findings could be attributable to pneumonia
symptoms and the previous history of NMS supported the diagnosis of NMS in this instance (Bourgeois e

3.3.16.B.5 Pain

a) Incidence: 7% (Prod Info SEROQUEL(R) oral tablets, 2007)

b) In placebo-controlled clinical trials for the treatment (monotherapy) of schizophrenia (up to 6 weeks) a
to 12 weeks) in adults, pain was reported in 7% of patients receiving quetiapine fumarate tablets (n=719)
placebo (n=404); doses ranged from 75 to 800 milligrams/day (Prod Info SEROQUEL(R) oral tablets, 20

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info SEROQUEL(R) oral tablets,

a) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other)
controlled studies in women or studies in women and animals are not available. Drugs should be given only if
justifies the potential risk to the fetus.

2) Australian Drug Evaluation Committee's (ADEC) Category: B3(Australian Government Department of Health a
Therapeutic Goods Administration, 2006)

a) Drugs which have been taken by only a limited number of pregnant women and women of childbearing ag
in the frequency of malformation or other direct or indirect harmful effects on the human fetus having been ob
animals have shown evidence of an increased occurrence of fetal damage, the significance of which is consi
humans.

See Drug Consult reference: PREGNANCY RISK CATEGORIES

3) Crosses Placenta: Unknown

4) Clinical Management

a) There are no adequate and well-controlled studies in pregnant women. Two cases of quetiapine use durin
produced no abnormalities in the infants (Gentile, 2006; Tenyi et al, 2003). Until more information is available
quetiapine during pregnancy only if the potential benefit to the mother justifies the potential risk to the fetus (P
(R) oral tablets, 2007).

5) Literature Reports

a) A prospective, observational study of 54 women (mean age, 30.7 years) recruited from the Emory Women
program exposed to antipsychotic medication during pregnant showed permeability of the placental barrier. C
determined by maternal and umbilical cord blood samples taken at delivery and though data collected from m
medical records. Placental passage showed a significant difference between antipsychotic medications, olan
CI, 46.8%-97.5%) being the highest, followed by haloperidol 65.5% (95% CI, 40.3%-90.7%), risperidone 49.2
84.8%), and quetiapine 24.1% (95% CI, 18.7%-29.5%), showing the lowest placental passage. In the quetiap
there was one case of preterm labor (< less than 37 weeks gestation) and 2 infants that required neonatal int
admission. Seven neonates developed respiratory complications and 2 developed cardiovascular events. Lo
2500 g) occurred in one infant (Newport et al, 2007).

b) Treatment of a 33-year-old woman with fluvoxamine 200 mg/day and quetiapine 400 mg/day during her s
resulted in an uneventful pregnancy and the birth of a healthy female infant. The patient was being treated wi
quetiapine when she was diagnosed with a severe postpartum psychotic depression after the birth of her first
attempts at reducing her medication led to relapse. After being informed of the risk-benefit of fluvoxamine/que
during pregnancy, the patient decided to go forward with a second pregnancy while maintaining her drug regi
and quetiapine with the addition of folate 5 mg/day throughout the pregnancy. The patient gained 9 kg with no
psychiatric instability. Routine biochemical tests were within the normal range and 5 echographic reports four
abnormalities. The presence of an intrauterine myoma led to an elective caesarean-section. A healthy female
g and measuring 49 cm in length was delivered, with Apgar scores of 9 and 10 at 1 minute and 5 minutes, re
2006).

c) One case report describes the maternal use of quetiapine 300 to 400 mg throughout gestation, and the su
healthy male infant without abnormality. At 6 months of age, the infant was developing normally (Tenyi et al,

d) In pregnant rats and rabbits treated with quetiapine 0.3 to 2.4 times the maximum recommended human d
to 2.4 times the MRHD, no teratogenicity was observed. However, embryo/fetal toxicity was observed in rats
0.6 to 2.4 times the MRHD and 1.2 to 2.4 times the MRHD, respectively. The high quetiapine dose in rats and
produced maternal toxicity. In a perio/postnatal reproductive study in rats, no quetiapine-related effects were
0.12, and 0.24 the MRHD. There were, however, increased fetal and pup death and decreased mean litter we
MRHD (Prod Info SEROQUEL(R) oral tablets, 2007).

B) Breastfeeding

1) Thomson Lactation Rating: Infant risk cannot be ruled out.
a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk wh breastfeeding. Weigh the potential benefits of drug treatment against potential risks before prescribing this dr breastfeeding.
2) Clinical Management
a) Limited data on the safety of quetiapine in nursing infants demonstrates no evidence of toxicity (Rampono 2006). It is recommended that nursing woman who are receiving quetiapine should not breast-feed (Prod Info tablets, 2007). If quetiapine treatment is required in a nursing mother, monitor infant progress and periodically in the infant's plasma (Rampono et al, 2007).
3) Literature Reports
a) A case report of a 26-year-old woman prescribed quetiapine while breast-feeding her 3-month-old infant d plasma (M:P) ratio of 0.29 (an estimated relative infant dose of 0.09% of the maternal weight-adjusted dose) of exposure generally acceptable for breast-feeding. The woman was prescribed quetiapine 400 mg at night f treatment of nonresponsive depression with concomitant chronic pain. At 16 months prior to the study, she w quetiapine 300 mg with an increase to 400 mg during month 4 of her pregnancy and continuing to the study d treated with oxycodone 20 mg 3 times daily and fluoxetine 40 mg daily during gestation and up to the study d weighing 3.4 kg (50th percentile) was delivered at week 37. On the study day, the 3-month-old infant weighed percentile). During the study, the infant was receiving oral morphine 120 mcg 3 times daily for opioid depende fed 6 to 7 times daily. Blood samples were collected immediately prior to the mother's quetiapine dose and 5 elimination phase (between 12.8 and 23.1 hours after the dose). Due to limited plasma concentration measur quetiapine dosing, the M:P ratio, calculated using the milk and average plasma concentration during the elim 0.29 (0.09% of the maternal weight-adjusted dose). The infant's plasma contained quetiapine 1.4 mcg/L equi maternal plasma concentration. Upon clinical examination, the infant was healthy and his Denver age was th chronological age (Rampono et al, 2007).
b) Treatment with fluvoxamine 200 mg/day and quetiapine 400 mg/day in a 33-year-old woman during her se resulted in an uneventful pregnancy and the birth of a healthy female infant weighing 2600 g and measuring 4 Apgar scores of 9 and 10 at 1 minute and 5 minutes, respectively. The patient chose to breast-feed; however to supplement her breast milk due to insufficient milk production. In the 3 months that the infant received brea with formula, no adverse effects were detected and the infant continues to develop normally (Gentile, 2006).

3.5.1.A Acecainide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of acecainide and quetiapine is not recommended due to the risk of additive ef interval. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreud
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of acecainide and quetiapine is not recommended du inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as acecainide and additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.B Ajmaline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006; Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj 2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended ((TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).

b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther
Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip
studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th
significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine
treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL
to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1
haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we
changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo
changes than an elimination alteration (Young et al, 1993).

3.5.1.C Amiodarone

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of amiodarone and quetiapine is not recommended due to the risk of additive e
interval. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreud
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of amiodarone and quetiapine is not recommended c
inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular
ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol
quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as amiodarone and
additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.D Amitriptyline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod
haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c
2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac
been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod
2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr
corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves.
studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m
mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl
(R), 1999b).

3.5.1.E Amobarbital

1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu
P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien
and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.F Amoxapine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod
haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c
2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac
been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod
2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl (R), 1999b).

3.5.1.G Amprenavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.H Aprindine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of quetiapine with other drugs that potentially prolong the QTc interval, such a be approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring 2001o; Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of aprindine and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.I Aprobarbital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.J Arsenic Trioxide
1) Interaction Effect: prolongation of the QTc interval and/or torsades de pointes
2) Summary: Arsenic trioxide can prolong the QT interval in some patients, which may result in ventricular ta fibrillation, and torsades de pointes and should not be administered with other drugs that may prolong the QT Trisenox(R), 2001a). Several antipsychotic agents have demonstrated QT prolongation including amisulpride 1999m), haloperidol (O'Brien et al, 1999i), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets (Duenas-Laita et al, 1999p), sertindole (Agelink et al, 2001m), quetiapine (Owens, 2001s), sultopride (Lande ziprasidone (Prod Info GEODON(R) intramuscular injection, oral capsule, 2005), and zotepine (Sweetman, 2
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of arsenic trioxide and antipsychotics is not recomme
7) Probable Mechanism: additive effects on QTc prolongation
8) Literature Reports
a) QT/QTc prolongation should be expected during treatment with arsenic trioxide and torsade de pointe heart block has been reported. Over 460 ECG tracings from 40 patients with refractory or relapsed APL t trioxide were evaluated for QTc prolongation. Sixteen of 40 patients (40%) had at least one ECG tracing greater than 500 msec. Prolongation of the QTc was observed between 1 and 5 weeks after arsenic triox returned towards baseline by the end of 8 weeks after arsenic trioxide infusion. In these ECG evaluations experience more pronounced QT prolongation than men, and there was no correlation with age (Prod Int

3.5.1.K Astemizole

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod I haloperidol (O'Brien et al, 1999h), quetiapine (Owens, 2001q), risperidone (Duenas-Laita et al, 1999n; Prod I risperidone, 2002a), sertindole (Agelink et al, 2001l), sultopride (Lande et al, 1992k), and zotepine (Sweetma no formal drug interaction studies have been done, the coadministration of astemizole and other drugs known interval, including antipsychotics, is not recommended (Prod Info Hismanal(R), 1996).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of astemizole and agents that prolong the QT interva antipsychotics, is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) A total of 7 patients developed torsade de pointes after therapeutic use of haloperidol in high doses (I 1993e; Wilt et al, 1993c). Three patients developed the dysrhythmia after administration of 211 to 825 m 2 days for agitated delirium. These 3 patients recovered from the initial episodes, but 1 patient subseque arrest upon readministration of haloperidol. Four patients developed the dysrhythmia after administration over 1 to 4 days for delirium associated with bacterial meningitis (1), status asthmaticus (2) or respirator patients recovered with no adverse sequelae.

3.5.1.L Atazanavir

1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.M Azimilide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of azimilide and quetiapine is not recommended due to the risk of additive effe If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of azimilide and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as azimilide and qu additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.N Bepridil

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated other agents which lengthen the QT interval (Prod Info Geodon(TM), 2002a; Agelink et al, 2001c; Owens, 20 1999d; Prod Info Haldol(R), 1998a). In U.S. clinical trials, bepridil increased QT and QTc intervals which was torsades de pointes in approximately 1% of patients. Other drugs that increase the QT interval may exaggera the QT interval observed with bepridil (Prod Info Vascor(R), 1997). Pimozide is contraindicated in patients tak may prolong the QT interval (Prod Info Orap(R), 1999d).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of antipsychotics and agents that prolong the QT inte is contraindicated. In particular, pimozide is contraindicated in individuals with congenital QT syndrome, patie cardiac arrhythmias, or patients taking other drugs which may prolong the QT interval.
7) Probable Mechanism: additive effects on QT prolongation

8) Literature Reports

a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl (R), 1999c).

b) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe (Duenas-Laita et al, 1999d; Ravin & Levenson, 1997a).

3.5.1.O Betamethasone

1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir P450 3A.

7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.P Bretylium

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Concurrent use of bretylium and quetiapine is not recommended due to the risk of additive effe If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong

3) Severity: major

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of bretylium and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo

7) Probable Mechanism: additive QT prolongation

8) Literature Reports

a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as bretylium and qu additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.Q Butabarbital

1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.

7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.R Butalbital

1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.

7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.S Carbamazepine

1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving carbamazepine, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001a).

3) Severity: moderate

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Caution is indicated when quetiapine is administered with carbamazepine or other i

cytochrome P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic sympto
receiving quetiapine and carbamazepine.
7) Probable Mechanism: unknown

3.5.1.T Chloral Hydrate
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Chloral hydrate has been shown to prolong the QTc interval at the recommended therapeutic d
1986). Even though no formal drug interaction studies have been done, the administration of drugs known to
interval, such as antipsychotics and chloral hydrate is not recommended. Several antipsychotic agents have
prolongation including amisulpride (Prod Info Solian(R), 1999k), haloperidol (O'Brien et al, 1999g), quetiapine
risperidone (Duenas-Laita et al, 1999m), sertindole (Agelink et al, 2001k), sultopride (Lande et al, 1992j), and
2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of chloral hydrate and antipsychotics is not recomme
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) The overall incidence of QT interval prolongation with sertindole is estimated at 1.9% to 4%, and the
developing torsades de pointes has been estimated at 0.13% to 0.21% (Brown & Levin, 1998a). Periodic
monitoring is required in the United Kingdom per sertindole's official labeling (Cardoni & Myer, 1997).
b) A total of 7 patients developed torsade de pointes after therapeutic use of haloperidol in high doses (
1993d; Wilt et al, 1993b). Three patients developed the dysrhythmia after administration of 211 to 825 m
2 days for agitated delirium. These 3 patients recovered from the initial episodes, but 1 patient subseque
arrest upon readministration of haloperidol.

3.5.1.U Chloroquine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Chloroquine has been shown to prolong the QTc interval at the recommended therapeutic dos
effect would be anticipated if administered with other agents which lengthen the QT interval (Prod Info Aralen
antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999v),
et al, 1999o), quetiapine (Owens, 2001ab), risperidone (Duenas-Laita et al, 1999w), sertindole (Agelink et al,
(Lande et al, 1992u), and zotepine (Sweetman, 2004).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of antipsychotics and agents that prolong the QT inte
chloroquine is not recommended.
7) Probable Mechanism: additive effect on QT prolongation
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe
(Duenas-Laita et al, 1999v; Ravin & Levenson, 1997e).

3.5.1.V Chlorpromazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concomitant use of phenothiazines and antipsychotic agents may cause additive effects on the
recommended. Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Co
Prod Info Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects,
available. Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info
haloperidol (O'Brien et al, 1999f), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006),
2001n), risperidone (Duenas-Laita et al, 1999l), sertindole (Agelink et al, 2001j), sultopride (Lande et al, 1992
Info GEODON(R) intramuscular injection, oral capsule, 2005), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as phen
antipsychotics, is not recommended.
7) Probable Mechanism: additive QT prolongation

3.5.1.W Cisapride
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated
other agents which lengthen the QT interval (Prod Info Geodon(TM), 2002; Owens, 2001a; Prod Info Orap(R)
pointes and QT prolongation have been reported with cisapride (Prod Info Propulsid(R), 2000).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of antipsychotics and agents that prolong the QT inte

cisapride, is contraindicated. In particular, pimozide is contraindicated in individuals with congenital QT syndr history of cardiac arrhythmias, or patients taking other drugs which may prolong the QT interval.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl (R), 1999).
b) Fatal QRS prolongation and QTc prolongation have been reported in patients taking risperidone (Due 1999a; Ravin & Levenson, 1997).

3.5.1.X Clarithromycin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999b), quetiapine (Owens, 2001g), risperidone (Duenas-Laita et al, 1999e), sertin 2001d), sultopride (Lande et al, 1992c), and zotepine (Sweetman, 2004). Even though no formal drug interac been done, concomitant use of clarithromycin and antipsychotic agents may cause additive effects on the QT recommended (Prod Info Biaxin(R), 2002).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of clarithromycin and agents that prolong the QT inte antipsychotics, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) A 32-year-old male with schizoaffective disorder and metabolic syndrome experienced a significant in concentration following administration of quetiapine. The patient, hospitalized for acute psychotic sympto 50 mg quetiapine daily, with a gradual increase in dosage to 700 mg over 10 days. Psychotic symptoms weeks. On day 28, the patient developed a lower airway infection, and was orally treated with 750 mg su clarithromycin along with his evening dose of quetiapine 400 mg. The following morning, 750 mg sultami clarithromycin, and the morning 300-mg quetiapine dose were given. Within hours the patient became so sample testing resulted in 826.8 microgram/L (normal range, 70 to 170 microgram/L). The patient develo consciousness and respiratory depression. Quetiapine overdose was suspected and treatment was disc levels were continually measured over the course of a week until complete recovery was achieved (Schu 2008).
b) A total of 7 patients developed torsade de pointes after therapeutic use of haloperidol in high doses (1993a; Wilt et al, 1993). Three patients developed the dysrhythmia after administration of 211 to 825 mg 2 days for agitated delirium. These 3 patients recovered from the initial episodes, but 1 patient subseque arrest upon readministration of haloperidol. Four patients developed the dysrhythmia after administration over 1 to 4 days for delirium associated with bacterial meningitis (1), status asthmaticus (2) or respirator patients recovered with no adverse sequelae.
c) Prolongation of the QTc interval was reported in 8 patients receiving risperidone (Prod Info Risperdal

3.5.1.Y Cortisone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other i P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.Z Darunavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri

protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.AA Deflazacort
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.AB Dehydroepiandrosterone
1) Interaction Effect: reduced effectiveness of quetiapine
2) Summary: Dehydroepiandrosterone (DHEA) levels within the normal range of 100 to 400 microgram/decil conducive for optimal treatment of patients with psychosis (Howard, 1992a). In case reports, patients have be antipsychotics when DHEA levels were elevated (Howard, 1992a). Patients being treated with quetiapine sho supplementation.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of dehydroepiandrosterone (DHEA) and quetiapine. If DHEA treatment with dexamethasone 1 mg orally per day may be used to normalize DHEA levels.
7) Probable Mechanism: elevated dehydroepiandrosterone (DHEA) blood levels may reduce responsiveness
8) Literature Reports
a) A 24-year-old female diagnosed with schizophrenia was resistant to daily doses of haloperidol 20 mill fluphenazine 40 mg, lithium carbonate 1200 mg, and lithium carbonate 900 mg plus thioridazine 300 mg Cushinoid with moon face, acne, facial hair, abdominal hair, and a 40 pound weight gain in the previous Dehydroepiandrosterone (DHEA) measured as part of an endocrine panel was 725 micrograms/deciliter to 400 mcg/dL). Dexamethasone 1 mg orally at bedtime resulted in substantial improvement within one w appeared calmer, more alert with improved psychotic symptoms and ability to concentrate. At two weeks level was within normal range (328 mcg/dL). The author concluded that elevated DHEA levels were assc psychosis resistant to conventional antipsychotic therapy (Howard, 1992).
b) A 13-year-old male decompensated with a subsequent two-year period of emotional problems accom of LSD, hashish, barbiturates, and alcohol. His mental status included bizarre, disorganized, delusional t visual hallucinations, paranoia, lack of attention to personal hygiene, agitation, and combativeness. He w chronic paranoid schizophrenia; schizophrenia, chronic undifferentiated type, and schizoaffective disorde was resistant to daily doses of trifluoperazine 40 mg, chlorpromazine 400 mg, and imipramine 100 mg. H to combination therapy with chlorpromazine 400 mg with thiothixene 80 mg, thioridazine 1000 mg, perph lithium carbonate 1200 mg, clonazepam 4 mg, and carbamazepine 1200 mg daily. Baseline DHEA level mcg/dL. A seven-day suppression test with dexamethasone 1 mg orally at bedtime resulted in a normal l mcg/dL. By day 5, psychosis improved and the patient was well-oriented, conversational, and was makir Once dexamethasone was discontinued, rapid decompensation and florid psychosis ensued despite "sul psychotropic medications". DHEA increased to 536 mcg/dL. The author concluded that elevated DHEA l with florid psychosis resistant to conventional antipsychotic therapy (Howard, 1992).

3.5.1.AC Desipramine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c 2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod 2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhyt (R), 1999b).

3.5.1.AD Dexamethasone

1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.AE Dibenzepin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c 2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod 2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhyt (R), 1999b).

3.5.1.AF Disopyramide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006; Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj 2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended ((TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1 haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo changes than an elimination alteration (Young et al, 1993).

3.5.1.AG Dofetilide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of dofetilide and quetiapine is not recommended due to the risk of additive effe If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised. Dofetilide should l 2 days before any interacting drug is initiated (Yamreudeewong et al, 2003a).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of dofetilide and quetiapine is not recommended due inducing life-threatening arrhythmias. Dofetilide should be stopped for at least 2 days before any interacting d concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised.

7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have also demonstrated QT including quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as dofetili have additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.AH Dolasetron
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999e), quetiapine (Owens, 2001l), risperidone (Duenas-Laita et al, 1999j), sertind 2001h), sultopride (Lande et al, 1992g), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of dolasetron and other drugs known to prolong the QTc interval, including a recommended (Prod Info Anzemet(R), 1997a).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of dolasetron and agents that prolong the QT interva antipsychotics, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) In several studies, dolasetron resulted in significant, dose-related increases in mean PR, QRS, and Q to baseline values. Measured changes in ECG parameters were transient, reversible, and asymptomatic QRS intervals may be due to prolongation of maximum upstroke velocity (Vmax) due to binding of dolase channels. The cause of QTc interval prolongation appears to be due to prolongation of the QRS interval, rate, or both (Prod Info Anzemet(R), 1997; Hunt et al, 1995; Kris et al, 1994).
b) A total of 7 patients developed torsade de pointes after therapeutic use of haloperidol in high doses (1993c; Wilt et al, 1993a). Three patients developed the dysrhythmia after administration of 211 to 825 m 2 days for agitated delirium. These 3 patients recovered from the initial episodes, but 1 patient subseque arrest upon readministration of haloperidol. Four patients developed the dysrhythmia after administration over 1 to 4 days for delirium associated with bacterial meningitis (1), status asthmaticus (2) or respirator patients recovered with no adverse sequelae.
c) Prolongation of the QTc interval was reported in 8 patients receiving risperidone (Prod Info Risperdal

3.5.1.AI Doxepin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c 2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod 2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl (R), 1999b).

3.5.1.AJ Droperidol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999l), quetiapine (Owens, 2001y), risperidone (Duenas-Laita et al, 1999s), sertinc 2001q), sultopride (Lande et al, 1992r), and zotepine (Sweetman, 2003). Droperidol has been shown to prolo the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coa droperidol and other drugs known to prolong the QTc interval, including antipsychotics is not recommended (2002).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of droperidol and antipsychotics is not recommendec
7) Probable Mechanism: additive cardiac effects

3.5.1.AK Encainide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of quetiapine with other drugs that potentially prolong the QTc interval, such a be approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring 2001o; Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of encainide and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AL Enflurane

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated other agents which lengthen the QT interval (Agelink et al, 2001y; Owens, 2001ah; Prod Info Haldol(R), 1998 1992z). Even though no formal drug interaction studies have been done, antipsychotic agents should not be other drugs which are also known to prolong the QTc interval, including enflurane (Owens, 2001ah).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of enflurane and agents that prolong the QT interval, antispychotics, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe (Duenas-Laita et al, 1999aa; Ravin & Levenson, 1997h).

3.5.1.AM Erythromycin

1) Interaction Effect: increased quetiapine serum concentrations
2) Summary: Coadministration of ketoconazole (200 mg once daily for 4 days), a potent inhibitor of CYP3A, clearance of quetiapine by 84%, resulting in a 335% increase in maximum plasma concentration of quetiapin studied, a similar interaction could be expected with other inhibitors of CYP3A (e.g., itraconazole, fluconazole Therefore, use caution and a reduced quetiapine dosage when it is administered concomitantly with a potent including erythromycin (Prod Info SEROQUEL(R) oral tablets, 2008a). There may also be some potential for prolongation with the concomitant administration of erythromycin and quetiapine. Erythromycin significantly ir QTc interval versus baseline in a retrospective study of 49 patients (Oberg & Bauman, 1995). Erythromycin h prolongation in combination with other drugs that prolong the QT interval (Prod Info PCE(R), 2000). Although QT interval prolongation has been reported with quetiapine during postmarketing use (Prod Info SEROQUEL 2008a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Use caution and a reduced quetiapine dose if it is administered concomitantly with Info SEROQUEL(R) oral tablets, 2008a). Monitor the patient for quetiapine adverse events (tardive dyskinesi hypotension) as well as for QTc interval prolongation.
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism by erythromycin

3.5.1.AN Eterobarb

1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.AO Flecainide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of quetiapine with other drugs that potentially prolong the QTc interval, such a be approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring 2001o; Prod Info Tambocor(R), 1998; Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of flecainide and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AP Fluconazole
1) Interaction Effect: increased quetiapine serum concentrations
2) Summary: Coadministration of ketoconazole (200 mg once daily for 4 days), a potent inhibitor of CYP3A, clearance of quetiapine by 84%, resulting in a 335% increase in maximum plasma concentration of quetiapin studied, a similar interaction could be expected with other inhibitors of CYP3A (e.g., itraconazole, fluconazole Therefore, use caution and a reduced quetiapine dosage when it is administered concomitantly with a potent including fluconazole (Prod Info SEROQUEL(R) oral tablets, 2008a). There may also be some potential for a prolongation with the concomitant administration of fluconazole and quetiapine. Case reports have described prolongation and torsades de points associated with fluconazole (Khazan & Mathis, 2002; Wassmann et al, 1 result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Although data are conflicting, prolongation has been reported with quetiapine during postmarketing use (Prod Info SEROQUEL(R) oral tabl
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Use caution and a reduced quetiapine dose if it is administered concomitantly with SEROQUEL(R) oral tablets, 2008a). Monitor the patient for quetiapine adverse events (tardive dyskinesia, sc hypotension) as well as for QTc interval prolongation.
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism by fluconazole

3.5.1.AQ Fluoxetine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest
2) Summary: Fluoxetine has been shown to prolong the QTc interval at the recommended therapeutic dose 2001). Even though no formal drug interaction studies have been done, the coadministration of antipsychotics known to prolong the QTc interval, including fluoxetine, is not recommended. Several antipsychotic agents ha prolongation including amisulpride (Prod Info Solian(R), 1999o), quetiapine (Owens, 2001u), sertindole (Agel sultopride (Lande et al, 1992n), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of fluoxetine and antipsychotics is not recommended
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AR Fosamprenavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) o
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.AS Foscarnet
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest
2) Summary: Foscarnet can prolong the QT interval in some patients, which may result in ventricular tachyca fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prolongation includi Info Solian(R), 1999z), haloperidol (O'Brien et al, 1999q), quetiapine (Owens, 2001ag), risperidone (Duenas- sertindole (Agelink et al, 2001x), sultopride (Lande et al, 1992y), and zotepine (Sweetman, 2003). Because a prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of foscarnet and a recommended (Prod Info Foscavir(R), 1998; Ravin & Levenson, 1997g).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of foscarnet and antipsychotics is not recommended
7) Probable Mechanism: additive cardiac effects

3.5.1.AT Fosphenytoin
1) Interaction Effect: decreased quetiapine efficacy
2) Summary: Fosphenytoin is a prodrug of phenytoin and the same interactions that occur with phenytoin are

with fosphenytoin (Prod Info Cerebyx(R), 1999). Coadministration of quetiapine 250 mg three times daily and three times daily increased the mean oral clearance of quetiapine by 5-fold. Quetiapine is metabolized by cyt isoenzymes, which are induced by the administration of phenytoin (Prod Info Seroquel(R), 1997).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Increased doses of quetiapine may be required to maintain control of psychotic sym receiving quetiapine and fosphenytoin. Caution should be taken if fosphenytoin is withdrawn from therapy or inducing anticonvulsant.
7) Probable Mechanism: induction of quetiapine metabolism by phenytoin

3.5.1.AU Gemifloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although pharmacokinetic studies between gemifloxacin and drugs that prolong the QT interva antipsychotics, have not been performed, gemifloxacin should be used cautiously in patients receiving antips (Prod Info Factive(R), 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of two drugs that prolong the QT interval, such as ge antipsychotics, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AV Halofantrine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Halofantrine can prolong the QT interval in some patients, which may result in ventricular tachy fibrillation, and torsades de pointes. Some antipsychotic agents prolong the QT interval and an additive effec if administered with other agents which lengthen the QT interval (Agelink et al, 2001a; Owens, 2001d; Prod In Prod Info Haldol(R), 1998; Lande et al, 1992a). The concurrent administration of halofantrine with antipsycho recommended (Prod Info Halfan(R), 1998).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of halofantrine and an antipsychotic is not recommer
7) Probable Mechanism: additive cardiac effects

3.5.1.AW Haloperidol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Haloperidol is associated with QTc prolongation and torsade de pointes (Hassaballa & Balk, 20 (R), 2001a). Quetiapine may prolong the QT interval at therapeutic and toxic doses. Coadministration of halo daily with quetiapine 300 mg twice daily did not alter the steady-state pharmacokinetics of quetiapine (Prod In 2003). Caution is advised with coadministration of drugs that potentially prolong the QTc interval.
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is advised if haloperidol and quetiapine are used concomitantly. Screen pa that may predispose to QT prolongation and torsade de pointes (i.e. cardiomyopathy, alcohol abuse, hypothy ECG and electrolytes at baseline and throughout therapy.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Numerous case reports have described significant QTc prolongation and torsades de pointes (TdP) a haloperidol. Hemodynamically significant ventricular tachyarrhythmias, ventricular fibrillation, asystole, a reported. The risk of TdP appears to be greater with intravenous haloperidol, but has occurred with oral a The risk increases with doses greater than 35 milligrams (mg) over 24 hours, though TdP has been assc low as 10 mg administered intravenously over 4 hours. To prevent haloperidol-induced TdP, screen patie dilated cardiomyopathy or alcohol abuse, testing for hypothyroidism before therapy, obtaining an electro and throughout therapy, and monitoring potassium, magnesium, and calcium. In patients with a baseline milliseconds (msec), haloperidol should be used cautiously or an alternative agent should be used. Disc the QTc increases more than 25% from baseline or if flattening of T-waves or development of U-waves c Balk, 2003).

3.5.1.AX Halothane
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated other agents which lengthen the QT interval (Agelink et al, 2001i; Owens, 2001m; Prod Info Solian(R), 1999i; 1998c; Lande et al, 1992h). Even though no formal drug interaction studies have been done, antipsychotic ag coadministered with other drugs which may also prolong the QTc interval, including halothane (Owens, 2001
3) Severity: major

4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of halothane and agents that prolong the QT interval antispsychotics, is not recommended.
7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe (Duenas-Laita et al, 1999k; Ravin & Levenson, 1997c).

3.5.1.AY Hydrocortisone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other i P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.AZ Hydroquinidine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006; Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj 2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended ((TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1 haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo changes than an elimination alteration (Young et al, 1993).

3.5.1.BA Ibutilide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of ibutilide and quetiapine is not recommended due to the risk of additive effect concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of ibutilide and quetiapine is not recommended due t inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as ibutilide and que additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.BB Imipramine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c

2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac
been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod
2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr
corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves.
studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m
mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl
(R), 1999b).

3.5.1.BC Indinavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co
ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine
335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co
other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are
quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) o
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as
elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri
protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.BD Isoflurane
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated
other agents which lengthen the QT interval (Agelink et al, 2001w; Owens, 2001ae; Prod Info Solian(R), 1999
(R), 1998g; Lande et al, 1992x). Even though no formal drug interaction studies have been done, antipsychot
be coadministered with other drugs which are also known to prolong the QTc interval, including isoflurane (O
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of isoflurane and agents that prolong the QT interval,
antipsychotics, is not recommended.
7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking risper
(Duenas-Laita et al, 1999y; Ravin & Levenson, 1997f).

3.5.1.BE Isradipine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Isradipine can prolong the QT interval in some patients, which may result in ventricular tachyca
fibrillation, and torsades de pointes, and its use with other drugs known to cause QT prolongation is not recor
DynaCirc(R), 2000). Several antipsychotic agents have demonstrated QT prolongation including amisulpride
1999f), haloperidol (O'Brien et al, 1999c), quetiapine (Owens, 2001i), risperidone (Duenas-Laita et al, 1999g)
al, 2001a), and zotepine (Sweetman, 2004).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of isradipine and an antipsychotic is not recommende
7) Probable Mechanism: additive cardiac effects

3.5.1.BF Itraconazole
1) Interaction Effect: increased quetiapine serum concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co
ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine
335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co
other CYP3A inhibitors such as itraconazole. Therefore, caution and a reduced quetiapine dosage are recom
quetiapine is administered to patients receiving itraconazole concomitantly (Prod Info SEROQUEL(R) oral tab
3) Severity: moderate
4) Onset: unspecified

5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take itraconazole as this r quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administering conco itraconazole (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A4-mediated quetiapine metabolism

3.5.1.BG Ketoconazole
1) Interaction Effect: increased quetiapine serum concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent inhibitor of CYP3A, reduced oral clearance of quetiapi a 335% increase in maximum plasma concentration of quetiapine. Therefore, caution and a reduced quetiapi recommended when quetiapine is administered to patients receiving ketoconazole concomitantly (Prod Info S tablets, 2008a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor patients for an increased incidence of quetiapine adverse effects and toxici somnolence, hypotension). A reduced quetiapine dosage is recommended when administering concomitantly (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A4-mediated quetiapine metabolism by ketoconazole

3.5.1.BH Lidoflazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Lidoflazine has been shown to prolong the QTc interval at the recommended therapeutic dose 1983). Even though no formal drug interaction studies have been done, the coadministration of antipsychotics known to prolong the QTc interval is not recommended. Several antipsychotic agents have demonstrated QT amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), quetiapine (Owens, 2001), risperid al, 1999), sertindole (Agelink et al, 2001), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of lidoflazine and antipsychotics is not recommended
7) Probable Mechanism: additive cardiac effects

3.5.1.BI Lopinavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.BJ Lorcainide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of quetiapine with other drugs that potentially prolong the QTc interval, such a be approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring 2001o; Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of lorcainide and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BK Mefloquine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Even though no formal drug interaction studies have been done, caution is advised if mefloquin drugs which can prolong the QTc interval (Prod Info Lariam(R), 1999). Mefloquine was associated with signifi in a study of 46 healthy subjects (Davis et al, 1996). Antipsychotics including haloperidol (Prod Info Haldol(R) (Owens, 2001w), risperidone (Prod Info Risperdal(R) risperidone, 2000a), amisulpride (Prod Info Solian(R), 1 (Agelink et al, 2001p); sultopride (Lande et al, 1992p), and zotepine (Sweetman, 2004) have been shown to p

at therapeutic doses.
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if mefloquine and antipsychotics are used concomitantly.
7) Probable Mechanism: additive effect on QT interval

3.5.1.BL Mephobarbital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.BM Mesoridazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although citing no data, the manufacturer of mesoridazine states that concomitant use with oth prolong the QT interval is contraindicated (Prod Info Serentil(R), 2001). Several antipsychotic agents have de prolongation including amisulpride (Prod Info Solian(R), 1999r), haloperidol (O'Brien et al, 1999k), paliperidor (TM) extended-release oral tablets, 2006), quetiapine (Owens, 2001x), risperidone (Duenas-Laita et al, 1999 et al, 2001o), sultopride (Lande et al, 1992q), ziprasidone (Prod Info GEODON(R) intramuscular injection, ora zotepine (Sweetman, 2004).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as antips mesoridazine, is contraindicated.
7) Probable Mechanism: additive QT prolongation

3.5.1.BN Methohexital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.BO Methylprednisolone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.BP Nelfinavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as

elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri
protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.BQ Nortriptyline
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod I
haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c
2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac
been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod
2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr
corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves.
studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m
mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhyt
(R), 1999b).

3.5.1.BR Octreotide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Octreotide has been shown to prolong the QTc interval at the recommended therapeutic dose
(R), 1999). Even though no formal drug interaction studies have been done, the coadministration of antipsych
known to prolong the QTc interval, including octreotide, is not recommended. Several antipsychotic agents ha
prolongation including amisulpride (Prod Info Solian(R), 1999t), haloperidol (O'Brien et al, 1999m), risperidon
1999t), sertindole (Agelink et al, 2001r), quetiapine (Owens, 2001z), sultopride (Lande et al, 1992s), and zote
2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of octreotide and antipsychotics is not recommended
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BS Paramethasone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir
P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.BT Pentamidine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Pentamidine has been shown to prolong the QTc interval at the recommended therapeutic dos
1990). Even though no formal drug interaction studies have been done, the coadministration of antipsychotics
known to prolong the QTc interval, including pentamidine, is not recommended (Agelink et al, 2001e; Owens,
Haldol(R), 2001; Prod Info Solian(R), 1999e; Duenas-Laita et al, 1999f; Duenas-Laita et al, 1999f; Prod Info M
Metzger & Friedman, 1993b; Lande et al, 1992d).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of pentamidine and antipsychotics is not recommend
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BU Pentobarbital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable

6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu
P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien
and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.BV Phenobarbital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu
P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien
and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.BW Phenylalanine
1) Interaction Effect: increased incidence of tardive dyskinesia
2) Summary: Taking phenylalanine concomitantly with certain neuroleptic drugs may exacerbate tardive dysl
1992a). Abnormal phenylalanine metabolism in certain patients may lead to phenylalanine accumulation in th
reduced brain availability of other large neutral amino acids. This may interfere with the synthesis of catechol
1992a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if phenylalanine is administered with a neuroleptic agent. Monito
for signs of tardive dyskinesia.
7) Probable Mechanism: reduced brain availability of other large neutral amino acids and interference with ca
synthesis
8) Literature Reports
a) Phenylalanine tended to increase the incidence of tardive dyskinesia in patients taking neuroleptics ir
groups of patients were studied: (1) patients with unipolar depression with tardive dyskinesia (n=11), (2)
tardive dyskinesia with current or past exposure to greater than or equal to 100 milligrams (mg) of a chlo
for at least 3 months (n=10), and (3) patients with no tardive dyskinesia not previously exposed to a neur
Neuroleptic agents were taken during the study by 6 patients in group 1, and 5 patients in group 2. Patie
phenylalanine 100 mg/kilogram dissolved in orange juice after an overnight fast. Blood samples were ob
phenylalanine administration and 2 hours after administration. Three patients in group 1 (with tardive dys
highest postloading phenylalanine plasma levels, this group as a whole had higher (though nonsignificar
levels than the other groups. Tardive dyskinesia score (measured using the Abnormal Involuntary Mover
nonsignificantly increased in group 1. Postloading phenylalanine level and postloading AIMS scores were
positively correlated in group 1 (rs=0.347, p less than 0.05; Spearman correlation coefficient 0.543, p les
Postloading phenylalanine level and baseline AIMS scores demonstrated a trend toward correlation (rs=
Spearman correlation coefficient 0.679, p less than 0.05). In all patients, phenylalanine loading increased
phenylalanine levels approximately eight-fold, and plasma tyrosine increased 2.5 times as a result of cor
phenylalanine to tyrosine. Plasma levels of competing large neutral amino acids such as tryptophan decr
(Gardos et al, 1992).

3.5.1.BX Phenytoin
1) Interaction Effect: decreased quetiapine efficacy
2) Summary: Coadministration of quetiapine 250 mg three times daily and phenytoin 100 mg three times dai
oral clearance of quetiapine by 5-fold. Quetiapine is metabolized by cytochrome P450 3A4 isoenzymes, whic
administration of phenytoin (Prod Info Seroquel(R), 2003b; Wong et al, 2001a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: Increased doses of quetiapine may be required to maintain control of psychotic sym
receiving quetiapine and phenytoin. Caution should be taken if phenytoin is withdrawn from therapy or replac
anticonvulsant.
7) Probable Mechanism: induction of quetiapine metabolism by phenytoin
8) Literature Reports
a) Coadministration of phenytoin with quetiapine significantly decreased the plasma concentration-time
resulting in a 5-fold increase in oral clearance in patients with DSM-IV-diagnosed schizophrenia, schizoa
bipolar disorder. Seventeen patients participated in an open-label, nonrandomized, multiple-dose study t
pharmacokinetics and tolerability of quetiapine when administered alone or in combination with phenytoi
escalating doses of quetiapine from 25 to 250 mg three times daily on days 3 to 10. Maintenance doses
administered on days 11 to 22. Phenytoin 100 mg three times daily was administered between days 13 a
under the concentration-time curve (AUC) from 0 to 8 hours after dosing at steady-state with quetiapine

phenytoin was 3642 ng hr/mL and 728 ng hr/mL , respectively (P equal 0.0001). The maximum plasma c
steady-state (Cmax, ss) for quetiapine versus quetiapine plus phenytoin was 1,048 ng/mL and 359 ng/m
Clearance over bioavailability (CL/F) for quetiapine alone versus quetiapine plus phenytoin was 80.3 L/h
respectively. The induction of cytochrome P450 3A4 by phenytoin is the most likely mechanism for the a
quetiapine metabolism (Wong et al, 2001).

3.5.1.BY Pirmenol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop
paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM
Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006;
Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj
2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre
arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended (
(TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic
day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther
Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip
studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th
significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine
treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL
to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1
haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we
changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo
changes than an elimination alteration (Young et al, 1993).

3.5.1.BZ Prajmaline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop
paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM
Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006;
Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj
2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre
arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended (
(TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic
day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther
Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip
studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th
significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine
treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL
to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1
haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we
changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo
changes than an elimination alteration (Young et al, 1993).

3.5.1.CA Prednisolone

1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified

5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir
P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.CB Prednisone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir
P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.CC Primidone
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu
P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien
and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.CD Probucol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Even though no formal drug interaction studies have been done, the coadministration of drugs
QTc interval is not recommended. Probucol has been shown to prolong the QTc interval (Gohn & Simmons, 1
Lorelco(R), 1991). Antipsychotics including haloperidol (Prod Info Haldol(R), 1998d), quetiapine (Owens, 200
Info Risperdal(R) risperidone, 2000), amisulpride (Prod Info Solian(R), 1999n), sertindole (Brown & Levin, 19
(Lande et al, 1992m), and zotepine (Sweetman, 2004) have been shown to prolong the QT interval at therape
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if probucol and antipsychotics are used concomitantly.
7) Probable Mechanism: additive effect on QT interval

3.5.1.CE Procainamide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride, halop
paliperidone, quetiapine, risperidone, sertindole, sultopride, ziprasidone, and zotepine (Prod Info FANAPT(TM
Prod Info Solian(R), 1999x; O'Brien et al, 1999p; Prod Info INVEGA(TM) extended-release oral tablets, 2006;
Duenas-Laita et al, 1999x; Agelink et al, 2001v; Lande et al, 1992w; Prod Info GEODON(R) intramuscular inj
2005; Sweetman, 2003). Because Class IA antiarrhythmic agents may also prolong the QT interval and incre
arrhythmias, the concurrent administration of antipsychotics with a drug from this class is not recommended (
(TM) oral tablets, 2009; Prod Info Quinaglute(R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic and an antipsychotic is r
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) In an open-label QTc study of patients with schizophrenia or schizoaffective disorder (n=160), iloperic
day was associated with QTc prolongation of 9 msec (Prod Info FANAPT(TM) oral tablets, 2009).
b) QRS widening, QTc interval prolongation, and torsades de pointes may occur with disopyramide ther
Norpace(R), 1997).
c) The effects of combined therapy with quinidine (Class IA antiarrhythmic agent) and haloperidol (antip
studied by giving 12 healthy volunteers haloperidol 5 mg alone and with 250 mg of quinidine bisulfate. Th
significant increases in the plasma concentrations of haloperidol when given concurrently with quinidine
treatment alone. The mean area under the concentration curve (AUC) was increased from 54.3 ng/h/mL
to 103.2 ng/h/mL on combined therapy. The peak concentration (Cmax) also showed an increase from 1
haloperidol to 3.8 ng/mL on combined therapy. Half-life (T1/2) and time to peak concentration (Tmax) we
changed, thereby suggesting to the authors that a tissue binding mechanism is more likely responsible fo
changes than an elimination alteration (Young et al, 1993).

3.5.1.CF Prochlorperazine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concomitant use of phenothiazines and antipsychotic agents may cause additive effects on the recommended. Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Co Prod Info Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, available. Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info haloperidol (O'Brien et al, 1999f), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), 2001n), risperidone (Duenas-Laita et al, 1999l), sertindole (Agelink et al, 2001j), sultopride (Lande et al, 1992 Info GEODON(R) intramuscular injection, oral capsule, 2005), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as phen antipsychotics, is not recommended.
7) Probable Mechanism: additive QT prolongation

3.5.1.CG Propafenone

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Coadministration of quetiapine with other drugs that potentially prolong the QTc interval, such a should be approached with caution. If concurrent use cannot be avoided, cautious dosing and telemetric mon (Owens, 2001o; Larochelle et al, 1984).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of propafenone and quetiapine is not recommended inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CH Protriptyline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c 2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod 2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pro corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhyth (R), 1999b).

3.5.1.CI Rifampin

1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving rifampin, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with rifampin or other inducers 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by rifampin

3.5.1.CJ Risperidone

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Risperidone can prolong the QT interval in some patients, which may result in ventricular tachy fibrillation, and torsades de pointes, and its use with other agents that may prolong the QT interval, such as q recommended (Prod Info Risperdal(R), 2002; Owens, 2001r). Coadministration of risperidone 3 mg twice dail mg twice daily did not alter the steady-state pharmacokinetics of quetiapine (Prod Info Seroquel(R), 2003a).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable

6) Clinical Management: Because of the potential additive effects on the QT interval, the concurrent administ
and risperidone is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Sometimes fatal QRS prolongation and QTc prolongation have been reported in patients taking rispe
(Duenas-Laita et al, 1999o; Ravin & Levenson, 1997d; Gesell & Stephen, 1997; Lo Vecchio et al, 1996;

3.5.1.CK Ritonavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co
ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine
335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co
other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are
quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) o
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as
elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri
protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.CL Saquinavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co
ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine
335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co
other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are
quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) o
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as
elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri
protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.CM Secobarbital
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer
receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu
P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien
and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.CN Sematilide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of sematilide and quetiapine is not recommended due to the risk of additive eff
interval. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreud
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of sematilide and quetiapine is not recommended du
inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular
ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol
quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as sematilide and q
additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CO Sotalol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of sotalol and quetiapine is not recommended due to the risk of additive effects

concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of sotalol and quetiapine is not recommended due to inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as sotalol and queti additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CP Spiramycin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Spiramycin has been shown to prolong the QTc interval at the recommended therapeutic dose al, 1997). Even though no formal drug interaction studies have been done, the coadministration of antipsycho known to prolong the QTc interval, including spiramycin, is not recommended. Several antipsychotic agents h prolongation including amisulpride (Prod Info Solian(R), 1999u), haloperidol (O'Brien et al, 1999n), quetiapine risperidone (Duenas-Laita et al, 1999u), sertindole (Agelink et al, 2001s), sultopride (Lande et al, 1992t), and 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of spiramycin and antipsychotics is not recommende
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CQ Sulfamethoxazole
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cotrimoxazole has been shown to prolong the QTc interval at the recommended therapeutic do 1987). Even though no formal drug interaction studies have been done, the coadministration of antipsychotics known to prolong the QTc interval, including cotrimoxazole, is not recommended. Several antipsychotic agen QT prolongation including amisulpride (Prod Info Solian(R), 1999g), haloperidol (O'Brien et al, 1999d), quetia risperidone (Duenas-Laita et al, 1999h), sertindole (Agelink et al, 2001f), sultopride (Lande et al, 1992e), and 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of cotrimoxazole and antipsychotics is not recommer
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CR Tedisamil
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concurrent use of tedisamil and quetiapine is not recommended due to the risk of additive effe If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of tedisamil and quetiapine is not recommended due inducing life-threatening arrhythmias. If concurrent use cannot be avoided, cautious dosing and telemetric mo
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) Class III antiarrhythmics have been shown to prolong the QT interval, which may result in ventricular ventricular fibrillation, and torsades de pointes. Several antipsychotic agents have demonstrated QT prol quetiapine (Owens, 2001c). Concomitant use of Class III antiarrhythmic agents such as tedisamil and qu additive effects on the QT interval and is not recommended (Yamreudeewong et al, 2003).

3.5.1.CS Telithromycin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotic agents prolong the QT interval and an additive effect would be anticipated other agents which lengthen the QT interval (Agelink et al, 2001g; Owens, 2001k; Prod Info Haldol(R), 1998b Even though no formal drug interaction studies have been done, antipsychotic agents should not be coadmin drugs which are also known to prolong the QTc interval, including telithromycin (Owens, 2001k).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Due to the potential for additive effects on the QT interval, the concurrent administra and an antipsychotic is not recommended.

7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Fatal QRS prolongation and QTc prolongation have been reported in patients taking risperidone thera Laita et al, 1999i; Ravin & Levenson, 1997b).

3.5.1.CT Terfenadine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Some antipsychotics have been shown to prolong the QTc interval at the recommended therap Geodon(TM), 2002b; Owens, 2001af; Prod Info Orap(R), 1999f). Even though no formal drug interaction stud the coadministration of terfenadine and other drugs known to prolong the QTc interval, including antipsychoti (Anon, 1997).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of terfenadine with any drug that prolongs the QT int antipsychotic agents, is contraindicated.
7) Probable Mechanism: additive effect on QT interval
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhyt (R), 1999e).

3.5.1.CU Thiopental
1) Interaction Effect: decreased serum quetiapine concentrations
2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a barbiturate, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001c).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with barbiturates or other indu P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic symptoms in patien and barbiturates.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by barbiturates

3.5.1.CV Thioridazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although citing no data, the manufacturer of thioridazine states that concomitant use with other the QT interval is contraindicated (Prod Info Mellaril(R), 2001). Several antipsychotic agents have demonstra including amisulpride (Prod Info Solian(R), 1999p), haloperidol (O'Brien et al, 1999j), pimozide (Prod Info Ora quetiapine (Owens, 2001v), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), risper et al, 1999q), sertindole (Agelink et al, 2001o), sultopride (Lande et al, 1992o), ziprasidone (Prod Info GEOD injection, oral capsule, 2005), and zotepine (Sweetman, 2004).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as antips thioridazine, is contraindicated.
7) Probable Mechanism: additive QT prolongation

3.5.1.CW Tipranavir
1) Interaction Effect: increased quetiapine plasma concentrations
2) Summary: In vitro studies indicated that quetiapine is metabolized by the CYP3A4 isozyme in the liver. Co ketoconazole (200 mg once daily for 4 days), a potent CYP3A inhibitor, reduced oral clearance of quetiapine 335% increase in maximum plasma concentration of quetiapine. Although not studied, a similar interaction co other CYP3A inhibitors such as protease inhibitors. Therefore, caution and a reduced quetiapine dosage are quetiapine is administered to patients receiving protease inhibitors concomitantly (Prod Info SEROQUEL(R) c
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing quetiapine to patients who take protease inhibitors as elevated quetiapine plasma concentrations. A reduced quetiapine dosage is recommended when administeri protease inhibitors (Prod Info SEROQUEL(R) oral tablets, 2008a).
7) Probable Mechanism: inhibition of CYP3A-mediated quetiapine metabolism

3.5.1.CX Triamcinolone
1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving a glucocorticoid, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001b).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Caution is indicated when quetiapine is administered with glucocorticoids or other ir P450 3A.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of quetiapine by glucocorticoid

3.5.1.CY Trifluoperazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Concomitant use of phenothiazines and antipsychotic agents may cause additive effects on the recommended. Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Co Prod Info Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, available. Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info haloperidol (O'Brien et al, 1999f), paliperidone (Prod Info INVEGA(TM) extended-release oral tablets, 2006), 2001n), risperidone (Duenas-Laita et al, 1999l), sertindole (Agelink et al, 2001j), sultopride (Lande et al, 1992 Info GEODON(R) intramuscular injection, oral capsule, 2005), and zotepine (Sweetman, 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of agents that prolong the QT interval, such as phen antipsychotics, is not recommended.
7) Probable Mechanism: additive QT prolongation

3.5.1.CZ Trimethoprim
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cotrimoxazole has been shown to prolong the QTc interval at the recommended therapeutic do 1987). Even though no formal drug interaction studies have been done, the coadministration of antipsychotics known to prolong the QTc interval, including cotrimoxazole, is not recommended. Several antipsychotic agen QT prolongation including amisulpride (Prod Info Solian(R), 1999g), haloperidol (O'Brien et al, 1999d), quetia risperidone (Duenas-Laita et al, 1999h), sertindole (Agelink et al, 2001f), sultopride (Lande et al, 1992e), and 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of cotrimoxazole and antipsychotics is not recommer
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.DA Trimipramine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod haloperidol (O'Brien et al, 1999a), risperidone (Duenas-Laita et al, 1999c), sertindole (Agelink et al, 2001b), c 2001e), sultopride (Lande et al, 1992b), and zotepine (Sweetman, 2003). Even though no formal drug interac been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod 2001; Marshall & Forker, 1982).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is n
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included pr corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 m mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhytl (R), 1999b).

3.5.1.DB Vasopressin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Antipsychotics and vasopressin have been shown to prolong the QTc interval at the recommen (Owens, 2001b; Prod Info Solian(R), 1999a; Duenas-Laita et al, 1999b; Brown & Levin, 1998; Harry, 1997; P 1996; Metzger & Friedman, 1993; Mauro et al, 1988). Even though no formal drug interaction studies have be coadministration of drugs known to prolong the QTc interval is not recommended.
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of drugs that prolong the QT interval, such as antipsy

vasopressin, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.DC Warfarin
1) Interaction Effect: potentiation of anticoagulant effects
2) Summary: A 71-year-old female experienced enhanced anticoagulant effects from warfarin when quetiapi drug regimen. Her medications included phenytoin 300 mg daily with a serum concentration of 9.87 mg/L, wa with an international normalized ratio (INR) of 2.6, benztropine 0.5 mg daily, and olanzapine 20 mg daily. Ola discontinued, and quetiapine therapy was initiated at 200 mg daily. Five days later, the INR was 2.7. After tw treatment, the INR increased to 9.2. Quetiapine was discontinued and two doses of vitamin K 10 mg were ad clinical signs observed in the patient were a small amount of bleeding at the site of the vitamin K injection an The INR decreased back to baseline with the discontinuation of quetiapine (Rogers et al, 1999).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Closely monitor the international normalized ratio (INR) in patients receiving concur quetiapine therapy.
7) Probable Mechanism: competitive inhibition of cytochrome P450 3A4 and 2C9 by quetiapine

3.5.1.DD Zolmitriptan
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest
2) Summary: Zolmitriptan has been shown to prolong the QTc interval at the recommended therapeutic dose 2001). Antipsychotics including haloperidol (Prod Info Haldol(R), 1998f), quetiapine (Owens, 2001ac), risperi Risperdal(R) risperidone, 2000b), amisulpride (Prod Info Solian(R), 1999w), sertindole (Agelink et al, 2001u); al, 1992v), and zotepine (Sweetman, 2004) have been shown to prolong the QT interval at therapeutic doses formal drug interaction studies have been done, the coadministration of drugs known to prolong the QT interv recommended.
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of zolmitriptan and antipsychotics is not recommende
7) Probable Mechanism: additive effect on QT interval

3.5.2 Drug-Food Combinations

3.5.2.A Ethanol
1) Interaction Effect: potentiation of the cognitive and motor effects of alcohol
2) Summary: Quetiapine potentiated the cognitive and motor effects of alcohol in a clinical trial in subjects wi disorders. Alcoholic beverages should be avoided while taking quetiapine (Prod Info Seroquel(R), 2001d).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Patients should be instructed to avoid ethanol ingestion while taking quetiapine.
7) Probable Mechanism: additive CNS depression

3.5.3 Drug-Lab Modifications

Methadone measurement, urine

Tricyclic antidepressant measurement

3.5.3.A Methadone measurement, urine
1) Interaction Effect: false-positive urine drug screen for methadone
2) Summary: There have been cases of false-positive methadone urine drug screens with the use of assays Methadone II testkit(R) in patients treated with quetiapine. Clinicians should consider confirming positive met more specific methods, such as gas chromatography/mass spectrometry, or other quantitative methods parti whose results do not coincide with medical history, or current behaviors and observations (Cherwinski et al, 2 et al, 2007).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Clinicians should be aware that there have been cases of false-positive urine meth patients receiving quetiapine. Consider confirming a positive urine methadone screen with more specific met chromatography/mass spectrometry, or other quantitative methods, particularly in patients whose results do r medical history, or current behaviors and observations (Cherwinski et al, 2007; Widschwendter et al, 2007).

7) Probable Mechanism: mechanism unknown
8) Literature Reports
a) In a retrospective chart review, 12 pediatric patients (mean age of 15.5 years) admitted to a behavior treated with quetiapine from 125 to 160 mg daily had false methadone-positive urine drug screens with t (R) by Roche. Although 5 of these patients had positive substance abuse history, none were admitted fo issues. All patients denied current methadone use, and final clinical impressions were that they had not u substances. Results of confirmatory testing using gas chromatography/mass spectroscopy, performed in were negative for methadone (Cherwinski et al, 2007).
b) Three schizophrenic patients, being treated with quetiapine monotherapy, had false-positive urinalysi methadone using the Cobas Integra Methadone II testkit(R) by Roche. This method, used for semiquanti detection of methadone in urine, has a threshold of 300 ng/mL for methadone positivity. Blood samples t day after quetiapine administration ended also tested positive for methadone with mass spectrometry. H medical histories of the patients, these results were unexpected. Further screening of the patient's plasm quantitative assay did not reveal methadone positivity (Widschwendter et al, 2007).

3.5.3.B Tricyclic antidepressant measurement
1) Interaction Effect: a false-positive urine tricyclic antidepressant assay
2) Summary: A 34-year-old male patient receiving quetiapine 600 mg daily showed a positive toxicology scre antidepressants despite his denial of tricyclic use. Quetiapine is structurally similar to tricyclic antidepressants as the cause of this assay abnormality. A laboratory test confirmed that quetiapine is capable of causing a fal screen for tricyclic antidepressants (Sloan et al, 2000).
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Clinicians should be aware that quetiapine may cause false-positive test results in a tricyclic antidepressants. This possibility should be considered in patients receiving quetiapine who deny tricy use but have a positive urine screen for tricyclics.
7) Probable Mechanism: assay interference

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters
A) Quetiapine Fumarate
1) Therapeutic
a) Physical Findings
1) In schizophrenic patients, improvements of positive symptoms (eg, delusions, hallucinations, paranoi negative symptoms (eg, blunted affect, poverty of speech, amotivation) are indicative of a therapeutic res
2) Reassess the need for maintenance treatment and appropriate dose periodically (Prod Info SEROQU release oral tablets, 2007).
2) Toxic
a) Laboratory Parameters
1) Quetiapine use has been associated with exacerbation of pre-existing diabetes, hyperglycemia, diabe diabetic coma, and death. For patients with diabetes mellitus risk factors (eg, obesity, family history), per glucose testing at the beginning of and periodically during quetiapine therapy. For patients with pre-exist monitor fasting blood glucose regularly during quetiapine therapy to detect worsening of glucose control. SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).
2) Quetiapine use has been associated with leukopenia, neutropenia, and agranulocytosis, which has in Perform CBC frequently during the first few months of therapy in patients with a pre-existing low WBC or induced leukopenia/neutropenia. Monitor patients for severe neutropenia (absolute neutrophil count less which will necessitate discontinuing quetiapine therapy (Prod Info SEROQUEL(R) oral tablets, 2007; Pro XR extended-release oral tablets, 2007).
b) Physical Findings

1) Patients should be carefully monitored for clinical worsening of depression, suicidality, and unusual cl which make be precursors to suicidality, especially if symptoms are severe, abrupt or unusual. This is es the initial few months of antidepressant therapy or during dose changes. Adult and pediatric patients with disorder may experience unusual changes in behavior and onset of suicidal behavior (suicidality). Antide be associated with the emergence of suicidality and inducing worsening of depression in patients, espec treatment phase and in children, adolescents, and young adults ages 18 to 24 years. It is important that to patients with major depressive disorder or other psychiatric and nonpsychiatric disorders be vigilant in emergent anxiety, agitation, hostility, aggressiveness, impulsivity, akathisia, hypomania, mania, irritability changes in behavior (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended 2007).

2) In patients with neutropenia, carefully monitor for fever or other signs or symptoms of infection (Prod oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

3) Quetiapine use has been associated with exacerbation of pre-existing diabetes, hyperglycemia, diabe diabetic coma, and death. Monitor all patients receiving quetiapine for symptoms of hyperglycemia (eg, p polyphagia, weakness). For patients with diabetes mellitus risk factors (eg, obesity, family history), perfo glucose testing at the beginning of and periodically during quetiapine therapy. Patients with pre-existing regularly monitor fasting blood glucose during quetiapine therapy to detect worsening of glucose control SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

4) Quetiapine use has been rarely associated with the development of neuroleptic malignant syndrome should be monitored for signs and symptoms of NMS, such as hyperpyrexia, muscle rigidity, altered mer autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythm SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007).

5) Due to the risk of developing irreversible, involuntary, dyskinetic movements, patients should be obse symptoms of extrapyramidal effects and tardive dyskinesia. Monitoring is especially critical in elderly pati longer duration of treatment, and higher total cumulative doses, but has occurred after relatively brief du (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets

6) Although a causal relationship has not been established, long-term quetiapine therapy has been impl changes. Ocular examination (eg, slit lamp exam) to detect cataract formation is recommended at treatm every 6 months during chronic quetiapine treatment (Prod Info SEROQUEL(R) oral tablets, 2007; Prod I extended-release oral tablets, 2007).

7) Quetiapine use may induce postural hypotension, dizziness, tachycardia, and syncope has been repo (Prod Info SEROQUEL(R) oral tablets, 2007; Prod Info SEROQUEL(R)XR extended-release oral tablets pressure and heart rate during quetiapine therapy. Perform ECG at baseline and periodically during ther Kecskemeti, 2004).

4.2 Patient Instructions

A) Quetiapine (By mouth)

Quetiapine

Treats schizophrenia and symptoms of bipolar disorder (manic-depressive illness).

When This Medicine Should Not Be Used:
You should not use this medicine if you have had an allergic reaction to quetiapine.

How to Use This Medicine:
Long Acting Tablet, Tablet

Your doctor will tell you how much of this medicine to use and how often. Your dose may need to be changed order to find out what works best for you. Do not use more medicine or use it more often than your doctor tell start with a low dose, even if you have used this medicine before.
Your doctor may tell you to take the medicine at bedtime, because quetiapine can make you sleepy.
This medicine should come with a Medication Guide. Read and follow these instructions carefully. Ask your d you have any questions. Ask your pharmacist for the Medication Guide if you do not have one. Your doctor m some forms to show that you understand this information.

If a Dose is Missed:

If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next d use the medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.

How to Store and Dispose of This Medicine:

Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after your treatment. You will also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, a

Make sure your doctor knows if you are also using levodopa, Sinemet®, erythromycin (Ery-Tab®), lorazepam (Rifadin®, Rifamate®), or a steroid medicine (such as dexamethasone, prednisolone, prednisone, or Medrol®

Tell your doctor if you are also using medicine for seizures (such as carbamazepine, divalproex, phenytoin, p
Depakote®, Dilantin®, Luminal®, or Tegretol®), medicine to treat a fungus infection (such as fluconazole, itra
ketoconazole, Diflucan®, Nizoral®, or Sporanox®), or other antipsychotic medicine such as thioridazine (Mell
Make sure your doctor knows if you are also using medicine to lower blood pressure. Some blood pressure m
hydrochlorothiazide (HCTZ), lisinopril, metoprolol, quinapril, Accupril®, Cozaar®, Diovan®, Lotrel®, Norvasc®
Zestril®.
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and a
narcotic pain relievers, and sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:
Make sure your doctor knows if you are pregnant or breastfeeding, or if you have liver disease, Alzheimer's d
problems, or a history of seizures or breast cancer. Tell your doctor if you have diabetes or a family history of
Make sure your doctor knows if you have heart disease or circulation problems, such as heart failure, low blo
problems, blood problems, high cholesterol, or a history of heart attack or stroke. Also tell your doctor if you h
condition called neuroleptic malignant syndrome (NMS) in the past.

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, o
breathing.
Agitation, anxiety, or restlessness.
Changes in behavior, or thoughts of hurting yourself or others.
Constant muscle movement that you cannot control (often in your lips, tongue, jaw, arms, or legs).
Decrease in how much or how often you urinate, increased thirst, increased hunger, or weakness.
Fast heartbeat.
Fever, sweating, confusion, uneven heartbeat, muscle stiffness.
Lightheadedness or fainting (more common at the beginning or when changing doses).
Painful, prolonged erection of the penis.
Seizures or tremors.
Severe drowsiness, dizziness, or sleepiness.
Trouble seeing, or bright light bothering your eyes.
Trouble swallowing.
Unusual tiredness.

If you notice these less serious side effects, talk with your doctor:
Back pain.
Changes in menstrual periods.
Headache, sore throat.
Increased appetite.
Nausea, vomiting, constipation, dry mouth, upset stomach, or stomach pain.
Stuffy or runny nose.
Weight gain.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Current users of atypical antipsychotic drugs (including quetiapine) and typical antipsychotic drugs had a similar do
sudden cardiac death, according to a retrospective cohort of 93,300 adult users of antipsychotic drugs and 186,600 m
study included patients age 30 to 74 years (mean 45.7 +/- 11.8 years) with similar cardiovascular risk at baseline who

prescription and had 1 outpatient visit in each of the 2 preceding years. Sudden cardiac death was defined as occurrin and excluded deaths of patients admitted to the hospital, non-sudden deaths, deaths due to extrinsic causes, or cause ventricular tachyarrhythmia. Current use was defined as the interval between the time the prescription was filled and th supply. Low and high doses was defined as comparable to less than 100 milligrams (mg) of chlorpromazine, and dose chlorpromazine 300 mg or greater, respectively. The adjusted rate of sudden cardiac death (incidence-rate ratio) in cu antipsychotic drugs in 79,589 person-years was 2.26 (95% CI, 1.88 to 2.72, p less than 0.001) which was similar to the of typical antipsychotic drugs in 86,735 person-years which was 1.99 (95% CI, 1.68 to 2.34, p less than 0.001). The ris death in current quetiapine users in 17,355 person-years was 1.88 (95% CI, 1.3 to 2.71, p less than 0.001). The risk o death significantly increased with increasing dose in both the typical and atypical antipsychotic drug groups. In atypica the incidence rate ratio increased from 1.59 (95% CI, 1.03 to 2.46) in low-dose use to 2.86 (95% CI, 2.25 to 3.65) in hi the effects of confounding of the study results, there was a secondary analysis performed in a cohort of patients matc score, which resulted in a similar risk of sudden death as the primary cohort analysis (Ray et al, 2009). In an editorial i Journal of Medicine, it has been suggested that antipsychotic drugs continue to be used in patients with clear evidence vulnerable populations with cardiac risk profiles (eg, elderly patients), there should be an age-dependent justification r administration. It has also been suggested (although not formally tested) that ECGs be performed before and shortly a antipsychotic therapy to screen for existing or emergent QT interval prolongation (Schneeweiss & Avorn, 2009).
B) Quetiapine is indicated for the treatment of depressive episodes associated with bipolar disorder and acute manic with bipolar I disorder as either monotherapy or adjunct therapy to lithium or divalproex. Quetiapine is also indicated fo schizophrenia (Prod Info SEROQUEL(R) oral tablets, 2006).
See Drug Consult reference: FIRST- VS SECOND-GENERATION ANTIPSYCHOTIC AGENTS FOR SCHIZOPHREN

4.4 Mechanism of Action / Pharmacology

A) Quetiapine Fumarate

1) PHARMACOLOGY

a) Quetiapine is a dibenzothiazepine antipsychotic agent bearing structural similarity to clozapine and olanza 1998; Fabre et al, 1995; Anon, 1995; Green, 1999).

b) Quetiapine has been shown to have affinity for multiple neurotransmitter receptors in in vitro binding studi high affinity for serotonergic type 2 (5-HT2) receptors and moderate affinity for dopamine type 2 (D2) recepto antagonism of D1 and 5-HT1A receptors is relatively weak. Appreciable affinity for alpha-1 adrenergic, alpha- histamine H1 receptors has also been observed (Saller & Salama, 1993; Fulton & Goa, 1995; Anon, 1995). C clozapine, affinities of quetiapine for all receptor types are lower; notably, the binding affinities of quetiapine f adrenergic receptors are 11 times and 7 times lower, respectively, than affinities for clozapine (Saller & Salar clozapine, quetiapine has essentially no affinity for benzodiazepine receptors; unlike clozapine, quetiapine de affinity for muscarinic receptor types (Anon, 1995; Saller & Salama, 1993; Fulton & Goa, 1995). Despite relat receptor binding, these collectively suggest the similarity of clozapine and quetiapine with respect to mixed 5- (which may contribute to lower EPS potential), and that quetiapine may be less likely than clozapine to induc antiadrenergic effects.

c) Quetiapine's D2/5-HT2a affinity profile has not yet been established with certainty. Affinity for 5-HT2 recep reported as greater than for D2 receptors with both quetiapine and risperidone, another atypical agent, althou the D2 receptor is relatively weak with quetiapine and very high with risperidone (similar to haloperidol) (Boris However, others report higher D2-receptor affinity for quetiapine (Caley & Rosenbaum, 1998). Atypical antips generally share higher affinity for 5-HT2 receptors.

d) Platelet serotonin-2 (5-HT(2)) receptor density in schizophrenic patients appears to have increased with s quetiapine therapy in a small (n=9), double-blind, placebo-controlled study, (Faustman et al, 1996). Two patie maximum dose of 250 milligrams/day; one of these patients dropped out after 2 weeks. Two patients receive mg/d and one patient received 750 mg/d for the final 12 days before he dropped out at day 38 of the study. T platelet 5-HT(2) receptor density increased over the mean baseline value for the quetiapine-treated patients b group (n=4). Similar increases have been seen during clozapine therapy. The clinical significance of these re addressed by the authors.

2) REVIEW ARTICLES

a) The use of atypical antipsychotics for the treatment of drug- induced psychosis in Parkinson's disease has (Friedman & Factor, 2000).

b) The pharmacology and clinical efficacy of quetiapine have been reviewed (Green, 1999; Goren & Levin, 1 1995).

c) The new antipsychotic medications including quetiapine have been reviewed (Keck et al, 2000; Glazer, 20

d) The use of atypical antipsychotic medications in adults (Markowitz et al, 1999; Brown et al, 1999), older a 1999), and children (Malone et al, 1999; Lewis, 1998; Toren et al, 1998) has been reviewed.

e) The side effects of antipsychotics, including quetiapine, in adults and the elderly were reviewed (Garver, 2

b) Summary:

Quetiapine is indicated for the treatment of depressive episodes associated with bipolar disorder (Pr
(R) oral tablets, 2008a)

Quetiapine monotherapy was well-tolerated and more effective than placebo in the treatment of bipo
(Calabrese et al, 2005)

c) Adult:

1) Quetiapine was more effective than placebo in the treatment of depressive episodes associated with
identical 8-week, randomized, double-blind, placebo-controlled studies (n=1045), patients with either bip
those with or without a rapid cycling course received quetiapine fixed doses of either 300 milligrams (mg
daily. The change from baseline in Montgomery-Asberg Depression Rating Scale (MADRS) score at wee
endpoint for both studies. Quetiapine was superior to placebo in reducing the MADRS score. In both stu
symptoms as measured by the change in MADRS score relative to placebo was observed on day 8 (We
The Quality of Life Satisfaction Scale Questionnaire (Q-LES-Q(SF)) measurement showed statistically si
improvements in overall quality of life and satisfaction, related to various areas of functioning, for the 300
the placebo; however, no additional benefit was observed with the 600 mg dose (Prod Info SEROQUEL(
2007b).

2) Quetiapine monotherapy was well-tolerated and more effective than placebo in the treatment of bipol
a double-blind, randomized, fixed-dose, placebo-controlled, parallel-group study, patients with bipolar I (
with a major depressive episode (DSM-IV) were assigned to 8 weeks of quetiapine 600 (n=180) or 300 n
(n=181) or placebo (n=181). An initial dose of 50 mg was given on day 1 and titrated up to 300 mg by da
8, and all doses were given at bedtime. In this study, effects of treatment were evaluated by Montgomery
Rating Scale (MADRS) total score (primary end-point, mean change from baseline to week 8), Clinical G
severity and improvement, Hamilton Anxiety Rating Scale, Pittsburgh Sleep Quality Index, and Quality of
Satisfaction Questionnaire. Statistically significant improvement in MADRS total score from week 1 onwa
both quetiapine groups compared with placebo. The mean change in MADRS total score from baseline t
(intent-to-treat) was -16.73, -16.39, and -10.26 for the 600 mg, 300 mg and placebo groups, respectively
both quetiapine doses vs placebo). At the final assessment, both quetiapine groups had significantly high
(defined as at least 50% MADRS score improvement) when compared with placebo (58.2% in 600 mg/da
300 mg/day group vs 36.1% in placebo; p less than 0.001). In addition, 52.9% of patients in both quetiap
remission criteria (MADRS score of 12 or less) compared to 28.4% of patients in the placebo group (p les
Significant improvements from baseline were observed in 9 of 10 and 8 of 10 MADRS items in the quetia
mg/day groups, respectively, compared with placebo (p less than 0.05). Quetiapine and placebo groups
rates of treatment-emergent mania (3.2% and 3.9%, respectively). The rates of serious adverse events w
different across treatment groups, and none were treatment related (5% in the 600 mg/day group and 3.4
group compared with 8.9% in the placebo group). The overall rates of study discontinuation due to adver
(n=47), 16% (n=29), and 8.8% (n=16) for the 600 mg/day group, 300 mg/day group, and placebo group,
(Calabrese et al, 2005).

4.5.B.3 Bipolar disorder, Maintenance

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Indicated for the maintenance treatment of bipolar I disorder as adjunctive therapy to lithium or dival
SEROQUEL(R) oral tablets, 2008a)

As adjunct therapy to lithium or divalproex, quetiapine was more effective than placebo in maintenar
bipolar I disorder in 2 double-blind, randomized, placebo-controlled studies (n=1326) (Prod Info SEF
tablets, 2008a)

c) Adult:

1) As adjunct therapy to either lithium or divalproex, quetiapine was more effective than placebo in main
bipolar I disorder. Two identical, randomized, double-blind studies evaluated patients (n=1326), with bipo
defined by the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV). Patients m
could be manic, depressed, or mixed, with or without psychotic characteristics. Once in the open-label pl
required to be stabilized on quetiapine plus lithium or divalproex for a minimum of 12 weeks, (mean was
were to continue either lithium or divalproex, and were randomized to quetiapine twice daily for a total da

milligrams (mg) to 800 mg or to placebo. The primary outcome was time to recurrence of a mood event. defined as medication intervention, or requirement of hospitalization for a mood occurrence, a Young Ma (YMRS) score, or a Montgomery-Asberg Depression Rating Scale (MADRS) score greater than or equal discontinuation of study due to a mood event. During the double-blind phase, by day 280, approximately quetiapine group discontinued, and by day 117, approximately 50% of patients in the placebo group disc revealed quetiapine as superior to placebo at improving length of time before recurrence of any mood ev was independent of subgroup specifics, such as concomitant mood stabilizers, gender, age, race, or mo episode, or rapid cycling episode (Prod Info SEROQUEL(R) oral tablets, 2008a)

4.5.B.4 Bipolar disorder - Cocaine dependence

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

A small, 12-week, open-label, add-on study (n=17) demonstrated that quetiapine may be effective ir symptoms and drug cravings in patients with bipolar disorder and comorbid cocaine dependence (B

c) Adult:

1) The results of an open-label study indicate that quetiapine therapy may be effective in decreasing psy and drug cravings in patients with bipolar disorder and cocaine dependence. In this small, 12-week, ope patients with bipolar I or II disorder with comorbid cocaine dependence received quetiapine at initial dose milligrams (mg) daily with weekly titrations as indicated for symptoms (mean dose at exit, 229 mg/day)(n was an add-on therapy, patients continued to take their current psychiatric medications and those enrolle treatment programs continued with that therapy as well. Psychiatric symptoms were measured at baselir intervals using the Hamilton Depression Rating Scale (HDRS), and Young Mania Rating Scale (YMRS). were assessed at baseline and at weekly intervals using a version of the Cocaine Craving Questionnaire report of dollar amount spent on cocaine was used to assess weekly drug use. In the intent to treat grou HDRS, YMRS, and BPRS were significantly decreased from baseline to exit (p less than 0.01). In additic significantly reduced from baseline to exit in this group (p=0.05). Money spent on cocaine, days of drug u positive urine drug screens were reduced; however, this change was not significant (Brown et al, 2002).

4.5.B.5 Delirium

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Effective in the treatment of delirium in two small, prospective, open-label studies (Pae et al, 2004; Sasa

c) Adult:

1) Low-dose quetiapine therapy may be effective in the treatment of delirium. In a prospective, open-lab Korean patients (mean age, 69 years; age range, 48 to 85 years) with delirium secondary to a medical c lung cancer, intra- cranial hemorrhage, cerebrovascular attack, femur neck fracture, or acquired immune received quetiapine for the treatment of delirious symptoms. Patients received quetiapine at a mean dail milligrams (mg) (initial mean dose, 37.5 mg/day; maximum mean dose, 177.3 mg/day) for an average of reductions in the mean severity scores for the Delirium Rating Scale-revised-98 (DRS-R-98) and Clinical Severity (CGI-S) scale were observed from baseline to post-treatment (21.8 vs 9.3 and 4.9 vs 2.1, respe 0.0001, both values). A reduction in the DRS-R-98 and CGI-S scores of at least 50% was observed in 19 (77.3%) patients, respectively. Sedation was the most common adverse event and no extrapyramidal sy observed. Controlled trials are needed to confirm these findings (Pae et al, 2004).

2) Symptoms of delirium resolved in twelve patients (mean age 67.3 years) following treatment with que prospective, open-label study, patients with delirium received oral quetiapine (mean dose, 44.9 milligram mean dose, 63.5 mg/day) at flexible dosing schedules for a time period lasting at least until remission of was defined as a Delirium Rating Scale-Japanese version (DRS-J) score of less than 12 points in additic assessment that symptoms of delirium had remitted clinically. Remission of delirium was achieved in all following a mean treatment duration of 4.8 days. From baseline to time of remission, the mean DRS-J sc 18.1 to 9.3. In an assessment of 8 of the 12 patients, the mean score for the Mini Mental Health State Ex version significantly improved from 19.6 at baseline to 24 after remission (p=0.0256). No adverse events quetiapine was generally well tolerated. Randomized, controlled studies are needed to substantiate thes al, 2003).

4.5.B.6 Delirium, Refractory

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive

Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Improved symptoms of treatment-refractory delirium in two hospitalized patients (52-year-old male and 5
Samarrai et al, 2003)

c) Adult:
1) Quetiapine therapy improved symptoms of agitation and aggression in two hospitalized patients with
delirium. A 52 year-old male and a 50-year-old female patient with delirium refractory to treatment with ri
haloperidol responded to quetiapine therapy. Trials of quetiapine in the male and female patient (initial 5
titrated to 400 mg/day and 200 mg/day, respectively) effectively controlled aggression and agitation in bo
improved cognitive ability (Al-Samarrai et al, 2003).

4.5.B.7 Dementia
See Drug Consult reference: BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA

4.5.B.8 Gilles de la Tourette's syndrome

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Pediatric, Evidence favors efficacy
Recommendation: Pediatric, Class IIb
Strength of Evidence: Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
In a small, 8-week, prospective, open-label study (n=12) of pediatric patients with Tourette's disorder, pa
reduction in motor and phonic tics with quetiapine therapy (Mukaddes & Abali, 2003)

c) Pediatric:
1) Quetiapine therapy was effective in the reduction of motor and phonic tics in pediatric patients with To
prospective, open-label study (n=12) patients 8 to 16 years of age (11 boys, 1 girl) with Tourette's disord
quetiapine therapy at an initial dose of 25 milligrams (mg) daily, titrated to maximum doses of 75 mg/day
100 mg/day (12 years and older). The mean dose of quetiapine was 72.9 mg/day with a range of 50 to 1
total tic score of the Yale Global Tic Severity Scale was significantly reduced from baseline to 4 weeks (6
respectively; p less than 0.01), and from baseline to 8 weeks (61.17 vs 24.17, respectively; p less than 0
patients demonstrated a 30% to 100% improvement in tic severity (mean change, 61.91; 95% CI=50.03
Mild, transient sedation was reported in three patients; however, extrapyramidal adverse effects and stat
weight gain were not observed. Larger, randomized, controlled studies are needed to confirm the safety
quetiapine for the treatment of Tourette's disorder in children (Mukaddes & Abali, 2003).

4.5.B.9 Manic bipolar I disorder
FDA Labeled Indication

a) Overview
FDA Approval: Adult, yes (regular-release oral tablets); Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Indicated for the treatment of acute manic episodes associated with bipolar I disorder as either mon
therapy to lithium or divalproex (Prod Info SEROQUEL(R) oral tablets, 2008a)
As monotherapy, two studies revealed that quetiapine was more effective than placebo in the treatm
patients with bipolar I disorder (McIntyre et al, 2005; Bowden et al, 2005)
As adjunct therapy, quetiapine was more effective than placebo in the treatment of acute manic sym
bipolar I mania(Sachs et al, 2004; Yatham et al, 2004)

c) Adult:
1) Monotherapy
a) Quetiapine monotherapy was more effective than placebo in the treatment of acute mania in pati
disorder. This international, 12 week, multicenter, double-blind, parallel-group study randomized pat
quetiapine (n=107), lithium (n=98), or placebo (n=95). Primary inclusion criteria allowed for adult pat
hospitalized for less than 3 weeks, with diagnosis of bipolar I disorder, and who were presently expe
manic episode based on the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (
were required to have at least 1 previously, well documented manic or mixed episode, however, pat
and mixed episodes, based on DSM-IV criteria were excluded. Patients required a score of at least
Young Mania Rating Scale (YMRS), items of irritability, speech, content, and disruptive/aggressive b
baseline YMRS scores for the quetiapine group was (32.7) and (34) for the placebo group. Quetiapi
as a flexible, twice daily dose, starting at 100 milligrams (mg) on day 1, 200 mg on day 2, 300 mg or
on day 4. By day 5, the patients' dose could be increased to 600 mg/day, and up to 800 mg/day from
84. The average dose of quetiapine in the responders was 586 mg/day in the week prior to day 21.
was the change from baseline of the YMRS score at day 21. The parallel group evaluated lithium ve

and secondary outcomes were analyzed on the intent to treat (ITT) groups and included all randomi
at least 1 dose of study treatment and who had at least 1 set of post-baseline YMRS scores. The av
was 38 years and 56.1% of them were male. At day 21, change in YMRS score from baseline was s
in the quetiapine groups versus placebo (-14.62 vs -6.71; p less than 0.001). Change in YMRS scor
versus placebo group was also statistically significant (-15.20 vs -6.71; p less than 0.001); however,
between quetiapine and lithium groups was not significant. Secondary outcomes of note include sig
in the change in YRMS score from baseline through treatment day 84 (-20.28 vs -9; p less than 0.0
defined as 50% or greater reduction in YMRS score from baseline at day 21 were significant (53.3%
0.001). YMRS remission rates, defined as a YMRS score of 12 or less at day 21 were also significar
less than 0.001). Adverse effects were considered mild to moderate. The most common, occurring a
included dry mouth, somnolence, weight gain, dizziness, insomnia, headache, asthenia, depression
(Bowden et al, 2005).

b) Quetiapine monotherapy was more effective than placebo in the treatment of acute mania in pati
disorder. This international, 12 week, multicenter, double-blind, parallel-group study randomized pat
quetiapine (n=101), haloperidol (n=98), or placebo (n=100). Primary inclusion criteria allowed for ad
age of 42.8 years, 36.6% male, who were hospitalized for less than 3 weeks, with diagnosis of bipol
without psychotic characteristics, and who were presently experiencing an acute manic episode bas
and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV). Patients were required to have
well documented manic or mixed episode, however, patients with rapid cycling and mixed episodes
criteria were excluded. Patients required a score of at least 4, on 2 of the core Young Mania Rating
of irritability, speech, content, and disruptive/aggressive behavior. Mean baseline YMRS scores for t
was (34) and (33.1) for the placebo group. Quetiapine was administered twice daily, starting at 100 r
1, 200 mg on day 2, 300 mg on day 3, and 400 mg on day 4. By day 5, the patients' dose could be i
mg/day based on efficacy and tolerability, and up to 800 mg/day thereafter from treatment days 6 to
recommended target dose was 600 mg/day. The average dose of quetiapine in the responders was
primary outcome was the change from baseline of the YMRS score at day 21. The parallel group ev
versus placebo. Primary and secondary outcomes were analyzed on the intent to treat (ITT) groups
randomized patients who took at least 1 dose of study treatment and who had at least 1 set of post-
scores. At day 21, change in YMRS score from baseline was statistically significant in the quetiapine
placebo (-12.29 vs -8.32; p less than 0.01). Change in YMRS scores for the haloperidol versus plac
statistically significant (-15.71 vs -8.32; p less than 0.001). Secondary outcome of change from base
day 84 revealed quetiapine and haloperidol treated patients continued to experience statistically sig
17.52 and -18.92 vs -9.48, respectively; p less than 0.001 for both comparisons to placebo). The mo
effects occurring greater than 10% included insomnia, somnolence, and extrapyramidal-related effe
and extrapyramidal syndromes were significantly more frequent with haloperidol compared to quetia
less than 0.001) (McIntyre et al, 2005).

2) Adjunct Therapy

a) Quetiapine with lithium or divalproex was more effective than lithium or divalproex monotherapy
acute mania in patients with bipolar I disorder. This 3-week, double blind, placebo controlled, paralle
patients to receive quetiapine (n=81) as add on therapy to lithium or divalproex versus placebo (n=8
divalproex. Inclusion criteria allowed for adult patients, average age of 39.6 years, 49 patients were
of bipolar I disorder based on the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edit
required hospitalization for less than 3 weeks for a current manic episode and treatment with lithium
least 7 days of the immediately preceding 28 days prior to randomization. Patients were also require
previously, well documented manic or mixed episode prior to the current episode, and a score of at l
core YMRS items of irritability, speech, content, and disruptive/aggressive behavior. Patients with ra
were excluded. Eligible patients either began or continued lithium or divalproex on day 1 of study. Q
administered twice daily, morning and evening, starting at 100 milligram (mg) on day 1, 200 mg on d
3, and 400 mg on day 4. By day 5, the patients' dose could range from 200 milligram per day (mg/da
based on efficacy and tolerability, and up to 800 mg/day on days 6 to 21. Study guidelines encourag
quetiapine dosage to at least 600 mg/day prior to patients withdrawing from the study due to lack of
last-week quetiapine dose among the responders was 584 mg/day. The primary outcome was the ch
the YMRS score at final assessment. Mean baseline YMRS scores for the quetiapine with lithium or
(31.5) and (31.1) for the placebo group. Outcomes were analyzed on the intent to treat (ITT) groups
YMRS score from baseline was statistically significant in the quetiapine group versus placebo (-13.7
Secondary outcomes, also statistically significant were YRMS response rates, defined as 50% or gr
YMRS score from baseline at day 21, (54.3% vs 32.6%; p=0.005). As well as, YMRS remission rate
score of 12 or less at day 21, (45.7% vs 25.8%; p=0.007). The most common adverse effects occur
were somnolence, headache, dry mouth, asthenia, postural hypotension, and dizziness (Sachs et al

b) Quetiapine with lithium or divalproex was more effective than lithium or divalproex monotherapy
acute mania in patients with bipolar I disorder. This double blind, placebo controlled study randomiz
quetiapine (n=185) as add on therapy to lithium or divalproex versus placebo (n=185) with lithium or
weeks or 6 weeks duration. Eligible patients were adult patients, average age of 39.2 years, 54.1% r
bipolar I disorder, with or without psychotic features, based on the Diagnostic and Statistical Manual
Fourth Edition (DSM-IV). Patients required hospitalization for less than 3 weeks for a current manic
with lithium or divalproex for at least 7 days prior to randomization, and a history of at least 1 manic
the last 5 years. Patients with rapidly cycling or mixed episodes were excluded. Patients required a
on 2 of the core Young Mania Rating Scale (YMRS) items of irritability, speech, content, and disrupt

behavior, and a score of 4 or greater on the Clinical Global Impression-Bipolar (CGI-BP) Severity of
randomization, patients were to continue lithium or divalproex treatment. Clinicians could adjust lithi
doses for efficacy, for reduction of adverse effects, and for established, therapeutic range (0.7 to 1.0
liter, (mEq/L) lithium, or 50 to 100 microgram per milliliter (mcg/mL) divalproex). Quetiapine was adn
starting at 100 milligram per day (mg/day) on day 1, 200 mg/day on day 2, 300 mg/day on day 3, an
4. By day 5, quetiapine could be administered up to 600 mg/day, and up to 800 mg/day from day 6 t
treatment. By day 21, the average dose of quetiapine in the responders was 492 mg/day. The prima
change from baseline of the YMRS score at day 21. Because the protocol was identical for the 3 we
treatment group, the results were combined for analysis to increase the power of the study to identif
important effects. Mean baseline YMRS scores for the quetiapine with lithium or divalproex group wa
the placebo group. Outcomes were analyzed on the intent to treat (ITT) groups. At day 21, change i
baseline was statistically significant in the quetiapine group versus placebo (-15.29 vs -12.19; p less
statistically significant secondary outcomes were change in response rate, defined as 50% or greate
score from baseline at day 21, (55.7% vs 41.6%; p less than 0.01). YMRS remission rates, defined a
or less at day 21, was statistically significant (48.7% vs 33%; p less than 0.01). Common adverse ef
or greater, and at least twice that of placebo were somnolence, dry mouth, asthenia, postural hypote
and pharyngitis (Yatham et al, 2004).

4.5.B.10 Obsessive-compulsive disorder, Refractory

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Obsessive-compulsive disorder (OCD) symptoms were reduced when quetiapine was added to SSRI (se
reuptake inhibitor) treatment (Denys et al, 2002; Mohr et al, 2002)

c) Adult:

1) The addition of quetiapine to selective serotonin reuptake inhibitor (SSRI) therapy was effective in pro
of symptom activity in patients with treatment-refractory obsessive-compulsive disorder (OCD). In a sma
patients with at least a 5-year history of OCD symptoms who failed a minimum of 3 adequate treatments
scored at least 18 on the Yale-Brown Obsessive Compulsive Scale (YBOCS) received quetiapine for 8 w
their current SSRI (n=10). Using a fixed dosing schedule, quetiapine was given at an initial dose of 75 m
titrated to 200 mg/day (100 mg/day in week 2, 150 mg/day in week 3, 200 mg/day in week 4). Overall, th
reduction (35.4%) in patients' mean YBOCS score from baseline to endpoint (p=0.002). Quetiapine was
sedation being the most common adverse event (Denys et al, 2002).

2) Symptoms of obsessive-compulsive disorder (OCD) were reduced by treatment with quetiapine, in co
selective serotonin reuptake inhibitor (SSRI). The charts of 8 patients who had been treated for OCD by
tolerated dose of an SSRI for at least 12 weeks and who were then given add- on treatment of quetiapin
Quetiapine doses were started at 25 milligrams (mg) daily and increased to a maximum of 300 mg daily.
Brown Obsessive-Compulsive Scale improved for 4 of the patients, at doses of 50, 75 (2 patients), and 3
patient was unable to tolerate quetiapine (Mohr et al, 2002).

4.5.B.11 Parkinson's disease - Psychotic disorder

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

In several studies and case reports, quetiapine therapy controlled psychotic symptoms in patients with P
(Fernandez et al, 2000; Weiner et al, 2000; Fernandez et al, 1999; Friedman & Factor, 2000a)(Parsa & E

c) Adult:

1) A study designed to measure the effectiveness of clozapine replacement by quetiapine in 15 patients
induced psychosis in Parkinson's disease concluded that quetiapine is an effective alternative to clozapi
assessed at baseline, and 4 and 8 weeks after discontinuation of clozapine. At baseline, the starting cloz
reduced by 6.25 milligrams (mg) per week for 2 weeks, 12.5 mg per week for 2 weeks, and 25 mg per w
was discontinued. The baseline initiation dose of quetiapine was 12.5 mg daily for 1 week and was incre
mg per day until the patient was no longer receiving clozapine. Quetiapine dosage adjustments were per
titration period, which ranged from 1 to 10 weeks. The average quetiapine ending dose was 62.5 mg. An
standardized weekly telephone interview was performed on all patients and their caregivers. Twelve of th
transition without a worsening of cognition or loss of antipsychotic effect at the 4 and 8-week visits. All 12
quetiapine. Side-effects noted were mild and transient. Only 1 patient had increased dyskinesia and 4 pa
transient worsening of tremor. At the end of 12 months, 9 of 12 patients were stable on quetiapine. Two
experienced a decline in motor function switched back to clozapine (Fernandez et al, 2000).

2) An 81-year-old man with a 14-year history of Parkinson's disease who developed levodopa-induced p

successfully treated with quetiapine after olanzapine was discontinued due to worsened parkinsonism. Q
6 weeks after the discontinuation of olanzapine and was titrated to a dose of 25 milligrams at bedtime. T
complete resolution of hallucinations, complete resolution of belligerent behavior, and no worsening of pa
al, 2000).
3) Quetiapine was shown to be beneficial and well tolerated in the treatment of drug-induced psychosis
Parkinson's disease (PD) (Fernandez et al, 1999). Thirty-five patients received a mean daily dose of que
milligrams. Of 24 neuroleptic-naive patients, 20 reported marked improvement of psychosis without a co
motor function. There was a clinically and statistically significant (p=0.024) improvement in Brief Psychia
(BPRS) in the patients that had a baseline and 4-week follow-up assessment. Five patients were able to
a transition from clozapine or olanzapine to quetiapine, while 6 could not due to confusion, erratic behavi
hallucinations. The data suggests quetiapine may be beneficial to treat DIP in PD but it should be used v
replacing other atypical antipsychotic drugs.
4) In a review of several smaller studies (n= 10 to 40), quetiapine (25 to 300 milligrams/day) was succes
Psychiatric Rating Scale (BPRS) scores and improving or not worsening motor functions (Friedman & Fa
5) A 52-week open-label pilot study reported successful use of quetiapine in treating psychosis in two ne
patients with Parkinson's disease (1 with and 1 without dementia) (Parsa & Bastani, 1998). For each pati
introduced at 25 milligrams (mg) per day; it was increased to a maximum dose of 200 mg/day over 16 we
without dementia (a 74-year-old man) and 400 mg/day over 12 weeks for the patient with dementia (a 74
Severity of psychiatric symptoms was measured by the Brief Psychiatric Rating Scale and a Clinical Glob
Severity of Illness scale. Treatment successfully controlled psychotic symptoms without worsening motor
patients, although improvement was not as pronounced in the patient with dementia.

4.5.B.12 Posttraumatic stress disorder

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Adjunctive quetiapine therapy reduced the posttraumatic stress disorder (PTSD) symptoms of a 49-year-
with severe PTSD (Sattar et al, 2002)

c) Adult:

1) Adjunctive quetiapine therapy reduced symptoms in one patient suffering from posttraumatic stress d
year-old Caucasian male with severe PTSD received adjunctive treatment with quetiapine after therapy w
of paroxetine (titrated to 40 milligrams (mg)/day) failed to control his symptoms. Initially, he received que
bedtime for 2 days, but continued to be irritable and anxious. The dose was then increased to 100 mg at
following 3 days his symptoms eased, however periodic episodes of severe anxiety persisted during the
dose was increased to 25 mg twice daily and 100 mg at bedtime and he showed continued improvement
His scores on the Hamilton-D rating scale for Depression (HAM-D) and clinician-administered PTSD scre
from 40 and 98 (on admission) to 11 and 60, respectively. His symptoms remained controlled at this dos
months. No adverse events were reported (Sattar et al, 2002).

4.5.B.13 Schizophrenia

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, no
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIa; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Quetiapine is indicated for the treatment of schizophrenia (Prod Info SEROQUEL(R) oral tablets, 20
SEROQUEL XR(TM) extended-release oral tablets, 2007)
In 3 short-term (6-week) controlled-trials of patients with schizophrenia who met DSM III-R criteria fo
higher quetiapine doses were generally more effective than lower doses in treating patients with sch
DSM III-R criteria for schizophrenia (Prod Info SEROQUEL(R) oral tablets, 2007b)
Moderate degree of efficacy for treating positive and negative symptoms in schizophrenic patients ir
studies (Wetzel et al, 1995b; Fulton & Goa, 1995b; Fabre et al, 1995b; Borison et al, 1996b; Anon, 1
In one 6-week placebo-controlled trial (n=109), the efficacy of quetiapine was not sustained beyond
(Borison et al, 1996b)
In an open-label, 12-week, prospective study (n=56), oral quetiapine, at doses ranging from 200 to 8
was well tolerated and yielded clinical benefit in symptoms of early-onset schizopreniform-spectrum
adolescents (Schimmelmann et al, 2007)
In a small, open-label study (n=10) of adolescents, quetiapine was well tolerated and effective in the
schizoaffective disorder or bipolar disorder with psychotic features (McConville et al, 2000; McConvi

c) Adult:

1) In 3 short-term (6-week) controlled-trials of patients with schizophrenia who met DSM III-R criteria for

quetiapine doses were generally more effective than lower doses in treating patients with schizophrenia
criteria for schizophrenia. One of the trials used a single fixed dose haloperidol arm as a comparative tre
single group was inadequate to provide a reliable and valid comparison of quetiapine and haloperidol (Pr
(R) oral tablets, 2007b).

a) A placebo-controlled trial (n=361) that involved 5 fixed doses of quetiapine 75, 150, 300, 600 and
day (mg/day) in 3 divided doses reported that the 4 highest doses were superior to placebo on the B
Scale (BPRS) total score, the BPRS psychosis cluster and the Clinical Global Impression (CGI) sev
maximal effect was observed at 300 mg/day, and this dose was superior to placebo on the Scale for
Symptoms (SANS). The observed effects of 150 to 750 mg/day were generally identical (Prod Info S
tablets, 2007b).

b) Another placebo-controlled trial (n=286) that involved the titration of quetiapine in high (up to 750
(mg/day) in 3 divided doses) and low (up to 250 mg/day in 3 divided doses) doses reported that only
quetiapine group was superior to placebo on the Brief Psychiatric Rating Scale (BPRS) total score, t
cluster, the Clinical Global Impression (CGI) severity score, and the Scale for Assessing Negative S
(Prod Info SEROQUEL(R) oral tablets, 2007b).

c) A dose regimen comparison trial (n=618) that compared two fixed doses of quetiapine (450 millig
3 divided doses and 50 mg/day in 2 divided doses) reported that only the 450 mg/day (225 mg twice
was superior to the 50 mg/day (25 mg twice daily) quetiapine dose group on the Brief Psychiatric Ra
total score, the BPRS psychosis cluster, the Clinical Global Impression (CGI) severity score, and on
Assessing Negative Symptoms (SANS) (Prod Info SEROQUEL(R) oral tablets, 2007b).

2) A 6-week, fixed-dose, placebo-controlled trial of patients who met DSM IV criteria for schizophrenia (r
that 400 milligram (mg), 600 mg, and 800 mg once daily doses of extended-release quetiapine were sup
Therapy was initiated with extended-release tablets at 300 mg/day (once daily) on Day 1. The dose was
400 mg or 600 mg on Day 2 or to 800 mg by Day 3. Change between baseline and endpoint (Day 42) fo
Negative Syndrome Scall (PANSS) was used as the primary efficacy measure. Analysis of PANSS total
quetiapine extended-release doses of 400 mg, 600 mg and 800 mg were all superior to placebo (Prod In
(TM) extended-release oral tablets, 2007).

3) Several open (Wetzel et al, 1995b; Fulton & Goa, 1995b) and placebo-controlled studies (Fabre et al,
1996b; Anon, 1995b; Fulton & Goa, 1995b) of short duration (6 weeks or less) have suggested the effica
for treating both positive and negative symptoms of schizophrenia (mostly patients with acute exacerbati
chronic illness). In these trials, effects of treatment were mainly evaluated by the Brief Psychiatric Rating
Clinical Global Impression (CGI) Severity of Illness score, and the modified Scale for Assessment of Neg
(SANS). Clinical responses were observed within 2 weeks of starting quetiapine therapy and were best v
300 milligrams daily; in one study, doses of up to 750 milligrams daily (mean, 360 milligrams daily) were
to lower doses (up to 250 milligrams daily; mean, 209 milligrams daily) and placebo at week 6 of treatme
and SANS (Anon, 1995b). The severity of extrapyramidal symptoms (EPS) was similar in patients treate
quetiapine.

4) Quetiapine therapy in 145 patients diagnosed with psychotic mood disorders was reviewed. All patier
with quetiapine, and 20% received quetiapine alone while 80% received other psychoactive drugs with q
was associated with more substantial clinical effects in patients with affective psychoses and in patients
chronically ill. The response rate for the majority of psychiatric diagnoses studied was equal or superior t
schizophrenia. These preliminary findings suggest that quetiapine may be useful as an alternative or adj
patients with affective psychosis when used with mood stabilizers. Controlled studies are needed (Zarate

5) An uncontrolled trial in elderly patients with psychotic disorders found quetiapine to be associated wit
improvement and to be well tolerated (McManus et al, 1999). An interim statistical analysis was performe
week 12. The median total daily dose of quetiapine was 100 milligrams/day. The most common adverse
the central nervous system (somnolence, dizziness, agitation) and cardiovascular system (postural hypo
Extrapyramidal symptoms occurred in 6% of patients. Mean Simpson-Angus Scale total score showed si
(p less than 0.0001) at endpoint. In addition, Brief Psychiatric Rating Scale (BPRS) and Clinical Global Ir
scores showed significant (p less than 0.0001 and p less than 0.01, respectively) improvement. This non
supports the need for further controlled clinical trials of quetiapine use in the elderly.

6) Considerable interindividual differences in the response to quetiapine have been reported (Wetzel et
Goa, 1995b), and in larger placebo-controlled trials, differences in favor of quetiapine have not always re
significance or were marginally significant and beneficial changes from baseline scores were at times sm
questionable clinical significance; up to one-third of patients receiving quetiapine have dropped out of tre
efficacy (Fulton & Goa, 1995b; Borison et al, 1996b; Anon, 1995b). One 6-week placebo-controlled trial (
1996b) reported a significant reduction in BPRS and CGI scores with oral quetiapine for three of the first
there was no significant difference in scores between placebo and quetiapine at week 6. Improvement in
sustained with quetiapine on days 21 to 42, although statistical significance was barely achieved. Thirty
treated patients discontinued therapy due to lack of benefit in this study.

d) Pediatric:

1) In an open-label, 12-week, prospective study (n=56), treatment with oral quetiapine, at doses ranging
milligrams (mg) per day, was well tolerated and led to significant improvement in symptoms of early-onse
spectrum disorders in adolescents. Following a 1- to 9-day washout period of prior psychoactive medicat
age, 15.9 years; range, 12-17.9 years; 67.9% male) meeting the DSM-IV criteria for schizophrenia, schiz
schizophreniform disorder and had a Positive and Negative Syndrome Scale (PANSS) total score of 60 o
with quetiapine for 12 weeks. Following a fixed titration protocol during week 1 (50 mg at day 1 increased
7), the quetiapine dose was adjusted based on clinical response and tolerability to a range of 200 to 800

dose, 605.6 mg/day (week 6) and 584.2 mg/day (week 12)). The use of benztropine (1 to 6 mg/day) to tr
symptoms (EPS) and benzodiazepines (diazepam or lorazepam; up to 40 mg/day of diazepam equivaler
agitation, or sleep disturbances were allowed during the study. Assessments occurred at weekly visits ur
visits every other week during weeks 6-12. The majority of study patients (76.8%) were antipsychotic-nai
week 12, 51.8% (n=25/52) of study participants had dropped out, with 30.4% discontinuing due to lack o
modified intent-to-treat (ie, patients with at least 1 post-baseline efficacy measurement) revealed a signif
mean +/- standard deviation PANSS total score (primary endpoint) from baseline (91.5 +/- 17.2) to week
less than 0.0001), yielding a difference of 24.9 points (95% confidence interval (CI), 17.3 to 32.4; effect s
difference was evident as early as week 1 and was maintained throughout the study. A 50% reduction in
occurred in 34.6% (n=18/52) at a median of 85 days while 51.9% (n=27/52) had a 40% reduction in PAN
median of 57 days. Among the PANSS sub-scales, the effect size at week 12 was greater for the positive
5.2 at baseline to 14.9 +/- 6.9; 95% CI, 4.8 to 9.1; effect size=0.91) than the negative sub-scale (22.8 +/-
18.2 +/- 8.7; 95% CI, 2 to 7.1; effect size=0.5). Additionally, significant improvements occurred among th
impulsivity/hostility, and anxiety/depression sub-scales of the PANSS, along with the Clinical Global Impr
Illness scale (5.2 +/- 0.9 at baseline to 3.7 +/- 1.8 at week 12) and the Subjective Well-being under Neuro
Scale (75.5 +/- 17.6 at baseline to 7.5 +/- 17.1 at week 12). Adverse events occurred in 78.6% of patient
(21.4%), fatigue (17.9%), and headache (17.9%) being the most common. Five (8.9%) and 2 (3.6%) pati
least 1 moderate EPS (at doses of 400 to 600 mg/day) and mild-to-moderate akithisia (at doses of 500 to
respectively; however, none required treatment or resulted in study discontinuation. Compared to baselir
significant increase in weight and BMI at week 12 (mean increase, 6.2 kilograms (weight), 2.1 kilograms/
with 60.7% of patients gaining more than 7% of their baseline weight (Schimmelmann et al, 2007).

2) A small study (n=10) of adolescents ranging in age from 12.3 through 15.9 years concluded quetiapir
and effective in the treatment of schizoaffective disorder or bipolar disorder with psychotic features. Quet
open-label, rising-dose trial was initiated at 25 milligrams (mg) twice daily and reached 400 mg twice dail
concluded on day 23. Quetiapine improved both positive and negative symptoms significantly (p less tha
and endpoint symptoms were compared and there were no unexpected side effects (McConville et al, 20
of this trial, all ten patients continued open-label treatment with quetiapine (initial, 800 mg/day titrated ov
optimal dose; mean dose, 600 mg/day) for up to 88 weeks. Significant improvements in mean scores fro
were seen at all time points through week 64 for the Brief Psychiatric Rating Scale (BPRS) and Clinical G
(CGI) Severity of Illness scale (p less than 0.05). Improvements in mean scores on the Scale for Assessi
Symptoms (SANS) were significant through week 52 (p less than 0.05). Quetiapine was well tolerated ar
were mild to moderate, with somnolence (60%), headache (50%), and pharyngitis (40%) being reported
Extrapyramidal symptoms were not observed during the trial, however, 30% of patients reported increas
body mass index as a "mild" adverse event. Larger, controlled studies are needed to further establish lor
efficacy and safety in this patient population (McConville et al, 2003).

4.5.B.14 Schizophrenia, Maintenance

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes (extended release only); Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

The extended-release formulation of quetiapine fumarate is indicated for the maintenance treatment
(Prod Info SEROQUEL(R)XR extended-release oral tablets, 2007)
In a randomized, double-blind, extension study (n=171), continued treatment with extended-release
400 to 800 milligrams per day led to a longer time to relapse compared to placebo in adult patients v
stabilized during 16 weeks of an open-label trial (Prod Info SEROQUEL(R)XR extended-release ora

c) Adult:

1) Maintenance treatment with extended-release quetiapine fumarate (quetiapine XR), at doses of 400 t
per day, led to a statistically significant delay in relapse compared to placebo in the double-blind, random
of an open-label trial. Clinically stable adult outpatients (n=171) who met the Diagnostic and Statistical M
Disorders (4th edition) criteria for schizophrenia and who remained stable following 16 weeks of open-lal
quetiapine XR 400 to 800 mg/day were included. Patients who had a Clinical Global Impression (CGI)-S
less and a Positive and Negative Syndrome Scale (PANSS) total score of 60 or less beginning to end of
(not exceeding a 10- or greater point increase in PANSS total score) were considered to be stabilized. In
extension phase, patients were randomized to continue receiving quetiapine XR at their current dose or
observed for possible relapse, which was defined as a 30% or greater increase in the PANSS total score
score of 6 or greater, hospitalization due to worsening of schizophrenia, or need for any other antipsycho
Treatment with quetiapine XR led to a significantly longer time to relapse than placebo (Prod Info SERO
release oral tablets, 2007).

4.5.B.15 Tardive dyskinesia

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy

Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Quetiapine treatment improved symptoms in three women with tardive dyskinesia (Chari et al, 2002)

c) Adult:
1) Treatment with quetiapine reduced persistent symptoms of tardive dyskinesia in three women receivi therapy. A 42-year-old Caucasian woman with a 25-year history of schizophrenia and scoring a 22 on th Involuntary Movement Scale (AIMS) was prescribed quetiapine for tardive dyskinesia. Within a year and treatment she no longer scored on the scale. The tardive dyskinesia symptoms of a 63-year-old Caucasi year history of schizoaffective disorder were also successfully treated with quetiapine. After a year of the was reduced from 19 to 3. In addition, a 52-year-old Asian woman with a 5-year history of psychotic illne quetiapine for tardive dyskinesia and after 24 weeks of treatment her AIMS score dropped from 17 to 10 are needed to substantiate these findings (Chari et al, 2002).

4.6 Comparative Efficacy / Evaluation With Other Therapies

Chlorpromazine

Haloperidol

Olanzapine

Paliperidone

Perphenazine

Risperidone

Ziprasidone

4.6.A Chlorpromazine

4.6.A.1 Schizophrenia

a) Based upon comparisons of minimum effective dosages identified in placebo- controlled, fixed-dose and f drug development trials, the minimum effective dose of quetiapine was 150 milligrams/day (equivalent to chlo milligrams/day) (Woods SW, 2003).

b) Quetiapine 75 to 750 milligrams daily (mean, 407 mg daily) offered no significant advantage over chlorpro milligrams daily (mean, 384 mg daily) in a double-blind, parallel-group trial involving patients with acute exace subchronic schizophrenia, or schizophreniform disorder (n=201). Both drugs were associated with similar red Psychiatric Rating Scale (BPRS) scores, Clinical Global Impression (CGI) scores, and negative scale scores Negative Syndrome Scale (PANSS) (negative symptom assessment). The severity of extrapyramidal sympto comparable (assessed by Simpson scale) (Fulton & Goa, 1995a).

4.6.B Haloperidol

4.6.B.1 Schizophrenia

a) In a study involving 361 patients, quetiapine (across 5 fixed doses) was found to be superior to placebo in symptoms in schizophrenic patients, while haloperidol (12 milligrams/day) was not. Additionally, depressive s improved in a greater proportion of patients treated with quetiapine versus haloperidol or placebo. None of th withdrew from the study due to extrapyramidal symptoms, while 4 haloperidol and 1 placebo patient withdrew Glazer, 2000).

b) A 6-week, multicenter, double-blind trial comparing quetiapine and haloperidol (mean total daily doses of milligrams, respectively) in the treatment of acute exacerbation of schizophrenia concluded that quetiapine in better tolerated than haloperidol. Both agents produced clear reductions in the Positive and Negative Syndro Clinical Global Impression Severity of Illness and Global Improvement scores. Quetiapine was better tolerate extrapyramidal symptoms. In addition, mean serum prolactin concentration decreased in quetiapine patients haloperidol patients (Copolov et al, 2000).

4.6.C Olanzapine

4.6.C.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp

generation antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychoti
before 18 months. Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 t
(mg/day), perphenazine 8 to 32 mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or zipr
mg/day for up to 19 months. Overall, 74% of patients discontinued treatment for any cause before 18 months
ranged from 64 to 82%. Time to discontinuation ranged from 3.5 months for ziprasidone to 9.2 months with o
discontinuation was significantly longer in the olanzapine group as compared with the quetiapine (hazard rati
confidence interval (CI), 0.52 to 0.76; p less than 0.001) or risperidone groups (HR, 0.75; 95% CI, 0.62 to 0.9
discontinuation due to adverse events were similar between all groups, but the rates ranged from 10% for risp
olanzapine (p=0.04). More patients discontinued olanzapine due to greater weight gain (average of 0.9 kilogr
greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides (Lieberman et al, 2005).

4.6.D Paliperidone

4.6.D.1 Schizophrenia, Recent exacerbation, in hospitalized patients

a) In a randomized, double-blind, placebo- and active-controlled clinical trial (n=394), treatment with paliperic
(ER) produced significantly improved Positive and Negative Syndrome Scale (PANSS) total scores compared
hospitalized patients with a recent exacerbation of schizophrenia. Hospitalized patients 18 to 65 years of age
(defined as lasting less than 4 weeks but more than 4 days) of schizophrenia (paranoid, disorganized, or und
diagnosed using Diagnostic and Statistical Manual of Mental Disorders Fourth edition (DSM-IV)), a Clinical G
Severity (CGI-S) scale score of 5 or greater, and symptom scores of 4 or greater on 2 or more of the following
hostility, excitement, tension, uncooperativeness, and poor impulse control (with a combined score of these it
were eligible for enrollment. Following the discontinuation of all psychotropic agents, patients were randomize
paliperidone ER (n=157; baseline mean PANSS total score, 102.8 +/- 13.1 points), quetiapine (n=157; baseli
score, 101.3 +/- 13.3 points), or placebo (n=80; baseline mean PANSS total score, 103.8 +/- 15.7 points). In a
phase, paliperidone ER was initiated at 6 milligrams (mg)/day on days 1 to 3 and then increased to 9 mg/day
an optional dose increase to 12 mg/day starting on day 8 if necessary (mean dose, 10.4 +/- 1.7 mg/day) and
at 50 mg/day on day 1, 100 mg/day on day 2, 200 mg/day on day 3, 400 mg/day on day 4, 600 mg/day on da
dose increase to 800 mg/day on day 8 (mean dose, 690.9 +/- 134.3 mg/day). Psychotropic medications (excl
additional paliperidone ER or quetiapine) could be added following the 14-day monotherapy phase (one or m
agents: paliperidone ER, 52.9%; quetiapine, 55.4%; placebo, 66.7%). The least-squares mean PANSS total s
baseline to day 14 was significantly decreased in the paliperidone ER arm (-23.4 +/- 1.8 (standard error (SE))
with the quetiapine arm (-17.1 +/- 1.8 (SE) points; p less than 0.001) (primary endpoint) and the placebo arm
between group analyses (using a least-squares mean differences in change scores with the last observation
patients in the paliperidone ER arm had significantly improved PANSS total score, PANSS scale negative sy
PANSS scale disorganized thoughts scores, PANSS scale uncontrolled hostility/excitement scores, and CGI-
with patients in the quetiapine and placebo arms at day 14 and at the end of 6 weeks of treatment (day 42) (T
the PANSS scale positive symptoms score (PANSS-P) and Clinical Global Impression of Change (CGI-C) sc
improved in the paliperidone ER arm compared with the quetiapine and placebo arms at day 14 and paliperic
improved PANSS-P and CGI-C compared with placebo at day 42 (Table 1). Serious adverse events were rep
and 2.5% of patients in the paliperidone ER, quetiapine, and placebo arms, respectively. Extrapyramidal sym
significantly (p less than 0.001) higher in the paliperidone ER arm following the 14-day monotherapy phase c
quetiapine using the Simpson-Angus Rating Scale (total score). The incidence of movement disorders at day
significantly different between the 3 arms using the Barnes Akathisia Rating Scale and the Abnormal Involunt
(Canuso et al, 2009).

Table 1: Between Group Analyses

Outcome measures	Day 14			Day 42	
PANSS score Mean (SE)	Paliperidone ER versus Quetiapine	Paliperidone ER versus Placebo	Quetiapine versus Placebo	Paliperidone ER versus Quetiapine	Paliperido ER versus Placebo
Total	-6.3* (1.8)	-8.4* (2.2)	-2.1 (2.2)	-4.7* (2)	-7.8* (2.
Positive symptoms	-1.6* (0.6)	-2.1* (0.7)	-0.5 (0.7)	-1.1 (0.6)	-1.9* (0.

4.6.E Perphenazine

4.6.E.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp generation antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychoti before 18 months. Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 t (mg/day), perphenazine 8 to 32 mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or zipr mg/day for up to 19 months. Overall, 74% of patients discontinued treatment for any cause before 18 months ranged from 64 to 82%. Time to discontinuation ranged from 3.5 months for ziprasidone to 9.2 months with o discontinuation was significantly longer in the olanzapine group as compared with the quetiapine (hazard rati confidence interval (CI), 0.52 to 0.76; p less than 0.001) or risperidone groups (HR, 0.75; 95% CI, 0.62 to 0.9 discontinuation due to adverse events were similar between all groups, but the rates ranged from 10% for risp olanzapine (p=0.04). More patients discontinued olanzapine due to greater weight gain (average of 0.9 kilogr greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides (Lieberman et al, 2005).

4.6.F Risperidone

Chronic schizophrenia

Psychotic disorder

4.6.F.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp generation antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychoti before 18 months. Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 t (mg/day), perphenazine 8 to 32 mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or zipr mg/day for up to 19 months. Overall, 74% of patients discontinued treatment for any cause before 18 months ranged from 64 to 82%. Time to discontinuation ranged from 3.5 months for ziprasidone to 9.2 months with o discontinuation was significantly longer in the olanzapine group as compared with the quetiapine (hazard rati confidence interval (CI), 0.52 to 0.76; p less than 0.001) or risperidone groups (HR, 0.75; 95% CI, 0.62 to 0.9 discontinuation due to adverse events were similar between all groups, but the rates ranged from 10% for risp olanzapine (p=0.04). More patients discontinued olanzapine due to greater weight gain (average of 0.9 kilogr greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides (Lieberman et al, 2005).

4.6.F.2 Psychotic disorder

a) Quetiapine and risperidone were similarly efficacious in treating psychotic symptoms and had similar over quetiapine treatment resulted in fewer extrapyramidal symptoms (EPS) and was more effective in reducing d month, open-label study, patients with schizophrenia, schizoaffective disorder, or other psychotic disorders (i disorder, major depressive disorder and various forms of dementia) were randomized in a ratio of 3:1 to recei or risperidone (n=175). The starting dosage of quetiapine was 50 milligrams/day (mg/day), which was increas increments every 1 to 2 days, to a maximum of 800 mg/day, given in divided doses. Risperidone was started with upward titration to a target dose of 3 mg twice daily by day 3. Dosages were individually titrated to maxin minimizing adverse reactions (mean prescribed dose: quetiapine 253.9 mg, risperidone 4.4 mg). At the begin approximately half of each group had EPS. There was a steady decline in the number of patients reporting EI the study progressed. The incidence of EPS in the quetiapine group was lower than in the risperidone group 47.3) but not at the end of the study (38.6 vs 39.2). The percentage of patients requiring a change of treatme requiring anti-EPS medication was lower in the quetiapine group than in the risperidone group (7% vs 20.5%) third of patients in each group withdrew before completion of the study. A higher percentage withdrew from ri for lack of efficacy (10.3% vs 5.8%) and a higher percentage withdrew from quetiapine treatment because of vs 5.1%). Somnolence was the most common adverse event in both groups, followed by dry mouth and dizzi occurred significantly more often with quetiapine treatment (p less than 0.05). Occurrence of weight gain was (Mullen et al, 2001).

4.6.G Ziprasidone

4.6.G.1 Chronic schizophrenia

a) When newer antipsychotic medications (olanzapine, quetiapine, risperidone, and ziprasidone) were comp generation antipsychotic, perphenazine, the majority of patients in each group discontinued their antipsychoti before 18 months. Patients (n=1493) with chronic schizophrenia were randomized to receive olanzapine 7.5 t

(mg/day), perphenazine 8 to 32 mg/day, quetiapine 200 to 800 mg/day, risperidone 1.5 to 6.0 mg/day, or zipr
mg/day for up to 19 months. Overall, 74% of patients discontinued treatment for any cause before 18 months
ranged from 64 to 82%. Time to discontinuation ranged from 3.5 months for ziprasidone to 9.2 months with o
discontinuation was significantly longer in the olanzapine group as compared with the quetiapine (hazard rati
confidence interval (CI), 0.52 to 0.76; p less than 0.001) or risperidone groups (HR, 0.75; 95% CI, 0.62 to 0.9
discontinuation due to adverse events were similar between all groups, but the rates ranged from 10% for ris
olanzapine (p=0.04). More patients discontinued olanzapine due to greater weight gain (average of 0.9 kilogr
greater increases in glycosylated hemoglobin, total cholesterol, and triglycerides (Lieberman et al, 2005).

DRUGDEX® Evaluations

DOXEPIN

0.0 Overview

1) Class

a) This drug is a member of the following class(es):

Antianxiety
Antidepressant
Antidepressant, Tricyclic
Antiulcer
Dermatological Agent

2) Dosing Information

a) Doxepin Hydrochloride

1) Adult

a) Alcoholism - Anxiety - Depression

1) very mild, 25 to 50 mg/day ORALLY initially, gradually increase as needed (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

2) mild to moderate, 75 mg ORALLY per day in single or divided doses, increase as needed; usual range is 75 to 150 mg/day (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

b) Anxiety - Depression

1) very mild, 25 to 50 mg/day ORALLY initially, gradually increase as needed (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

2) mild to moderate, 75 mg ORALLY per day in single or divided doses, increase as needed; usual range is 75 to 150 mg/day (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

c) Anxiety - Depression - Psychoneurotic personality disorder

1) outpatients: 75 mg/day ORALLY (divided into 1-3 doses); may increase up to a MAX of 150 mg/day

2) inpatients: 150 mg/day ORALLY (divided into 1-3 doses); may increase up to a MAX of 300 mg/day

d) Pruritus (Moderate), Due to atopic dermatitis or lichen simplex chronicus

1) 10 mg ORALLY at bedtime; may gradually increase to 25 mg ORALLY at bedtime

2) apply a thin film TOPICALLY to skin 4 times a day (3-4 hr between applications) for a MAX of 8 days

2) Pediatric

a) safety and effectiveness in children below the age of 12 years have not been established

1) Alcoholism - Anxiety - Depression

a) (12 years and older) very mild, 25 to 50 mg/day ORALLY initially, gradually increase as needed (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

b) (12 years and older) mild to moderate, 75 mg ORALLY per day in single or divided doses, increase as needed; usual range is 75 to 150 mg/day (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

2) Anxiety - Depression

a) (12 years and older) very mild, 25 to 50 mg/day ORALLY initially, gradually increase as needed (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

b) (12 years and older) mild to moderate, 75 mg ORALLY per day in single or divided doses, increase as needed; usual range is 75 to 150 mg/day (max, 300 mg/day) (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

3) Contraindications

a) Doxepin Hydrochloride

1) glaucoma (Prod Info SINEQUAN(R) oral capsules, 2007)

2) hypersensitivity to doxepin, other dibenzoxepines, or any component of the product (Prod Info SINEQUAN(R) oral capsules, 2007)

3) urinary retention (Prod Info SINEQUAN(R) oral capsules, 2007)

4) Serious Adverse Effects

a) Doxepin Hydrochloride

1) Agranulocytosis
2) Depression, worsening
3) Hypertension
4) Hypotension
5) Leukopenia
6) Pancytopenia
7) Purpuric disorder
8) Suicidal thoughts
9) Suicide
10) Tachyarrhythmia

11) Thrombocytopenia

5) Clinical Applications
a) Doxepin Hydrochloride
1) FDA Approved Indications
a) Alcoholism - Anxiety - Depression
b) Anxiety - Depression
c) Anxiety - Depression - Psychoneurotic personality disorder
d) Pruritus (Moderate), Due to atopic dermatitis or lichen simplex chronicus

1.0 Dosing Information

Drug Properties

Storage and Stability

Adult Dosage

Pediatric Dosage

1.1 Drug Properties

A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product Index)
B) Synonyms
Doxepin
Doxepin HCl
Doxepin Hydrochloride
C) Physicochemical Properties
1) Molecular Weight
a) 316 (Prod Info Zonalon, 94)

1.2 Storage and Stability

A) Oral route
1) Preparation and storage of bulk dilutions of the concentrate is not recommended (Prod Info Sinequan(R), 2004).
2) Store capsules at a controlled room temperature of 15 to 30 degrees Celsius (59 to 86 degrees Fahrenheit). Dispense in a tight, light-resistant container with a child-resistant closure (Prod Info Adapin(R), 1995).
3) Store doxepin topical cream at or below 27 degrees C (80 degrees F) (Prod Info Zonalon(R), 2004).

1.3 Adult Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage in Geriatric Patients

Dosage Adjustment During Dialysis

1.3.1 Normal Dosage

1.3.1.A Doxepin Hydrochloride

Oral route

Rectal route

Topical application route

1.3.1.A.1 Oral route

Anxiety - Depression

Urticaria

1.3.1.A.1.a Anxiety - Depression

1) Dosage ranges of 75 to 150 milligrams daily have been shown effective in anxiety associated with depression (Goldberg & Finnerty, 1972; Smith, 1971); (Goldstein, 1973)(Goldstein & Pinosky, 1969).

2) Doxepin in doses of 200 milligrams daily also have been shown effective and well tolerated in the elderly for anxiety-depression states (Bohlau et al, 1972).

3) Anxiety patients with psychotic symptoms may require higher doses than with neurotic illness (Pinder et al, 1977e).

4) DEPRESSION

a) Dosage must be individualized. Usual dosage range for outpatients is 75 to 150 milligrams daily and for hospitalized patients 150 to 300 milligrams daily (Grof et al, 1974; Bianchi et al, 1971a; Kiev, 1974; Gillmer, 1970). Additional therapeutic benefit is rarely obtained by using more than 300 milligrams/day (Prod Info Sinequan(R), 2004)(Prod Info Adapin(R), 1995a). However, initial and maintenance doses of 500 milligrams daily have been used (Krakowski, 1968).

b) Pulse dosing of doxepin (250 milligrams every 6 days) has not been found to be more effective than conventional dosing (Deuschle et al, 1997).

c) For patients on once-a-day dosing, the maximum recommended dose is 150 milligrams/day, usually given at bedtime (Prod Info Sinequan(R), 2004).

1.3.1.A.1.b Urticaria

1) Doxepin in doses of 10 to 30 milligrams orally daily has been effective in the treatment of IDIOPATHIC COLD URTICARIA (Neittaanmaki et al, 1984a).

2) Doxepin 5 milligrams orally twice daily was reported effective in the treatment of chronic idiopathic URTICARIA in a controlled study (Harto et al, 1985; Ledo et al, 1985).

3) Doxepin 25 milligrams orally three times daily was effective in the treatment of CHRONIC IDIOPATHIC URTICARIA in a placebo-controlled trial involving 16 adult patients (Goldsobel et al, 1986).

1.3.1.A.2 Rectal route

1.3.1.A.2.a Cancer pain; Adjunct

1) Doxepin capsules were administered rectally in four severely debilitated cancer patients with clinical neuropathic pain (Storey & Trumble, 1992). Commercially available capsules without modification were inserted rectally. Serum concentrations of N-desmethyldoxepin after two to five days of treatment with a constant dose of doxepin were 573 micrograms/milliliter and 403 micrograms/milliliter (with 50 milligrams three times daily), 204 micrograms/milliliter (with 50 milligrams twice daily) and less than 25 micrograms/milliliter (with 25 milligrams daily).

1.3.1.A.3 Topical application route

1.3.1.A.3.a Pruritus (Moderate), Due to atopic dermatitis or lichen simplex chronicus

1) Doxepin cream (5%), applied four times a day, with at least 3 to 4 hour intervals between applications, provides effective short-term (up to 8 days) management of moderate pruritus in adults with atopic dermatitis and lichen simplex chronicus (Prod Info Zonalon(R), 2004). Occlusive dressings should not be used with doxepin cream as it may increase dermal absorption.

1.3.1.A.4 MUCOSAL LOCAL

a) ORAL MUCOSAL PAIN

1) Five milliliters of a solution of doxepin 5 milligrams/milliliter, held in the mouth for 5 minutes and spat out, relieved mucosal pain in patients (n=41) with mucosal damage caused by cancer or cancer treatment. Relief lasted for more than 3 hours (Epstein et al, 2001).

1.3.1.A.5 LONG-TERM THERAPY

a) Long-term maintenance therapy with doxepin is safe and effective (Ayd, 1975a). Forty patients (31 to 73 years of age) were treated with doxepin 50 to 300 milligrams daily over a period of 57 to 93 months (total dose 194, 100 to 508, 500 milligrams) for recurrent depression. All patients experienced mood elevation, improved sleep and appetite, and increased energy and interest. Laboratory values revealed no serious toxicity and blood pressure was not significantly affected throughout therapy. Transient tachycardia with doses greater than 200 milligrams daily occurred in several patients and

weight gain in the first 6 months in a few other patients. Otherwise, adverse reactions were minimal.
b) Doxepin therapy has been used continuously for up to 15 years in the treatment of chronic depressive illness, with maintenance of efficacy and a low order of toxicity. Continuous therapy for 5 to 15 years in 52 patients did not reveal any changes in hematologic, renal or hepatic function tests, and the drug was well tolerated in patients with concomitant cardiovascular disorders (Ayd, 1984).

1.3.1.A.6 ONCE DAILY DOSING

a) The major portion or total daily dose of doxepin administered at bedtime is effective and may be of benefit in decreasing the incidence of daytime drowsiness. SINGLE BEDTIME DOSE is also of benefit in patients with mixed anxiety-depression with resultant sleep disturbances (Goldberg et al, 1974; Mendels & Schless, 1975). If the once-a-day schedule is used, the maximum daily dose is 150 milligrams/day (Prod Info Adapin(R), 1995a).

1.3.1.A.7 ORAL CONCENTRATE DILUTION

a) Doxepin oral concentrate should be diluted just prior to administration, with 120 milliliters water, skim milk, whole milk, orange juice, grapefruit juice, tomato juice, prune juice, or pineapple juice (Prod Info Sinequan(R), 2004).
b) Doxepin oral concentrate is not compatible in many carbonated beverages (Prod Info Sinequan(R), 2004).
c) Patients who are on methadone maintenance and require doxepin concentrate can mix the methadone and doxepin together and then dilute the mixture in Gatorade(R), lemonade, orange juice, sugar water, Tang(R), or water. Grape juice should not be used (Prod Info Sinequan(R), 2004).

1.3.1.A.8 WITHDRAWAL SCHEDULE

a) Delirium upon abrupt withdrawal of doxepin has been reported in a single case (Santos and McCurdy, 1980). After 2 weeks of therapy for depression, doxepin was abruptly discontinued because of lack of response and undue sedation. Two days later, the patient exhibited impaired attention, concentration, and short-term memory. He was agitated and moderately diaphoretic. Two days later, an abnormal EEG was recorded. Symptoms disappeared and the EEG returned to normal in 2 weeks. The patient had also been taking disulfiram, which could have contributed to the reaction.
b) Gradual reduction in dosage will prevent development of withdrawal symptoms (Prod Info Adapin (R), 1995a).

1.3.2 Dosage in Renal Failure

A) Doxepin Hydrochloride

1) Based upon the small amount of doxepin excreted unchanged in the urine, no dosage adjustment would appear to be necessary (Bennett et al, 1994a).

1.3.3 Dosage in Hepatic Insufficiency

A) Doxepin Hydrochloride

1) Data for other tricyclic antidepressants suggests the use of doxepin in patients with liver disease may result in increases in the incidence of adverse reactions. Dosage should be reduced and adjusted gradually.

1.3.4 Dosage in Geriatric Patients

A) Doxepin Hydrochloride

1) Caution should be taken when selecting a dosage schedule in an elderly patient. Therapy should be initiated on the low end of the dosing range to account for decreased hepatic, renal, or cardiac function or concomitant diseases/drug regimens that may be present in this patient population (Prod Info Sinequan(R), 2004)(FDA, 2000).
2) Dosage should be individualized with adjustments based upon patient response. Initial dosage should be 25 to 50 milligrams with adjustments made gradually (Pinder et al, 1977e).
3) Clinical guidelines for utilizing antidepressants in the treatment of depression in geriatric patients have been reviewed (Salzman, 1985).

1.3.5 Dosage Adjustment During Dialysis

A) Doxepin Hydrochloride

1) No dosage supplement is required in patients following hemodialysis or peritoneal dialysis (Bennett et al, 1994a).

1.4 Pediatric Dosage

1.4.1 Normal Dosage

1.4.1.A Doxepin Hydrochloride

1.4.1.A.1 Oral route

a) DOXEPIN is not recommended for use in children under 12 years of age (Prod Info Sinequan(R), 2004).

2.0 Pharmacokinetics

Onset and Duration

Drug Concentration Levels

ADME

2.1 Onset and Duration

A) Onset

1) Initial Response

a) Depression, oral: 2 to 3 weeks (Gilman et al, 1985b).

1) DOXEPIN may have an onset sooner than other tricyclic antidepressants (Barranco et al, 1979).

b) Anxiety, oral: 5 to 6 days (Pereira & Lipke, 1970)(DuBois, 1969).

2.2 Drug Concentration Levels

A) Therapeutic Drug Concentration

1) Depression, greater than 100 ng/mL (parent compound with active metabolite, desmethyldoxepin) (Amsterdam et al, 1980).

a) Other studies have found no correlation between serum concentration and therapeutic response (Ward et al, 1982; Brunswick et al, 1983; Norman et al, 1980).

b) Therapeutic response has been associated with 20 ng/mL or above of the active metabolite desmethyldoxepin (Pinder et al, 1977b).

B) Time to Peak Concentration

1) Oral: 30 minutes to 1 hour (Pinder et al, 1977b).

2) TOPICAL: 1.32 hours (Drake et al, 1999).

a) Time to peak concentration was 1.32 hours with a maximum concentration of 0.41 mcg/L in 12 subjects with pruritic atopic dermatitis who applied topical DOXEPIN 4 times daily every 4 hours for 7 days (Drake et al, 1999).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

Extracorporeal Elimination

2.3.1 Absorption

A) Bioavailability

1) Oral: well-absorbed (Pinder et al, 1977b).

2) Topical, percutaneous absorption may occur (Prod Info Zonalon(R), 1999).

a) Plasma DOXEPIN concentrations ranged from undetectable to 46 ng/mL in 19 eczema patients using topical doxepin (Prod Info Zonalon(R), 1999).

2.3.2 Distribution

A) Distribution Sites

1) Protein Binding

a) 79% to 84% (Virtanen et al, 1982)

2) OTHER DISTRIBUTION SITES

a) Tissues, initially high in the liver, kidney, spleen and lung. Large amounts of the active metabolite (desmethyldoxepin) also found in tissues (Hobbs, 1969).

B) Distribution Kinetics

1) Volume of Distribution

a) 9 to 33 L/kg (Bennett et al, 1994).

2.3.3 Metabolism

A) Metabolism Sites and Kinetics
1) LIVER
a) DOXEPIN undergoes hepatic metabolism to the active metabolite desmethyldoxepin (Prod Info Zonalon(R), 1999).
B) Metabolites
1) Desmethyldoxepin, active (Pinder et al, 1977b).
2) Doxepin-N-oxide, hydroxydoxepin and hydroxydoxepin glucuronide (Hobbs, 1969).

2.3.4 Excretion
A) Kidney
1) Renal Excretion (%)
a) 0.5% (Kimura, 1972a).
B) Other
1) OTHER EXCRETION
a) Bile, small amounts (Kimura, 1972).

2.3.5 Elimination Half-life
A) Parent Compound
1) ELIMINATION HALF-LIFE
a) 16.8 hours (range: 8 to 25 hours) (Bennett et al, 1994; Faulkner et al, 1983; Amsterdam et al, 1980).
B) Metabolites
1) Desmethyldoxepin, 51.3 hours (range: 33.2 to 80.7 hours) (Amsterdam et al, 1980).
a) Desmethyldoxepin half-life ranges from 28 to 52 hours (Prod Info Zonalon(R), 1999).

2.3.6 Extracorporeal Elimination
A) Hemodialysis
1) Dialyzable: No (Anderson et al, 1976).
a) Only 7.6% of DOXEPIN and 13.9% of desmethyldoxepin is extracted by hemodialysis (Faulkner et al, 1984).
B) Peritoneal
1) Dialyzable: No (Anderson et al, 1976).

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING
1) Doxepin Hydrochloride
a) Oral (Capsule; Solution)
Suicidality and Antidepressant Drugs
Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorders. Anyone considering the use of doxepin hydrochloride or any other antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antidepressants compared to placebo in adults beyond age 24; there was a reduction in risk with antidepressants compared to placebo in adults aged 65 and older. Depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide. Patients of all ages who are started on antidepressant therapy should be monitored appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber. Doxepin hydrochloride is not approved for use in pediatric patients (Prod Info SINEQUAN(R) oral capsules, 2007).

3.1 Contraindications
A) Doxepin Hydrochloride
1) glaucoma (Prod Info SINEQUAN(R) oral capsules, 2007)
2) hypersensitivity to doxepin, other dibenzoxepines, or any component of the product (Prod Info SINEQUAN(R)

oral capsules, 2007)
3) urinary retention (Prod Info SINEQUAN(R) oral capsules, 2007)

3.2 Precautions

A) Doxepin Hydrochloride

1) suicidal ideation and behavior or worsening depression; increased risk, particularly in children, adolescents, and young adults during the first few months of therapy or following changes in dosage (Prod Info SINEQUAN(R) oral capsules, 2007)
2) alcohol, excessive use; increased danger of intentional or unintentional doxepin overdose (Prod Info SINEQUAN(R) oral capsules, 2007)
3) bipolar disorder; increased risk of precipitation of a mixed/manic episode(Prod Info SINEQUAN(R) oral capsules, 2007)
4) concomitant use of monoamine oxidase inhibitors (MAOIs) or use of doxepin within 14 days of MAOI discontinuation (Prod Info SINEQUAN(R) oral capsules, 2007)
5) elderly; increased risk of confusion and oversedation (Prod Info SINEQUAN(R) oral capsules, 2007)

3.3 Adverse Reactions

Cardiovascular Effects

Dermatologic Effects

Endocrine/Metabolic Effects

Gastrointestinal Effects

Hematologic Effects

Hepatic Effects

Immunologic Effects

Ophthalmic Effects

Otic Effects

Psychiatric Effects

Renal Effects

Reproductive Effects

Other

3.3.1 Cardiovascular Effects

3.3.1.A Doxepin Hydrochloride

Abnormal ECG

Cardiovascular finding

Hypotension

3.3.1.A.1 Abnormal ECG

a) ELECTROCARDIOGRAPHIC CHANGES have been reported with doxepin and manifest as INCREASED PR INTERVAL and PROLONGATION OF QRS COMPLEX. Some studies suggest doxepin has a relatively lesser influence on intracardiac conduction than other tricyclic antidepressants (Pinder et al, 1977f).

b) Available evidence does not support the contention that DOXEPIN is the antidepressant of choice for the treatment of depression in cardiac patients or the elderly. The incidence of toxicity of the drug in therapeutic and toxic doses appears to be similar to that of other tricyclic antidepressants. In therapeutic doses, doxepin is capable of producing prolongations of the PR, QRS, and QTc intervals, ST-T changes, sinus tachycardia, bundle branch block, arrhythmias, orthostatic hypotension, and rarely congestive heart failure. Additionally, in higher doses (overdose), the drug is capable of producing second or third degree AV block, atrial or ventricular arrhythmias, supine hypotension, and decreases in myocardial contractility (Marshall & Forker, 1982ah). However, therapeutic doses of doxepin in healthy adult patients are generally free of clinically important adverse cardiovascular effects, except for orthostatic hypotension (Mahapatra et al, 1986; Cassem, 1982; Glassman, 1984; Glassman & Bigger, 1981). Patients at highest risk are those with preexisting bundle branch block; these patients are at greater risk of developing potentially serious conduction abnormalities during tricyclic antidepressant therapy as compared to patients with normal pretreatment EKG's (Roose et al, 1987; Glassman & Bigger, 1981).

c) Tricyclic antidepressants are thought to resemble quinidine with respect to certain effects on cardiac rhythm (Glassman, 1984; Glassman & Bigger, 1981). Doxepin may be associated with the improvement of ventricular arrhythmias when used in the treatment of depression in some patients. The efficacy of doxepin as an antiarrhythmic agent was studied in 10 cardiac patients with symptoms of frequent ventricular premature depolarizations in a dose-ranging study. Suppression of ventricular premature depolarizations (equal to or greater than 80%) was observed in 4 patients (40%) with doxepin administration; 4 of 8 patients with pairs arrhythmia and 4 of 6 with ventricular tachycardia had 90% or greater suppression. Mean maximal doxepin doses were 115 mg daily, with mean nadir total doxepin concentrations being 61 ng/mL (mean nadir total desmethyldoxepin concentrations, 51 ng/mL). Increases in heart rate and PR, QRS and QTc intervals were also observed. No significant change in resting mean left ventricular ejection fraction was observed with doxepin, even in patients with moderate to severely diminished left ventricular performance. However, sedation and other side effects (dry mouth, weight gain, light-headedness, constipation, hypotension) limited dose ranging in this study, precluding complete evaluation of the antiarrhythmic efficacy of doxepin (Giardina et al, 1987a). More studies are required in larger patient populations, possibly using lower doses, to more fully evaluate antiarrhythmic effects of doxepin.

3.3.1.A.2 Cardiovascular finding

a) According to one study, the use of higher-dose tricyclic antidepressants (TCAs) was associated with an increased risk of SUDDEN CARDIAC DEATH, while lower doses did not increase this risk. In a cohort study including 481,744 persons and 1487 cases of sudden cardiac death occurring in a community setting, researchers found that compared to non-use, the current use of TCAs was associated with a dose-related increase in the risk of sudden cardiac death. For doses lower than 100 milligrams (mg) (amitriptyline or its equivalent), the rate ratio was 0.97 (95% CI, 0.72 to 1.29), however this increased to 2.53 (95% CI, 1.04 to 6.12) for doses of 300 mg or more (p=0.03, test for dose-response). In the entire cohort, users of TCAs in doses of 100 mg or higher (amitriptyline or its equivalent) had a 41% increased rate of sudden cardiac death (rate ratio, 1.41; 95% CI, 1.02 to 1.95). However, TCAs taken in doses of less than 100 mg (amitriptyline or its equivalent) were not associated with an increased risk of sudden cardiac death in the entire cohort or in any subgroups, including persons with treated cardiovascular disease. Use of selective serotonin reuptake inhibitors was not associated with an increased risk of sudden cardiac death (rate ratio, 0.95; 95% CI, 0.42 to 2.15) (Ray et al, 2004).

b) A systematic study of the cardiovascular effects of doxepin was conducted in depressed patients with preexisting cardiovascular disease. Doxepin had little effect on heart rate and did not adversely affect left ventricular function, but did have a significant antiarrhythmic effect, slowed cardiac conduction, and caused a significant increase in orthostatic hypotension. Five (16%) of the 32 patients dropped out of the study due to cardiovascular effects. The authors concluded that doxepin provided no more cardiovascular safety than imipramine or nortriptyline (Roose et al, 1991).

c) In a comparison of the cardiovascular effects of maprotiline (75 to 225 mg/day) with doxepin (50 to 200 mg/day) in 49 elderly depressed patients, there were no significant differences in orthostatic hypotension. Maprotiline caused fewer premature ventricular contractions (PVCs) and a longer PRS interval. Both drugs had a small but significant effect on heart rate and PR interval (Ahles et al, 1984).

d) VENTRICULAR ARRHYTHMIAS associated with doxepin and amitriptyline occurred in a 57-year-old man with preexisting heart disease. The patient was treated with a total doxepin dose of 250 mg/day, and after discontinuation of the cardiac medications, he developed a quadrigeminy pattern of ventricular premature depolarizations (VPDs) without atrioventricular or intraventricular conduction defects. Upon discontinuation of doxepin, progressive decrease of the VPDs were seen. Subsequent challenge with amitriptyline again resulted in VPDs which also ceased upon discontinuation of the drug. For this

patient, doxepin had no advantage over amitriptyline in terms of relative cardiotoxicity. A significant correlation was found between the occurrence of premature ventricular depolarization and serum levels of both antidepressants (Todd & Faber, 1983).
e) Since an overdose of tricyclic antidepressants has been associated with cardiotoxicity, it has been assumed that tricyclic antidepressants should not be used in cardiac patients. This theory has been evaluated in a double-blind, randomized trial involving 24 depressed patients with heart disease treated with imipramine, doxepin, or placebo for 4 weeks (Veith et al, 1982). Many patients were also receiving cardiac medications throughout the trial period. Patients were administered imipramine or doxepin 50 milligrams (mg) at bedtime or placebo. Doses were gradually increased every 3 days until side effects or a dose of 150 mg given at bedtime was achieved. After examination revealed that there was no evidence of cardiovascular adverse effects in patients receiving tricyclic antidepressants, dosages were allowed to be increased over 150 mg. Two patients required doses less than 50 mg/day due to severe nausea, ataxia, and sedation. As measured by radionuclide ventriculograms, tricyclic antidepressants had no effect on left ventricular ejection fraction at rest or during maximal exercise. The incidence of premature ventricular contractions was reduced in patients treated with imipramine; however, no consistent change was observed in patients receiving doxepin or placebo. Imipramine- and doxepin-treated patients showed a significant improvement (p less than 0.001) in depression when compared with placebo-treated patients. This study would indicate that in the absence of severe impairment of myocardial performance, depressed patients with preexisting heart disease can be treated effectively with imipramine or doxepin without an adverse effect on ventricular rhythm or hemodynamic function. However, further evaluation of the tricyclics and their effect on cardiovascular function is required.
f) The literature was reviewed to ascertain the validity of suggestions that doxepin caused fewer cardiovascular effects than other antidepressants (Luchins, 1983). After reviewing the studies comparing antidepressant effects on cardiac conduction, cardiac rhythm, heart rate, blood pressure, and mechanical function of the heart, the author concluded that there is little evidence that doxepin has fewer cardiovascular effects than other antidepressants.

3.3.1.A.3 Hypotension

a) Incidence: rare
b) POSTURAL HYPOTENSION and TACHYCARDIA have been reported during doxepin therapy at an incidence of 3% to 4% (Pitts, 1969).

3.3.2 Dermatologic Effects

3.3.2.A Doxepin Hydrochloride

Contact dermatitis

Skin irritation

3.3.2.A.1 Contact dermatitis

a) Severe allergic contact dermatitis was reported in 6 patients after they used doxepin 5% cream for 2 weeks to 7 months (Shelley et al, 1996). Even though dosage recommendations limit its use to 8 days, many patients use it for a much longer period. Angioedema-like swelling, photodermatitis, and generalized weeping dermatitis were some of the reactions described. All patients were patch tested to rule out a reaction to the vehicle ingredients in the cream. The authors suggest that doxepin's histamine blocking activity may augment cell-mediated hypersensitivity.
b) A 40-year-old man developed vesicular eczema on his arms and legs within 2 weeks of initiation of DOXEPIN 5% cream for pruritic epidermolysis bullosa pruriginosa. The eczema cleared after withdrawal of doxepin. He had not previously used the oral form of this drug (Wakelin & Rycroft, 1999).

3.3.2.A.2 Skin irritation

a) The manufacturer reports that 23% of patients treated with doxepin 5% cream experienced stinging and/or burning at the site of application. Although mild in most instances, 25% of the patients who experienced this reaction categorized it as severe (Prod Info Zonalon(R), 2004).

3.3.3 Endocrine/Metabolic Effects

3.3.3.A Doxepin Hydrochloride

Body temperature above normal

Endocrine finding

Syndrome of inappropriate antidiuretic hormone secretion

Weight gain

3.3.3.A.1 Body temperature above normal

a) Drug fever associated with antidepressant use was reported in a 47-year-old woman with a history of major depression who was treated with a variety of antidepressants including doxepin, amitriptyline, trazodone, imipramine, maprotiline, and fluoxetine. Each time the remission of depression coincided with a low-grade fever, malaise, and sore throat. Upon discontinuation of the drug, the symptoms resolved and depression reappeared. The authors postulated this may be due to the action of serotonin on thermoregulation and this was a particularly sensitive individual to this mechanism (Zajecka et al, 1991).

b) A NEUROLEPTIC MALIGNANT SYNDROME (NMS)-like condition occurred with the use of lithium and doxepin in a 64-year-old male with a history of depression with psychotic features. Previously, he had been successfully treated with lithium and haloperidol or electroconvulsive therapy (ECT); he was then treated with lithium 300 mg twice a day and doxepin 100 mg at bedtime for recurrent depression. In two weeks, he began having periods of confusion and disorientation and in another two weeks was admitted for urinary retention. His symptoms worsened after discontinuing the lithium and doxepin with gradual improvement shown on days 5 to 8. He demonstrated classic NMS symptoms in the absence of neuroleptic exposure (fever, muscle rigidity, changes in levels of consciousness, autonomic dysfunction). He later showed improvement with ECT (Rosenberg & Pearlman, 1991).

3.3.3.A.2 Endocrine finding

a) Changes in libido, GYNECOMASTIA, GALACTORRHEA, changes in blood sugar levels, and weight gain have also been reported with doxepin (Prod Info Adapin(R), 1995).

3.3.3.A.3 Syndrome of inappropriate antidiuretic hormone secretion

a) SIADH-induced hyponatremia has been reported rarely with tricyclic antidepressant use.

3.3.3.A.4 Weight gain

a) Weight gain has occurred during doxepin therapy (Forsen, 1975).

3.3.4 Gastrointestinal Effects

3.3.4.A Doxepin Hydrochloride

Dental caries

Disorder of taste

Gastroesophageal reflux disease

Gastrointestinal tract finding

Increased appetite

Stomatitis

3.3.4.A.1 Dental caries

a) Doxepin has moderate anticholinergic properties which may lead to decreased salivation resulting in the development of dental caries (Kastrup, 1987; Winer & Bahn, 1967).

3.3.4.A.2 Disorder of taste

a) Decreased taste sensitivity has been reported with doxepin use.

3.3.4.A.3 Gastroesophageal reflux disease

a) Gastroesophageal reflux has been reported rarely with tricyclic antidepressant use.

3.3.4.A.4 Gastrointestinal tract finding

a) NAUSEA and sometimes VOMITING has been associated with doxepin (Sterlin, 1970)(Pinder et al, 1977f).

b) DRY MOUTH has been reported to occur in up to 15% of patients treated with doxepin (Pinder et al,

1977f).
c) CONSTIPATION has been reported to occur in approximately 4% of patients receiving therapeutic doses of doxepin (Pinder et al, 1977f).

3.3.4.A.5 Increased appetite
a) An increased appetite and craving for sweets was reported in geriatric outpatients receiving doxepin and other antidepressants for depressive disorders or other psychiatric illnesses. Of 93 patients, 34% were taking doxepin (average daily dose 119 mg) and this group showed the highest positive relationship to excessive appetite, craving for sweets, and weight gain (Stein et al, 1985).

3.3.4.A.6 Stomatitis
a) A 34-year-old depressed, asthmatic patient was placed on doxepin (50 mg at bedtime) and suffered severe anticholinergic effects manifested as dry mouth, blurred vision, and constipation. During the second week of therapy, the dose was increased to 100 mg at bedtime and 5 days later the patient developed stomatitis. The symptoms completely resolved 4 days after discontinuation of doxepin (Salem et al, 1981).
b) Approximately 7 days after beginning ampicillin and doxepin 25 mg three times/day plus 100 mg at bedtime, a 48-year-old female developed painful papular lesions on the dorsal surface of her tongue. The lesions resolved over a 3-week period following discontinuation of both medications. Because doxepin was relieving her depression, she began 25 mg three times/day and 50 mg at bedtime for a second time. Eight days later, generalized pain and erythema of the tongue developed and subsided over a 2-week period following doxepin discontinuation (Ives & Stewart, 1980).

3.3.5 Hematologic Effects

3.3.5.A Doxepin Hydrochloride

Hematology finding

Thrombocytopenia

3.3.5.A.1 Hematology finding
a) Isolated cases of ANEMIA, LEUKOPENIA, LYMPHOPENIA, AGRANULOCYTOSIS, and NEUTROPHILIA have occurred during doxepin therapy (Prod Info Adapin(R), 1995; Swanson & Cook, 1977).
b) Surveying the literature, the hematological effects of doxepin (Sinequan(R)) seem infrequent and limited to rare cases of transient neutrophilia (Voina et al, 1971)(Glick, 1973). Only one case of thrombocytopenia has been attributed to doxepin, within our knowledge (Nixon, 1972). A 73-year-old female was given 75 mg/day for depression, prior to admission into a hospital. Initiation of symptoms occurred 6 days afterwards with bone marrow aspirations revealing megakaryocytic hyperplasia. The author did not rule out other concurrent antidepressants administered, such as amitriptyline, not the rapid discontinuation of prednisone therapy for bleeding diathesis, as the possible cause. However, the time relationship between doxepin dosing and subsequent adverse effects and doxepin structural similarity to amitriptyline, which is known to cause blood dyscrasias, did not rule out its chance as the source.
c) Coombs-positive HEMOLYTIC ANEMIA and thrombocytopenia with acute renal failure occurred after a patient received doxepin for approximately 5 weeks (50 to 100 mg orally daily). The patient recovered following withdrawal of doxepin, exchange transfusion, and repeated hemodialysis. Doxepin was the only medication taken by the patient (Wolf et al, 1989).
d) Four patients who were receiving tricyclic antidepressants developed severe unexpected postsurgical bleeding and loss of local anesthetic effect after undergoing nasal surgery. The authors suggested that this resulted from vasodilation resulting from chronic tricyclic antidepressant administration leading to increased blood supply as well as enhanced removal of cocaine from its site of action (Schechter et al, 1982).

3.3.5.A.2 Thrombocytopenia
a) Incidence: rare
b) Thrombocytopenia has been reported secondary to doxepin (Nixon, 1972). A 73-year-old female received doxepin 75 mg daily over a period of 6 days for severe depressive reaction. On the sixth day of therapy, the patient developed SUBCONJUNCTIVAL HEMORRHAGES, generalized oozing from the mouth, and showers of PETECHIAE over the extremities and trunk. Lab data at this time revealed platelet count 1200/cubic mm, prothrombin time 15/13 seconds, and normal PTT and Lee white clotting time. Immunoelectrophoresis was normal. Bone marrow aspirations revealed MEGAKARYOCYTIC-HYPERPLASIA with many young megakaryocytes and decreased iron stores. Doxepin was discontinued and the patient was treated with prednisone 60 mg daily. The platelet count increased to

103,000/cubic mm within 3 days. Prednisone dose was tapered and the patient was started on imipramine. This had no effect on platelet count and was ineffective in the treatment of her depression. Amitriptyline was started resulting in the development of thrombocytopenia which was unresponsive to prednisone. Amitriptyline was discontinued and the platelet count returned to normal.

3.3.6 Hepatic Effects

3.3.6.A Doxepin Hydrochloride

3.3.6.A.1 Hepatotoxicity

a) A previously well, 50-year-old man, experienced 3 separate episodes of acute hepatitis one week after taking small doses of doxepin (25 to 50 mg). Due to the patient's complete recovery between doxepin doses, the absence of other possible causes for recurrent hepatitis, and the temporal relationship between doxepin dose and icteric symptoms, a causal relationship was assumed (Keegan, 1993).

b) Liver function tests have been reported as abnormal in several studies with doxepin (Pinder et al, 1977f).

3.3.7 Immunologic Effects

3.3.7.A Doxepin Hydrochloride

3.3.7.A.1 Cross sensitivity reaction

a) Two patients developed a skin rash during therapy with desipramine (Norpramin(R)) and amitriptyline (Elavil(R)). Discontinuation of these medications in each patient resulted in subsidence of the skin rash. Doxepin was substituted in the patient receiving desipramine and imipramine was substituted in the patient receiving amitriptyline. On both occasions, recurrence of the rash did not occur. These data would suggest that substitution of a structurally dissimilar antidepressant agent is a viable alternative in patients developing allergic skin reactions (Salem et al, 1982).

b) In a double-blind, single dose, noncrossover study, 33 healthy adult volunteers (32 males, 1 female) received a single 25-mg dose of oral desipramine or doxepin. The duration of H1-receptor blockade by these two tricyclic antidepressants, doxepin (the most potent antihistamine) and desipramine (the least potent) were compared. Results showed significant differences in the suppression of the weal-and-flare responses to histamine between the two drugs (Rao et al, 1988a). Desipramine suppressed the wheal for 2 days and flare for one day, whereas doxepin suppressed the wheal for 4 days and flare for 6 days. These results suggest that doxepin should be withheld for at least 7 days before allergy skin testing.

3.3.8 Musculoskeletal Effects

3.3.8.A Doxepin Hydrochloride

Fracture of bone, Nonvertebral

Hip fracture

3.3.8.A.1 Fracture of bone, Nonvertebral

a) In a prospective, population-based, cohort study (n=7983) with a mean follow-up of 8.4 years, there was an increased risk of nonvertebral fracture in adult participants older than 55 years of age (mean age of 77.5 years) who were currently using an tricyclic antidepressant (TCA), including amitriptyline, clomipramine, dosulepine, doxepine, imipramine, maprotiline, nortriptyline, and opipramol, compared to those who were not exposed to antidepressants. Current TCA use was associated with an increased risk of nonvertebral fracture (hazard ratio (HR), 1.6; 95% confidence interval (CI), 1.08 to 2.38) compared with no antidepressant use. Current TCA use was also associated with an increased risk of nonvertebral fracture (HR, 1.6; 95% CI, 1.02 to 2.5) compared with past antidepressant use (n=1217). Duration of TCA use of greater than 6 months was not associated with an increased risk of fractures when compared with no antidepressant use and with past antidepressant use. Fractures of the hip (most frequent), wrist, humerus, and pelvis were reported (Ziere et al, 2008).

3.3.8.A.2 Hip fracture

a) An increased incidence of hip fracture was reported in elderly patients receiving psychotropic agents. This study was a case-control evaluation of 1021 patients with hip fractures and 5606 controls. An increased risk of hip fracture was observed with the use of hypnotic/anxiolytic agents with a long elimination half-life (greater than 24 hours), tricyclic antidepressants, and antipsychotic agents. Current users were defined as subjects who had received a prescription in the 30-day period prior to the admission date for initial hospitalization. The long half-life hypnotic/anxiolytic agents studied were

lorazepam, diazepam, chlordiazepoxide, and barbiturates (excluding phenobarbital). The tricyclic antidepressants included amitriptyline, doxepin, and imipramine; antipsychotic agents evaluated were thioridazine, haloperidol, chlorpromazine, and perphenazine-amitriptyline. In contrast, shorter-acting hypnotic-anxiolytic agents (half-life of 24 hours or less) were not associated with an increased risk of hip fracture in these patients. The most frequently used agents in this category were diphenhydramine, hydroxyzine, and chloral hydrate. The increased risk of hip fracture observed in this study was directly related to the doses of the drugs. Analysis for confounding by dementia did not alter the results. Additional studies are needed to confirm these results in this and other populations and to evaluate the effects of other psychotropic drugs that have less pronounced sedative effects (Ray et al, 1987).

3.3.9 Neurologic Effects

Doxepin

Doxepin Hydrochloride

3.3.9.A Doxepin

3.3.9.A.1 Seizure

See Drug Consult reference: COMPARATIVE INCIDENCE OF SEIZURES FROM ANTIDEPRESSANTS

3.3.9.B Doxepin Hydrochloride

Central nervous system finding

Extrapyramidal sign

Myoclonus

Seizure

Tardive dyskinesia

3.3.9.B.1 Central nervous system finding

a) DROWSINESS is the most frequently reported side effect of doxepin and appears to be dose related (Sterlin et al, 1970; Toru et al, 1972a; Goldstein & Pinosky, 1969). Even topically applied doxepin cream (5%) has caused drowsiness in greater than 20% of patients who used it, particularly when applied to greater than 10% of total body surface area (Prod Info Zonalon(R), 2004).
b) Euphoria does not appear to occur with doxepin therapy and there are no cases of PHYSICAL DEPENDENCE associated with the drug (Pinder et al, 1977f).
c) In a case report, topical administration of doxepin 5% cream resulted in altered mental status in a 5-year-old female. Due to a generalized eczematous rash over approximately 50% of the body surface, the patient was prescribed doxepin 5% cream to alleviate itching. Over the course of 24 hours, 30 grams of cream was applied to the rash and the following day the patient was difficult to arouse and responded only to noxious stimuli. Physical examination revealed 3 millimeter bilaterally active pupils, a temperature of 37.2 degrees Celsius, blood pressure of 102/62, sinus tachycardia (heart rate = 120 beats per minute), and a respiratory rate of 24 breaths per minute. Serum concentrations of doxepin and desmethyldoxepin (major active metabolite) were 11.95 nanograms per milliliter (ng/mL) and 17.71 ng/mL, respectively. Eighteen hours following skin decontamination with soap and water, a full recovery was made and the patient was discharged (Zell-Kanter et al, 2000).
d) Confusion, dizziness disorientation, headache, fatigue, weakness, numbness, paresthesias, and ataxia have also been reported with doxepin (Prod Info Adapin(R), 1995).

3.3.9.B.2 Extrapyramidal sign

a) Extrapyramidal side effects including TREMOR, AKATHISIA and GAIT DISTURBANCES have been reported (Pinder et al, 1977f).
b) Extrapyramidal symptoms were seen in 109 of 1116 patients receiving doxepin less than 75 mg to greater than 300 mg daily for periods of 4 to 52 weeks (Pitts, 1969).
c) A dystonic reaction occurred in a 30-year-old female who had been on antidepressant (amitriptyline 100 mg at bedtime) therapy for 3 years before discontinuing for a pregnancy. After giving birth, she took a 75-mg dose for insomnia and immediately developed dystonic symptoms. Treatment with doxepin

was started and titrated up to 300 mg at bedtime. After the third 300-mg dose, she had another dystonic reaction. Later she took a single 150-mg dose for insomnia with another reaction. All symptoms resolved within 24 hours after discontinuing the medication (Lee, 1988).

3.3.9.B.3 Myoclonus

a) A high incidence of myoclonus during cyclic antidepressant therapy was reported with imipramine, desipramine, amitriptyline, doxepin, trazodone, nortriptyline, and maprotiline (Garvey & Tollefson, 1987). Ninety-eight patients with major depression (93) or panic disorder were treated with these agents in initial doses of 50 mg daily of imipramine or its equivalent increasing to a maximum of 300 mg daily after several weeks. Of these patients, 39 (40%) developed myoclonus that was clinically significant in 9 (9%) and resulted in withdrawal of the antidepressant or a medication change. Myoclonus occurred within 1 month of therapy in 81% of the 39 patients, with 46% of patients developing myoclonus within 2 weeks. The mean dose of antidepressant being administered at the time of myoclonus was 169 mg daily in imipramine equivalents, which was similar to the mean dose utilized by the patients not developing myoclonus (164 mg daily). Myoclonus was reversible upon withdrawal of the antidepressant but persisted if medication changes were not initiated; however, spontaneous remission of myoclonus was observed in 9 patients. No predictors for the development of myoclonus were observed.

3.3.9.B.4 Seizure

a) A retrospective review of 47 patients treated with doxepin for anxious or agitated depression revealed a seizure disorder in 19 patients. In these 19 patients, 15 exhibited improved seizure control during therapy with doxepin, while 2 exhibited no change and 2 exhibited decreased control. The authors concluded that doxepin reduced seizure frequency, and postulated 1 or a combination of 3 mechanisms: a direct antiepileptic effect; an indirect effect caused by improved affective state; or, a drug interaction with other anticonvulsants (Ojemann et al, 1983).

b) Seizures are a potential complication of doxepin overdosage, but the clinical data is quite limited with few case reports. In depressed patients, doxepin produces EEG changes that are similar to other tricyclic antidepressants (Pinder et al, 1977f).

3.3.9.B.5 Tardive dyskinesia

a) A prevalence study of tardive dyskinesia (TD) in the course of antidepressant therapy was conducted in 50 patients (Yassa et al, 1987). Of the 23 patients treated with doxepin, 2 men receiving doxepin 100 milligrams daily developed TD. The first was a 74-year-old man suffering from a major depressive disorder. He developed marked buccolingual chewing, lip smacking, and choreoathetoid movements of the body and extremities forty-five days after the start of antidepressant therapy. Seven months after the onset of TD the patient still had occasional lip smacking. The second man who developed TD was 64 years old. He had been started on doxepin 75 milligrams and increased to 100 milligrams daily after one month. Two days after the increase, chewing movements and lateral tongue movements of moderate intensity were noted without any signs of extrapyramidal symptoms. These movements persisted three months later despite a decrease in his dose to 50 milligrams daily.

3.3.10 Ophthalmic Effects

3.3.10.A Doxepin Hydrochloride

3.3.10.A.1 Eye / vision finding

a) BLURRED VISION is an autonomic (anticholinergic) side effect and has been reported to occur in approximately 3% of patients receiving therapeutic doses of doxepin (Pinder et al, 1977f).

b) OCULOGYRIC CRISIS has been reported following the use of doxepin 300 milligrams (Lee, 1988).

3.3.11 Otic Effects

3.3.11.A Doxepin Hydrochloride

3.3.11.A.1 Ototoxicity

a) Tinnitus has been reported during treatment of depression with doxepin in therapeutic doses in a 66-year-old female. The tinnitus recurred upon rechallenge (Golden et al, 1983).

3.3.12 Psychiatric Effects

3.3.12.A Doxepin Hydrochloride

Aggressive behavior

Suicidal thoughts

3.3.12.A.1 Aggressive behavior

a) Aggressiveness has been reported rarely with tricyclic antidepressant use.

3.3.12.A.2 Suicidal thoughts

a) Adult and pediatric patients being treated with antidepressants for major depressive disorder who experience symptoms of anxiety, agitation, panic attacks, insomnia, irritability, hostility (aggressiveness), impulsivity, akathisia (psychomotor restlessness), hypomania, or mania may be at risk of suicidal ideation and behavior (SUICIDALITY). This same concern applies to treating patients with other psychiatric and nonpsychiatric disorders. If these symptoms are observed, therapy should be reevaluated and it may be necessary to discontinue medications when symptoms are severe, sudden in onset, or were not part of the patient's initial symptoms. Patients and their caregivers should be provided with the Medication Guide that is available for this drug (Anon, 2004).

b) A causal role for antidepressants in inducing suicidality has been established in pediatric patients. Anyone considering the use of antidepressants in a child or adolescent must balance this risk with the clinical need. In pooled analyses of 24 short-term, placebo-controlled trials of nine antidepressants (citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, bupropion, mirtazapine, nefazodone, and venlafaxine extended-release) including over 4400 pediatric patients with major depressive disorder, obsessive compulsive disorder, or other psychiatric disorders, a greater risk of suicidal behavior or ideation during the first few months of therapy was demonstrated in patients receiving antidepressants as compared with placebo (4% vs 2%, respectively). The risk of suicidality was most consistently observed in the trials that included patients with major depressive disorder, but there were signs of risk emerging from trials in other psychiatric indications, such as obsessive compulsive disorder and social anxiety disorder. No suicides occurred in these trials. The risk of suicidality during longer-term use (ie, beyond several months) in pediatric patients is not known. It is also unknown whether this risk extends to adult patients (Anon, 2004).

3.3.13 Renal Effects

3.3.13.A Doxepin Hydrochloride

Nephrotoxicity

Urinary incontinence

3.3.13.A.1 Nephrotoxicity

a) Coombs-positive hemolytic anemia and thrombocytopenia with acute renal failure occurred in a patient who received doxepin for approximately 5 weeks (50 to 100 mg orally daily). The patient recovered following withdrawal of doxepin, exchange transfusion, and repeated hemodialysis. Doxepin was the only medication taken by the patient (Wolf et al, 1989).

3.3.13.A.2 Urinary incontinence

a) Urinary incontinence was described as a side effect of doxepin. An elderly patient received 25 mg doxepin four times a day over a period of 1 year for depression. The patient began voiding every hour and continued to have frequent urinary tract infections. In addition, he commonly had an itching rash which appeared on the thighs and buttocks. The rash did not respond to soothing lotions and doxepin was discontinued resulting in continuation of rash and disappearance of incontinence (Kimbrough, 1972).

3.3.14 Reproductive Effects

3.3.14.A Doxepin Hydrochloride

Priapism

Sexual dysfunction

3.3.14.A.1 Priapism

a) One case of priapism is reported in a patient receiving doxepin 20 mg at bedtime. Symptoms of testicular swelling and tingling resolved upon discontinuation (Mitchell & Popkin, 1983).

3.3.14.A.2 Sexual dysfunction

a) EJACULATORY DYSFUNCTION has been reported in patients taking doxepin, which resolves on

discontinuation. Decreased libido has also been reported (Mitchell & Popkin, 1983).
b) Improved sexual functioning has been noted in depressed patients with sexual dysfunction after 4 weeks of doxepin therapy in a mean dose of 122.2 mg (Renshaw, 1975).

3.3.16 Other

3.3.16.A Doxepin Hydrochloride

Adverse reaction to drug, General

Drug tolerance - finding

3.3.16.A.1 Adverse reaction to drug, General

a) Doxepin therapy has been used continuously for up to 15 years in the treatment of chronic depressive illness, with maintenance of efficacy and a low order of toxicity. Continuous therapy for 5 to 15 years in 52 patients did not reveal any changes in hematologic, renal or hepatic function tests, and the drug was well tolerated in patients with concomitant cardiovascular disorders (Ayd, 1984).

3.3.16.A.2 Drug tolerance - finding

a) Oral doxepin has not been shown to produce physical tolerance or psychological dependence (Prod Info Sinequan(R), 2004).

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category B (Prod Info Zonalon(R) cream, 1997) (All Trimesters)

a) Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal-reproduction studies have shown adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).

2) Australian Drug Evaluation Committee's (ADEC) Category: C (Batagol, 1996)

a) Drugs which, owing to their pharmacological effects, have caused or may be suspected of causing harmful effects on the human fetus or neonate without causing malformations. These effects may be reversible. Accompanying texts should be consulted for further details.

See Drug Consult reference: PREGNANCY RISK CATEGORIES

3) Crosses Placenta: Unknown

4) Clinical Management

a) Due to reported teratogenic effects with other tricyclic antidepressants, use of doxepin during pregnancy should be avoided if possible, especially during the first trimester. The dangers of failure to treat major depression, however, are obvious, and in each case these dangers must be weighed against the potential for teratogenic effects.

5) Literature Reports

a) Based on data collected through the Motherisk Program for a very small number of patients, there appear to be no differences in cognitive function, temperament and general behavior in children exposed to doxepin throughout gestation as compared to controls (Nulman et al, 2002). However, among infants who were exposed to either fluoxetine or tricyclic antidepressants thoughout gestation, those born to mothers with uncontrolled depressive symptoms showed lower cognitive and language achievements than those born to mothers who were well-controlled (Nulman et al, 2002).

b) Poor sucking and swallowing, muscle hypotonia, drowsiness, vomiting, and jaundice occurred in a neonate whose mother used doxepin in her third trimester and during the postpartum period. The doxepin dose had been 75 mg/day, but was tapered in the last weeks of pregnancy and was 35 mg/day at parturition (Frey et al, 1999).

B) Breastfeeding

1) American Academy of Pediatrics Rating: Drugs for which the effect on nursing infants is unknown but may be of concern. (Anon, 2001)

2) Thomson Lactation Rating: Infant risk has been demonstrated.

a) Evidence and/or expert consensus has demonstrated harmful infant effects when used during breastfeeding. An alternative to this drug should be prescribed or patients should be advised to discontinue breastfeeding.

3) Clinical Management

a) Both doxepin and its active metabolite have been found in breast milk, and the active metabolite has been found in infant serum at a concentration similar to therapeutic concentrations in adults. Sedation and respiratory depression has been reported in a breastfeeding infant (Matheson et al, 1985), therefore breastfeeding is not recommended during maternal doxepin therapy. Alternatively, available data suggest that clomipramine is a safer agent for use during breastfeeding, and clomipramine is considered compatible

with breastfeeding by the American Academy of Pediatrics.

4) Literature Reports

a) Doxepin and desmethyldoxepin levels were measured in the milk of a mother being treated with doxepin 150 mg daily for major depressive disorder (Kemp et al, 1985). The milk to plasma ratio averaged 1.46 for both doxepin and desmethyldoxepin. With an average maternal serum level of 46 mcg/L for doxepin and 90 mcg/L for desmethyldoxepin, a nursing infant would consume a dose of 237 mcg in 1.2 L of milk per day.

b) Respiratory depression occurred in an 8-week-old breastfed girl whose mother was receiving doxepin 25 mg TID. In the infant's serum, the level of doxepin was almost undetectable (3 mcg/mL); therefore, the respiratory depression was attributed to the high concentrations of N-desmethyldoxepin (58 and 66 mcg/mL) which were similar to the levels in the mother (Matheson et al, 1985). After discontinuing breastfeeding, the infant's respiration normalized within 24 hours.

c) Poor sucking and swallowing, muscle hypotonia, drowsiness, vomiting, and jaundice occurred in a neonate whose mother used doxepin in her third trimester and during the postpartum period. The doxepin dose had been 75 mg/day, but was tapered in the last weeks of pregnancy and was 35 mg/day at parturition. The amount of doxepin and desmethyldoxepin (active metabolite) ingested by the nursing infant was estimated at 10 to 20 mcg/kg/day (2.5% of the weight-adjusted dose of the mother) (Frey et al, 1999a).

5) Drug Levels in Breastmilk

a) Parent Drug

1) Milk to Maternal Plasma Ratio

a) 1.08-1.66 (Kemp et al, 1985)

b) Active Metabolites

1) DESMETHYLDOXEPIN (Bennett, 1996)

a) Milk to Maternal Plasma Ratio

1) 1.02-1.53 (Kemp et al, 1985)

3.5.1.A Acecainide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.B Acenocoumarol

1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970i; Williams et al, 1976i). Considerable interindividual differences may be found (Pond et al, 1975i).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased acenocoumarol metabolism; increased acenocoumarol absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975h). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970h). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.

c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976h). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.C Ajmaline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.

7) Probable Mechanism: additive cardiac effects

8) Literature Reports

a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.

b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).

c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.D Amiodarone

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).

3) Severity: major

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.

7) Probable Mechanism: additive QT prolongation

8) Literature Reports

a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).

b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.E Amisulpride

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac

arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.F Amobarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.G Amphetamine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.H Amprenavir

1) Interaction Effect: increased tricyclic serum concentrations and potential toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias)

2) Summary: Coadministered amprenavir may increase serum concentrations of tricyclic antidepressants, causing a potential risk of arrhythmias or other serious adverse effects. Currently no interaction study has been conducted. Amprenavir is metabolized by cytochrome P450 3A4 enzymes in addition to being a CYP3A4 inhibitor, and tricyclics may partially depend on this pathway for metabolism. Plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly in patients also receiving amprenavir (Prod Info Agenerase(R), 2000).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: If concomitant therapy with amprenavir and a tricyclic antidepressant is unavoidable, plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly. Also monitor patients for signs and symptoms of tricyclic toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias).

7) Probable Mechanism: inhibition of cytochrome P450-mediated tricyclic metabolism

3.5.1.I Anisindione

1) Interaction Effect: increased risk of bleeding

2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970c; Williams et al, 1976c). Considerable interindividual differences may be found (Pond et al, 1975c).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.

7) Probable Mechanism: decreased anisindione metabolism; increased anisindione absorption

8) Literature Reports

a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975b). This effect was not observed with warfarin.

b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970b). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.

c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976b). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated

mechanism.

3.5.1.J Aprobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.K Arbutamine

1) Interaction Effect: unreliable arbutamine test results

2) Summary: Because tricyclic antidepressants may affect heart rate, arbutamine should not be administered to a patient receiving a tricyclic antidepressant, since arbutamine test results may be unreliable (Prod Info GenESA(R), 1997).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Arbutamine should not be administered to a patient receiving tricyclic antidepressant therapy.

7) Probable Mechanism: alteration of heart rate by the tricyclic antidepressant

3.5.1.L Arformoterol

1) Interaction Effect: an increased risk of cardiovascular excitation

2) Summary: Concurrent administration of arformoterol with a tricyclic antidepressant (TCA) may lead to potentiation of arformoterol's adrenergic effects on the cardiovascular system. Therefore, extreme caution is advised if arformoterol is administered to patients who are being treated with a TCA (Prod Info BROVANA (TM) inhalation solution, 2006). Monitor patients closely for adverse cardiovascular effects.

3) Severity: moderate

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Extreme caution and close observation for adverse cardiovascular effects are warranted when arformoterol is administered concurrently with a tricyclic antidepressant (TCA) as the cardiovascular effects of arformoterol can be potentiated by TCAs (Prod Info BROVANA(TM) inhalation solution, 2006).

7) Probable Mechanism: potentiation of cardiovascular effects

3.5.1.M Arsenic Trioxide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Any drug known to have the potential to prolong the QT interval should not be used with arsenic trioxide. Possible pharmacodynamic interactions can occur between arsenic trioxide and potentially arrhythmogenic agents such as tricyclic antidepressants that prolong the QT interval (Prod Info Trisenox(R), 2000a). Even though no formal drug interaction studies have been done, the coadministration of arsenic trioxide and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999k; Marshall & Forker, 1982af).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of arsenic trioxide and other drugs that may prolong

the QTc interval, such as tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to zero out of 53 in the control group using a hospital based information system. The authors recommended that amitriptyline not be used in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972a; Coull et al, 1970a).
b) QT/QTc prolongation should be expected during treatment with arsenic trioxide and torsade de pointes as well as complete heart block has been reported. Over 460 ECG tracings from 40 patients with refractory or relapsed APL treated with arsenic trioxide were evaluated for QTc prolongation. Sixteen of 40 patients (40%) had at least one ECG tracing with a QTc interval greater than 500 msec. Prolongation of the QTc was observed between 1 and 5 weeks after arsenic trioxide infusion, and then returned towards baseline by the end of 8 weeks after arsenic trioxide infusion. In these ECG evaluations, women did not experience more pronounced QT prolongation than men, and there was no correlation with age (Prod Info Trisenox(R), 2000).

3.5.1.N Astemizole
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of astemizole and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999l; Prod Info Hismanal(R), 1996).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of astemizole and agents that prolong the QT interval, such as tricyclic antidepressants, is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) A comprehensive discussion of the cardiovascular effects of tricyclic antidepressants has been presented (Marshall & Forker, 1982ag). Electrocardiogram effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves.

3.5.1.O Atomoxetine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as doxepin. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with doxepin, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with doxepin.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by doxepin

3.5.1.P Azimilide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation

8) Literature Reports

a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).

b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.Q Baclofen

1) Interaction Effect: memory loss, loss of muscle tone

2) Summary: Baclofen when administered with antidepressants, specifically imipramine, amitriptyline, and clomipramine, has induced short term memory loss (Sandyk & Gillman, 1985a). In addition, concomitant imipramine and baclofen may result in additive muscle relaxant effects (Silverglat, 1981a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Due to the additive effects of both drugs, monitor for excess anticholinergic activity and muscle relaxant effects with concomitant therapy.

7) Probable Mechanism: unknown

8) Literature Reports

a) Baclofen when administered with antidepressants, specifically imipramine, amitriptyline, and clomipramine, has induced short-term memory loss in three patients. Specifically, the patients could not remember names of persons or places familiar to them. The interaction is believed to be caused by baclofen enhancing the anticholinergic effects of antidepressants, which may be partially reversed by piracetam (Sandyk & Gillman, 1985).

b) Concomitant imipramine and baclofen therapy has been reported to result in an additive muscle relaxant effect. A 54-year-old male with a 12-year history of multiple sclerosis and a two-year history of depression was maintained on baclofen 10 mg four times daily. The patient experienced good relief of spasticity with this regimen and maintained sufficient muscle tone to stand. Nortriptyline 50 mg nightly was added to relieve depression. On the sixth day of therapy, the patient was no longer able to stand. Nortriptyline was withdrawn and muscle tone returned within 48 hours. Two weeks later, imipramine 75 mg daily was given to the patient for treatment of depression, however, the patient again experienced loss of muscle tone. Muscle tone returned within two days of imipramine discontinuation. The additive effect between baclofen and the tricyclic antidepressants is attributed to an interaction affecting the neurotransmitters at the presynaptic membrane (Silverglat, 1981).

3.5.1.R Belladonna

1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)

2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with tricyclic antidepressants. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the clinical severity of the interaction with tricyclic antidepressants is unknown. Caution is advised.

3) Severity: minor

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.

7) Probable Mechanism: additive anticholinergic effect

3.5.1.S Belladonna Alkaloids

1) Interaction Effect: excessive anticholinergic activity (severe dry mouth, constipation, decreased urination, excessive sedation, blurred vision)

2) Summary: The anticholinergic activity of the active alkaloids present in belladonna may predispose the patient to excessive anticholinergic activity if taken with tricyclic antidepressants. Belladonna contains L-hyoscyamine, atropine, and scopolamine with a total alkaloid content of at least 0.3% in the leaves and 0.5% in the roots (Blumenthal et al, 1998). Because belladonna is typically available as a homeopathic preparation, the clinical severity of the interaction with tricyclic antidepressants is unknown. Caution is advised.

3) Severity: minor

4) Onset: rapid

5) Substantiation: theoretical
6) Clinical Management: Excessive anticholinergic activity may be manifested by dry mouth, constipation, urinary retention, tachycardia, decreased sweating, mydriasis, blurred vision, elevated temperature, muscular weakness, and sedation. If such effects are noted, belladonna should be discontinued immediately. In severe cases, paralytic ileus, confusion, psychoses, agitation, delusions, delirium, and paranoia may be encountered as well as tachycardia, dysrhythmia, and hypertension. In severe cases, immediate medical attention should be obtained.
7) Probable Mechanism: additive anticholinergic effect

3.5.1.T Bepridil

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: In US clinical trials, the QT and QTc intervals were commonly prolonged by bepridil in a dose-related fashion (Prod Info Vascor(R), 2000). Tricyclic antidepressants (TCAs) have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982t).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Concurrent use of bepridil and other drugs which may prolong the QTc interval, including tricyclic antidepressants, is contraindicated.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.U Bethanidine

1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Tricyclic antidepressants inhibit the uptake of bethanidine at its site of action in the adrenergic neuron. The antagonism may last for several days after discontinuation of the antidepressant. The interaction with doxepin is dose related (Oates et al, 1969; Fann et al, 1971); doxepin in doses less than 150 mg daily may be used with bethanidine, but the antidepressant effect may be insufficient at such a low dose (Skinner et al, 1969a; Avery, 1973; Feagin et al, 1969).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The combination of bethanidine and doxepin, as well as other tricyclic antidepressant agents, should be avoided. An alternative antihypertensive should be considered.
7) Probable Mechanism: decreased uptake of bethanidine into adrenergic neurons
8) Literature Reports
a) Adequate control of hypertension was reported in only two of eight adult hypertensive patients who received bethanidine or debrisoquine concurrently with a tricyclic antidepressant. In 24 control patients given the same drugs without antidepressants, blood pressure control was achieved in 18. Withdrawal of hypotension that necessitated a reduction in dosage of bethanidine or debrisoquine (Skinner et al, 1969).

3.5.1.V Bretylium

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.W Butabarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.X Butalbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.Y Cannabis

1) Interaction Effect: tachycardia and delirium
2) Summary: Concomitant tetrahydrocannabinol and tricyclic antidepressant therapy has increased the heart rate and cause delirium beyond that expected with either drug alone (Wilens et al, 1997a; Hillard & Vieweg, 1983a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Caution is advised if patients use cannabis with a tricyclic antidepressant. Monitor heart rate changes closely.
7) Probable Mechanism: possibly due to beta-adrenergic effect of cannabis coupled with the anticholinergic effect of tricyclic antidepressants
8) Literature Reports
a) A 21-year-old female receiving oral nortriptyline 30 milligrams at bedtime for 9 months developed marked sinus tachycardia (160 beats/minute) within 30 minutes of smoking a cannabis cigarette. The patient's heart rate was about 90 beats/minute before smoking the cannabis. She had used cannabis many times before starting the nortriptyline without ill effects (Hillard & Vieweg, 1983).

b) Four cases of tachycardia, cognitive changes, and delirium have been reported in adolescent males treated with tricyclic antidepressants who smoked marijuana. One of the four cases was evaluated by a physician, the others were later accounts of the event. The toxic effects were considered by the reporters to have resulted from a drug interaction because they occurred with lower doses of marijuana than are common in other reports of marijuana toxicity (usually greater than 20 mg). In case 1, a 16-year-old male taking nortriptyline 75 mg/day presented with tachycardia (130 beats/minute), delirium, confusion, and short-term memory loss 30 minutes after smoking one marijuana cigarette. Symptoms resolved spontaneously after 24 hours. In case 2, and 18-year-old male taking desipramine 200 mg/day presented 12 hours after smoking marijuana with symptoms of edginess, severe dry mouth, lightheadedness, confusion, short-term memory impairment, and tachycardia (110 beats/minute). Symptoms resolved within 48 hours. Case 3, a 15-year-old male taking desipramine 150 mg/day and sertraline 50 mg/day, reported mood lability, irritability, and a racing heart after smoking 2 marijuana cigarettes which resolved after 16 hours. Case 4, a 16-year-old male taking desipramine and clonidine reported hallucinations, confusion, mild shortness of breath, and elevated heart rate after smoking marijuana. This was different than the effect he experienced prior to taking desipramine (Wilens et al, 1997).

3.5.1.Z Carbamazepine

1) Interaction Effect: decreased doxepin effectiveness and possibly increased carbamazepine toxicity (diplopia, blurred vision, dizziness, tremor)
2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease doxepin levels (Leinonen et al, 1991a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for clinical efficacy of the doxepin therapy and for any signs of toxicity of carbamazepine. Serum levels of both agents should be considered when either agent is added or discontinued, with appropriate dosage adjustments made accordingly.
7) Probable Mechanism: increased doxepin metabolism
8) Literature Reports
a) The effect of carbamazepine on doxepin levels were examined in 17 psychiatric inpatients who were stabilized for a minimum of 7 days prior to measurement of baseline antidepressant concentrations. The average daily doxepin dosage was 201.5 mg. Carbamazepine was added in a mean dose of 593 mg and continued over a 4-week period. Serum doxepin concentrations were decreased to 46% in patients receiving combination therapy compared to patients receiving doxepin alone (Leinonen et al, 1991).

3.5.1.AA Chloroquine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Chloroquine can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of chloroquine and tricyclic antidepressants is not recommended (Prod Info Aralen(R), 1999; Marshall & Forker, 1982v).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of chloroquine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AB Chlorotrianisene

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973i), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972i). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972i) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984i).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten

patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mcg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972h).

b) A case reported demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg (Khurana, 1972h). The patient developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973h).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973e).

d) The effects of oral contraceptives on clomipramine were studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980d).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984h).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984d).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980d). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983d).

3.5.1.AC Cimetidine

1) Interaction Effect: doxepin toxicity (dry mouth, blurred vision, urinary retention)

2) Summary: Concomitant administration of doxepin 50 mg daily and cimetidine 600 mg twice daily was reported to result in significant increases in doxepin concentration and elimination half-life (Sutherland et al, 1987; Curry et al, 1987; Wells et al, 1986).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor serum tricyclic antidepressant levels within the first few days of starting or discontinuing cimetidine. An H2 blocker that does not impair the metabolism of the tricyclic agents, such as ranitidine or famotidine, may be an alternative.

7) Probable Mechanism: decreased doxepin metabolism

3.5.1.AD Cisapride

1) Interaction Effect: cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cisapride therapy has resulted in serious cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, torsades de pointes, and QT prolongation. Because tricyclic antidepressant agents also may prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of cisapride with a drug from this class is contraindicated (Prod Info Propulsid(R), 2000).
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent use of cisapride and tricyclic antidepressants is contraindicated.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AE Clarithromycin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and clarithromycin have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Biaxin(R), 2002; Marshall & Forker, 1982n). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as clarithromycin, is not recommended (Prod Info Elavil(R), 1999h).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of tricyclic antidepressants and agents that prolong the QT interval, such as clarithromycin, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AF Clonidine

1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Concomitant clonidine and tricyclic antidepressant (TCA) therapy may impair the antihypertensive effects of clonidine (Prod Info Catapres(R), 1996). Tricyclic antidepressants increase the release of noradrenaline, presumably through re-uptake blockade. Clonidine reduces the release of noradrenaline by stimulating pre-synaptic alpha-2 adrenoreceptors, whose function is to inhibit noradrenaline release (Briant et al, 1973a; Hicks et al, 1981; Hui, 1983; Glass et al, 1982a). Mianserin, a tetracyclic antidepressant, was not shown to exhibit the impairment of clonidine's antihypertensive effects seen with tricyclic antidepressants (Elliott et al, 1981; Elliott et al, 1983).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Blood pressure should be monitored for an appropriate clinical response. Higher doses of clonidine may be required. An alternative class of antihypertensive agents or an alternative class of antidepressants might be considered.
7) Probable Mechanism: pharmacological antagonism at central alpha-2 receptors
8) Literature Reports

a) The interaction between clonidine and desipramine was studied in five hypertensive patients. The results of this double-blind placebo controlled study showed that the introduction of the tricyclic antidepressant led to the loss of blood pressure control in four of the five subjects within two weeks. The rise in the arterial pressure was more prominent in the supine position than in the erect. The average blood pressure increase in the desipramine period compared to the placebo period was 22/15 mm Hg in the lying position and 12/11 mm Hg standing (Briant et al, 1973).

b) Eleven drug-free patients who met the Research Diagnostic Criteria for Major Depressive Disorder enrolled in a study to determine the effects of desipramine on central adrenergic function. Patients were given a clonidine infusion after 0, 1 and 3 weeks of treatment with desipramine. Results showed that the sedative and hypotensive effects of clonidine were significantly inhibited after three weeks of treatment with desipramine. This interaction was also seen at one week, but did not reach clinical significance. The authors concluded that the effects that were observed during the study were due to an acute drug effect, rather than to a chronic adaptive change (Glass et al, 1982).

c) One case report describes a 65-year-old man who was experiencing perineal pain following the excision of a carcinoma. Pain management of amitriptyline 75 mg nightly and sodium valproate 500 mg three times daily was initiated after slow-release morphine only had a limited effect. A clonidine spinal intrathecal injection of 75 micrograms was given when it was felt that the patient had become tolerant to opioid treatment. Within five minutes, the patient was found to be in severe pain, which resolved within 30 minutes after diamorphine was given. Two mechanisms for this interaction were postulated. In the first, the pain could have been the result of a clonidine-cholinergic interaction. In the second, the tricyclic augmentation of serotoninergic transmission may have unmasked an effect of clonidine at central receptors to enhance nociception (Hardy & Wells, 1988).

3.5.1.AG Clorgyline

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982e; Spigset et al, 1993f; Brodribb et al, 1994e; Neuvonen et al, 1993b). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991c). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971g; White & Simpson, 1984e).

3) Severity: major

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Concomitant use of a tricyclic antidepressant, such as doxepin, and a monoamine oxidase inhibitor (MAOI), such as clorgyline, should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine. If doxepin is replacing treatment with clorgyline, a minimum of 14 days should elapse after clorgyline is discontinued before doxepin therapy begins (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005). There is no specific washout period for replacing doxepin treatment with clorgyline. However, it is advisable to gradually taper the tricyclic antidepressant dosage before starting treatment with the MAOI (Remick, 2002).

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965c; Brachfeld et al, 1963b; Winston, 1971c; Schuckit et al, 1971f; Sargent, 1965b; Spiker & Pugh, 1976c). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965c).

b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982d).

c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993e).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994d).

e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986a).

f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987c).

g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974a; Winston, 1971c;

Schuckit et al, 1971f; White & Simpson, 1984d; Rom & Benner, 1972a). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991b). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991b). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977c; Schuckit et al, 1971f; Ashcroft, 1975b).

3.5.1.AH Conjugated Estrogens

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed

amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.AI Dexfenfluramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AJ Dexmethylphenidate

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine

analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AK Dextroamphetamine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info

DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AL Dicumarol

1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970k; Williams et al, 1976k). Considerable interindividual differences may be found (Pond et al, 1975k).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving oral anticoagulant therapy, the prothrombin time ratio or international normalized ratio (INR) should be closely monitored with the addition and withdrawal of treatment with doxepin, and should be reassessed periodically during concurrent therapy. Adjustments of the dicumarol dose may be necessary in order to maintain the desired level of anticoagulation.
7) Probable Mechanism: decreased dicumarol metabolism; increased dicumarol absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975j). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after eight days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in six healthy volunteers (Vesell et al, 1970j). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976j). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.AM Dienestrol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973g), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972g). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972g) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984g).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The

only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972f).

b) A case reported by (Khurana, 1972f) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973f).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973c).

d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980c).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984f).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984c).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980c). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983c).

3.5.1.AN Diethylpropion

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation

(Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.AO Diethylstilbestrol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973e), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972e). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972e) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984e).

3) Severity: minor

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972d).

b) A case reported by (Khurana, 1972d) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana,

1973d).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973b).
d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980b).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984d).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984b).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980b). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983b).

3.5.1.AP Disopyramide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.
b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).
c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on

imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.AQ Dofetilide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.AR Dolasetron

1) Interaction Effect: cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and dolasetron have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982c). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as dolasetron, is not recommended (Prod Info Elavil(R), 1999b; Prod Info Anzemet (R), 1997).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of dolasetron with other agents that may prolong the QTc interval, such as tricyclic antidepressants, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.AS Droperidol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Droperidol has been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of droperidol and other drugs known to prolong the QTc interval, including tricylclic antidepressants is not recommended (Prod Info Inapsine(R), 2002; Marshall & Forker, 1982aa).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of droperidol and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive cardiac effects

3.5.1.AT Duloxetine

1) Interaction Effect: increased tricyclic antidepressant serum concentrations and potential toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias)
2) Summary: The coadministration of duloxetine with a tricyclic antidepressant is likely to increase bioavailability of the tricyclic agent, increasing the risk of adverse events. Duloxetine is a moderately potent inhibitor of CYP2D6. When a single dose of the CYP2D6 substrate desipramine 50 mg and duloxetine 60 mg twice daily were coadministered, the desipramine AUC increased 3-fold over baseline (Prod Info CYMBALTA(R) delayed-release oral capsules, 2008).
3) Severity: moderate
4) Onset: unspecified

5) Substantiation: theoretical
6) Clinical Management: Use caution with the combined use of duloxetine with tricyclic antidepressants (TCAs). If concomitant therapy with duloxetine and a TCA is unavoidable, plasma concentrations of the tricyclic should be closely monitored and dose adjustments made accordingly (Prod Info CYMBALTA(R) delayed-release oral capsules, 2008). Also, monitor patients for signs and symptoms of TCA toxicity (anticholinergic effects, sedation, confusion, and cardiac arrhythmias).
7) Probable Mechanism: duloxetine inhibition of CYP2D6-mediated tricyclic agent metabolism

3.5.1.AU Enflurane
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest) and an increased risk of seizure activity
2) Summary: Enflurane may prolong the QT interval in some patients (Owens, 2001). Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of enflurane and tricyclic antidepressants is not recommended (Marshall & Forker, 1982a). Concomitant administration of amitriptyline and enflurane anesthesia has been reported to result in seizures in two cases (Sprague & Wolf, 1982a).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Avoid concurrent use of enflurane and tricyclic antidepressants, particularly in patients with a history of seizure activity or when hyperventilation or high concentrations of enflurane will be required.
7) Probable Mechanism: additive effects on QT prolongation
8) Literature Reports
a) Two case reports of patients on amitriptyline therapy who experienced seizure activity while receiving enflurane anesthesia have been documented (Sprague & Wolf, 1982). The first patient, a 42-year old female, was taking amitriptyline 100 mg daily. Anesthesia was induced with fentanyl, enflurane, and nitrous oxide. Approximately three hours after anesthesia was induced, clonic movements of the patient's right hand and forearm were noted. Enflurane concentration was 1% at the time. Changes in ventilation did not affect the involuntary movements, so enflurane was discontinued and replaced with halothane 1%. The movements decreased in frequency and amplitude and subsequently disappeared in approximately one minute. The second case report involved a 39-year old male who was taking amitriptyline 150 mg daily. Anesthesia was maintained with enflurane 1% to 2%, and intermittent clonic movements started in the right arm and leg approximately one hour into the surgery. Enflurane was discontinued and halothane was instituted, which caused the involuntary movements to disappear in approximately two minutes. No further movements were seen during the remaining three hours of anesthesia.

3.5.1.AV Epinephrine
1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.AW Erythromycin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Erythromycin significantly increased the mean QTc interval versus baseline in a retrospective study of 49 patients (Oberg & Bauman, 1995a). Erythromycin has demonstrated QTc prolongation in combination with other drugs that prolong the QT interval (Prod Info PCE(R), 1997). Tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982g). Caution is advised with coadministration of drugs that potentially prolong the QTc interval.

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Caution is advised if erythromycin and tricyclic antidepressants are used concomitantly. Monitor QT interval at baseline and periodically during treatment.

7) Probable Mechanism: additive effects on QT prolongation

8) Literature Reports

a) Erythromycin did not significantly affect the metabolism of tricyclic antidepressants in a study of 8 patients. Patients were maintained on desipramine (n equal to 5), imipramine (n equal to 1), doxepin (n equal to 1), or doxepin (n equal to 1). All patients received erythromycin stearate 250 mg four times daily for six days while maintaining their usual tricyclic regimen. No change in the antidepressant or active metabolite concentrations was seen during coadministration with erythromycin (Amsterdam & Maislin, 1991).

b) Tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982f).

c) Erythromycin significantly increased the QTc interval compared with baseline in a retrospective study of 49 patients. The erythromycin dose was 500 milligrams or 1 gram four times daily, with a mean of 15 doses received. Patients (n equal to 9) who received 60 mg/kg/day or more all developed increases in QT interval of 15% or greater. For all patients, the mean QTc interval increased from 432 milliseconds (msec) at baseline to 483 msec (p less than 0.01). In patients with delayed repolarization at baseline (n equal to 9), the QTc interval increased from 473 msec to 525 msec (p less than 0.01). In patients with heart disease (n equal to 30), all experienced an increase in QTc interval (mean of 15%), compared with an increase of 8% in patients without heart disease (p less than 0.05). In 5 patients (10%), the QTc interval was severely prolonged. One patient developed torsades de pointes attributed to erythromycin. Of 16 patients receiving cotrimoxazole concomitantly, 8 developed QT prolongation of 15% or greater (Oberg & Bauman, 1995).

3.5.1.AX Esterified Estrogens

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic

hypotension (Prange, 1972).
b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).
d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.AY Estradiol

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).
3) Severity: minor
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect

reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.AZ Estriol

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received

imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.BA Estrone

1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or

resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).
b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).
d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.BB Estropipate
1) Interaction Effect: possible attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973a), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972a). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972a) and may be of clinical importance primarily in patients previously

stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984a).
3) Severity: minor
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible inhibition of hepatic metabolism of the tricyclic antidepressant
8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mrg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972).

b) A 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973; Khurana, 1972).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973).

d) The effects of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983).

3.5.1.BC Eterobarb

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BD Ethinyl Estradiol
1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973k), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972k). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972k) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984k).
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972j).
b) A case reported by (Khurana, 1972j) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973j).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No

significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973f).

d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980e).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984j).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984e).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980e). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983e).

3.5.1.BE Etilefrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).

b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.BF Fenfluramine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d;

Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.BG Fluconazole

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Case reports have described QT prolongation and torsades de points associated with fluconazole (Wassmann et al, 1999). Several tricyclic antidepressants (TCAs) have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982u). Even though no formal drug interaction studies have been done, the coadministration of drugs known to prolong the QTc interval is not recommended.

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of fluconazole and a tricyclic antidepressant is not recommended.

7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BH Fluoxetine

1) Interaction Effect: tricyclic antidepressant toxicity (dry mouth, urinary retention, sedation) and an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Tricyclic antidepressants (TCAs) and fluoxetine have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Prozac(R), 2001; Marshall & Forker, 1982h). Even though no formal drug interaction studies have been done which demonstrate QT prolongation, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as fluoxetine, is not recommended (Prod Info Elavil(R), 1999d). In addition, concurrent use of fluoxetine and TCAs such as desipramine, nortriptyline, and imipramine has resulted in significant increases in TCA concentrations (Preskorn et al, 1994a; Preskorn et al, 1994a; Aranow et al, 1989a; Downs et al, 1989a; Goodnick, 1989a; Bell & Cole, 1988a).

3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of fluoxetine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: decreased tricyclic antidepressant metabolism; additive effects on QT prolongation
8) Literature Reports
a) Fluoxetine increased the level of tricyclic antidepressants (nortriptyline, imipramine, desipramine) in 4 patients. After the addition of fluoxetine, the ratio of antidepressant level to dose increased by 109% to 486% in the patients. Three patients developed clinical symptoms (anticholinergic effects, constipation, urinary hesitancy, sedation, unstable gait) as a result of the increased levels (Aranow et al, 1989).
b) Fluoxetine statistically and clinically significantly increased desipramine concentrations in 18 healthy subjects. When fluoxetine (20 mg daily) was added to desipramine (50 mg daily), the mean maximum concentration of desipramine increased by 278% and the area under the concentration-time curve increased by 342%. Desipramine trough concentrations continued to be 198% above baseline three weeks after fluoxetine was discontinued. The same study compared pharmacokinetics of desipramine when combined with sertraline. The impact of sertraline was modest, resulting in small and short-term increases in desipramine plasma concentrations (Preskorn et al, 1994).
c) A 75-year-old female experienced symptomatic increases in her desipramine serum concentrations when fluoxetine was added. Desipramine serum levels ranged from 109 to 150 ng/mL with oral doses of 300 mg at bedtime prior to fluoxetine therapy. Following the addition of oral fluoxetine 20 mg daily to the regimen, the desipramine serum level increased to 212 ng/mL within five days. The fluoxetine dose was increased to 40 mg/day three days later, and the desipramine serum level was 419 ng/mL after four days. A worsening of depression and severe fatigue coincided with the increases in desipramine serum levels. Withdrawal of fluoxetine and reduction in the desipramine dose to 200 mg daily reduced the desipramine serum level to 231 ng/mL within two weeks (Bell & Cole, 1988).
d) A 33-year-old depressed male developed adverse effects of dry mouth, tinnitus, and difficulties with alertness and memory while receiving fluoxetine 40 mg daily and desipramine 150 mg daily for five weeks; fluoxetine was discontinued and the blood levels of desipramine decreased from 938 to 48 ng/mL with resolution of clinical symptoms (Goodnick, 1989).
e) A 39-year-old female experienced symptomatic increases in her desipramine levels with concomitant fluoxetine therapy. Prior to fluoxetine therapy, the patient's measured levels of desipramine had ranged from 148 to 160 ng/mL on a regimen of 300 mg daily. Five weeks after the addition of fluoxetine 20 mg daily, she reported anticholinergic symptoms, sedation, and confusion with a desipramine level of 527 ng/mL. The desipramine dose was lowered to 200 mg/day; eleven days later, the level was 244 ng/mL; the patient reported decreased energy, impaired short-term memory, and some "garbled" speech, as well as an episode of nausea, dizziness, and syncope. The desipramine dose was reduced to 50 mg/day; the adverse effects resolved in six days. Eight days later, the desipramine level was 122 ng/mL (Downs et al, 1989).
f) Concomitant administration of fluoxetine and desipramine was reported to result in an increased desipramine level and new onset of delirium in a 69-year-old male within 10 days of the addition of fluoxetine to the patient's regimen (Preskorn et al, 1990).

3.5.1.BI Formoterol

1) Interaction Effect: an increased risk of cardiovascular excitation
2) Summary: Concurrent administration of formoterol with a tricyclic antidepressant (TCA) may lead to potentiation of formoterol's adrenergic effects on the cardiovascular system. Therefore, extreme caution is advised if formoterol is administered to patients who are being treated with a TCA (Prod Info FORADIL(R) AEROLIZER(R) inhalation powder, 2006). Monitor patients closely for adverse cardiovascular effects.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Extreme caution and close observation for adverse cardiovascular effects are warranted when formoterol is administered concurrently with a tricyclic antidepressant (TCA) as the cardiovascular effects of formoterol can be potentiated by TCAs (Prod Info FORADIL(R) AEROLIZER(R) inhalation powder, 2006).
7) Probable Mechanism: potentiation of cardiovascular effects

3.5.1.BJ Fosamprenavir

1) Interaction Effect: increased tricyclic agent serum concentrations and potential toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias)
2) Summary: Coadministration of fosamprenavir with a tricyclic antidepressant may provoke increased serum concentrations of the tricyclic antidepressant, causing a potential risk of arrhythmias or other serious adverse effects. Fosamprenavir is a prodrug of amprenavir, an inhibitor of the CYP3A4 isoenzyme in addition to being a CYP3A4 substrate. Tricyclic agents may partially depend on the CYP3A4 pathway for metabolism. Plasma concentrations of the tricyclic agent should be closely monitored in patients also receiving fosamprenavir (Prod Info LEXIVA(R) oral solution, oral tablets, 2009).

3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: If concomitant therapy with fosamprenavir and a tricyclic antidepressant is unavoidable, plasma concentrations of the tricyclic agent should be closely monitored. Also monitor patients for signs and symptoms of tricyclic toxicity (anticholinergic effects, sedation, confusion, cardiac arrhythmias) (Prod Info LEXIVA(R) oral solution, oral tablets, 2009).
7) Probable Mechanism: inhibition of CYP3A4-mediated tricyclic agent metabolism

3.5.1.BK Foscarnet
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Foscarnet can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of foscarnet and tricyclic antidepressants is not recommended (Prod Info Foscavir(R), 1998; Marshall & Forker, 1982r).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of foscarnet and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive cardiac effects

3.5.1.BL Fosphenytoin
1) Interaction Effect: an increased risk of phenytoin toxicity (ataxia, hyperreflexia, nystagmus, tremor)
2) Summary: Fosphenytoin is a prodrug of phenytoin and the same interactions that occur with phenytoin are expected to occur with fosphenytoin (Prod Info Cerebyx(R), 1999). A few case reports have indicated that imipramine inhibits phenytoin metabolism resulting in increased serum phenytoin concentration (Petti & Campbell, 1975; Perucca & Richens, 1977). Tricyclic antidepressants (TCAs) may lower the seizure threshold in epileptic patients stabilized on anticonvulsants. Theoretically, because phenytoin is an enzyme inducer, the metabolism of antidepressants may be increased resulting in reduced TCA serum levels.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Consider monitoring phenytoin serum levels if a tricyclic antidepressant is added to therapy or if the patient begins to exhibit signs of toxicity (tremor, nystagmus, ataxia, hyperreflexia); lower doses of phenytoin may be required. If phenytoin is added to tricyclic antidepressant therapy, monitor for clinical efficacy of the tricyclic agent.
7) Probable Mechanism: inhibition of phenytoin metabolism

3.5.1.BM Gatifloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Gatifloxacin may prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Although pharmacokinetic studies between gatifloxacin and other drugs which prolong the QT interval have not been performed, an additive effect cannot be excluded. Therefore, the concurrent administration of gatifloxacin and a tricyclic antidepressant is not recommended (Prod Info Tequin(TM), 1999).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of gatifloxacin and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BN Gemifloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although pharmacokinetic studies between gemifloxacin and drugs that prolong the QT interval, such as tricyclic antidepressants, have not been performed, gemifloxacin should be used cautiously when given concurrently with tricyclic antidepressants (Prod Info Factive(R), 2003).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of two drugs that prolong the QT interval, such as gemifloxacin and tricyclic antidepressants, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BO Grepafloxacin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Healthy volunteers who received grepafloxacin during a Phase I study experienced prolongation of the QTc interval. On an outpatient basis, grepafloxacin is contraindicated with other drugs that are known to also prolong the QTc interval or cause torsades de pointes, including tricyclic antidepressants. When appropriate cardiac monitoring can be assured, such as in the hospitalized patient, these two agents should be coadministered with caution (Prod Info Raxar(R), 1999).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The concurrent use of grepafloxacin and tricyclic antidepressants is contraindicated unless appropriate cardiac monitoring can be assured, such as in the hospitalized patient.
7) Probable Mechanism: additive cardiac effects

3.5.1.BP Guanadrel

1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Tricyclic antidepressants inhibit the uptake of guanethidine, and possibly guanadrel into the adrenergic neuron, resulting in an inhibition of its antihypertensive effect (Mitchell et al, 1967; Ober & Wang, 1973). When a patient is on concomitant tricyclic antidepressant and guanadrel therapy, caution should be exercised when the tricyclic antidepressant is discontinued, since an exaggerated effect of guanadrel may be seen (Prod Info Hylorel(R), 1995).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Blood pressure should be monitored for an appropriate clinical response; higher doses of guanadrel may be required. An alternative class of antihypertensive agents, such as an angiotensin-converting enzyme inhibitor might be considered.
7) Probable Mechanism: decreased uptake of guanadrel into adrenergic neurons

3.5.1.BQ Guanethidine

1) Interaction Effect: decreased antihypertensive effectiveness
2) Summary: Tricyclic antidepressants inhibit the uptake of guanethidine, and possibly guanadrel, into the adrenergic neuron, resulting in a inhibition of the antihypertensive effect (Meyer et al, 1970; Pinder et al, 1977).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Blood pressure should be monitored for an appropriate clinical response; higher doses of guanethidine may be required. An alternative class of antihypertensive agents, such as an angiotensin-converting enzyme inhibitor, might be considered.
7) Probable Mechanism: decreased uptake of guanethidine into adrenergic neurons
8) Literature Reports
a) Doses of doxepin of 200 mg daily or more progressively produce blockade of the effects of guanethidine (Fann et al, 1971a; Oates et al, 1969a). Antagonism of the effects of guanethidine developed slowly in one patient (over two to four days), even when given in a dose of 300 mg daily doxepin. Two other patients experienced reversal of the hypotensive effects of guanethidine at doses of doxepin 200 to 300 mg daily. In all cases, the antagonism of antihypertensive effects was less than that of desipramine (Fann et al, 1971a).
b) No antagonism of guanethidine was reported in two patients receiving doxepin 200 mg (Ayd, 1975). However, antagonism was observed at 300 mg doses (Ayd, 1971). A single case report describes a hypertensive crisis in a patient receiving guanethidine and chlorpromazine upon initiation of doxepin therapy less than 200 mg (Poe et al, 1979). Doses of 300 mg a day or more will usually completely reverse the hypotensive effects of guanethidine (Ayd, 1973).

3.5.1.BR Halofantrine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Halofantrine can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of halofantrine and tricyclic antidepressants is not recommended (Prod Info Halfan(R), 1998; Marshall & Forker, 1982x).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The concurrent administration of halofantrine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects

3.5.1.BS Haloperidol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.

7) Probable Mechanism: additive cardiac effects

8) Literature Reports

a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.BT Halothane

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Halothane may prolong the QT interval in some patients (Owens, 2001a). Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of halothane and tricyclic antidepressants is not recommended (Marshall & Forker, 1982o).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Because of the potential for additive QT interval prolongation, the concurrent administration of halothane and tricyclic antidepressants is not recommended.

7) Probable Mechanism: additive effects on QT prolongation

3.5.1.BU Heptabarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BV Hexobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of

TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.BW Hydroquinidine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.
b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).
c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.BX Ibutilide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major

4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.BY Iproniazid
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982o; Spigset et al, 1993p; Brodribb et al, 1994m; Neuvonen et al, 1993g). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991h). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971q; White & Simpson, 1984m).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. Consider using a 14 day washout period between treatment with both medicines. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965h; Winston, 1971h; Schuckit et al, 1971p; Spiker & Pugh, 1976h). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965h).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982n).
c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993o).
d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987h).
e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991g). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977h; Schuckit et al, 1971p; Ashcroft, 1975g).

3.5.1.BZ Isocarboxazid

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: The concurrent administration of isocarboxazid and doxepin is contraindicated (Prod Info Marplan(R), 1998). Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982r; Spigset et al, 1993s; Brodribb et al, 1994q; Neuvonen et al, 1993i). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991j). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971u; White & Simpson, 1984p).

3) Severity: contraindicated

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: The concurrent use of doxepin and isocarboxazid is contraindicated. In patients being transferred to isocarboxazid therapy from a dibenzazepine-related entity, allow at least a one-week medication-free interval and then initiate isocarboxazid at one-half of the normal dose for at least the first week of therapy. Also allow one week to elapse between the discontinuation of isocarboxazid and the administration of another MAO inhibitor or dibenzazepine-related entity.

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOI) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965j; Brachfeld et al, 1963f; Winston, 1971j; Schuckit et al, 1971t; Sargent, 1965f; Spiker & Pugh, 1976j). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965j).

b) The development of serotonin syndrome was first reported due to administration of a TCA after MAOI therapy. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982q).

c) A drug interaction was reported when a 76-year old woman who had been taking clomipramine 50 mg daily for several months was switched to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993r).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994p).

e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986e).

f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987i).

g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974e; Winston, 1971j; Schuckit et al, 1971t; White & Simpson, 1984o; Rom & Benner, 1972e). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants

(five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991i). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991i). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977j; Schuckit et al, 1971t; Ashcroft, 1975i).

3.5.1.CA Isoflurane

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Isoflurane may prolong the QT interval in some patients (Owens, 2001c). Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of isoflurane and tricyclic antidepressants is not recommended (Marshall & Forker, 1982s).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Because of the potential for additive QT interval prolongation, the concurrent administration of isoflurane and a tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effect on QT prolongation

3.5.1.CB Isradipine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Isradipine can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of isradipine with a tricyclic antidepressant is not recommended (Prod Info DynaCirc(R), 2000; Marshall & Forker, 1982w).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of isradipine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects

3.5.1.CC Levomethadyl

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Levomethadyl can prolong the QT interval in some patients, which may result in ventricular tachycardia, ventricular fibrillation, and torsades de pointes. Because doxepin may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of levomethadyl with doxepin is contraindicated (Prod Info Orlaam(R), 2001; Giardina et al, 1987).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of levomethadyl and doxepin is contraindicated.
7) Probable Mechanism: additive cardiac effects

3.5.1.CD Linezolid

1) Interaction Effect: increased risk of serotonin syndrome (hyperthermia, hyperreflexia, myoclonus, mental status changes)
2) Summary: Concomitant use of linezolid and a tricyclic antidepressant, such as doxepin, is contraindicated in the absence of monitoring for serotonin syndrome. If symptoms occur, consider discontinuation of either one or both of the drugs. Linezolid is a reversible, nonselective inhibitor of monoamine oxidase and may therefore interact with tricyclic antidepressants. Spontaneous reports of serotonin syndrome associated with the co-administration of linezolid and serotonergic agents have been reported (Prod Info ZYVOX(R) IV injection, oral tablets, oral suspension, 2008).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concurrent use of linezolid and tricyclic antidepressants, such as doxepin, is contraindicated unless patient is closely observed for signs and/or symptoms of serotonin syndrome. If concomitant use is clinically warranted, monitor for signs and symptoms of serotonin syndrome, such as neuromuscular abnormalities (including hyper-reflexia, tremor, muscle rigidity, clonus, peripheral hypertonicity, and shivering), autonomic hyperactivity (including tachycardia, mydriasis, diaphoresis, the presence of bowel sounds, and diarrhea), and mental status changes (including agitation and delirium). Serotonin syndrome can be life-threatening. If serotonin syndrome develops, discontinue the offending agents and provide supportive care and other therapy as necessary (Boyer & Shannon, 2005; Prod Info ZYVOX(R) IV injection, oral tablets, oral suspension, 2008).

7) Probable Mechanism: linezolid inhibition of monoamine oxidase resulting in an increased concentration of serotonin

3.5.1.CE Lisdexamfetamine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CF Mazindol

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such

therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CG Mephentermine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the

treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CH Mephobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CI Mesoridazine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Although citing no data, the manufacturer of mesoridazine states that concomitant use with other drugs which prolong the QT interval is contraindicated (Prod Info Serentil(R), 2001). Tricyclic antidepressants (TCAs) at therapeutic doses can cause QT prolongation (Marshall & Forker, 1982e).

3) Severity: contraindicated

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Concurrent administration of a tricyclic antidepressant and mesoridazine is contraindicated.

7) Probable Mechanism: additive effect on QT interval

3.5.1.CJ Mestranol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)

2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973k), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972k). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972k) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984k).

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.

7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic

8) Literature Reports

a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose

estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972j).

b) A case reported by (Khurana, 1972j) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973j).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973f).

d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980e).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984j).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984e).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980e). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983e).

3.5.1.CK Methamphetamine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other

sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CL Methohexital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.CM Methoxamine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs

are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).

b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CN Methylphenidate

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CO Midodrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions

of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).

b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CP Moclobemide

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982c; Spigset et al, 1993c; Brodribb et al, 1994b; Neuvonen et al, 1993a). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991b). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971e; White & Simpson, 1984c).

3) Severity: contraindicated

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Concomitant use of moclobemide and a tricyclic antidepressant, such as doxepin, is contraindicated. If doxepin is replacing treatment with moclobemide, a minimum of two days should elapse after moclobemide is discontinued and doxepin therapy is begun (Prod Info Manerix(R), 2001). However, the manufacturer of doxepin recommends that the monoamine oxidase inhibitor (MAOI) be discontinued for at least 14 days before treatment with doxepin is initiated (Prod Info SINEQUAN(R) oral capsule, 2005). There is no specific washout period for replacing doxepin treatment with moclobemide. However, it is advisable to gradually taper the tricyclic antidepressant dosage before starting treatment with and MAOI (Remick, 2002).

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info Manerix(R), 2001). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965b; Brachfeld et al, 1963a; Winston, 1971b; Schuckit et al, 1971d; Sargent, 1965a; Spiker & Pugh, 1976b). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965b).

b) A clinical study designed to detect an interaction between moclobemide and a tricyclic antidepressant (clomipramine) resulted in severe adverse effects, and the study was terminated. Information about interactions with moclobemide and other tricyclic antidepressants is limited (Prod Info Manerix(R), 2001).

c) A drug interaction occurred in which a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all

antidepressant medications (Spigset et al, 1993b).
d) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982b).
e) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994a).
f) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986).
g) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987a).
h) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974; Winston, 1971b; Schuckit et al, 1971d; White & Simpson, 1984b; Rom & Benner, 1972). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991a). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991a). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977b; Schuckit et al, 1971d; Ashcroft, 1975a).

3.5.1.CQ Moxifloxacin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Moxifloxacin has been shown to prolong the QT interval in some patients and should be avoided in those patients receiving agents that also prolong the QT interval, such as tricyclic antidepressants. Although pharmacokinetic studies between moxifloxacin and other drugs which prolong the QT interval have not been performed, an additive effect cannot be excluded. Therefore, moxifloxacin should be used with caution when given concurrently with a tricyclic antidepressant (Prod Info Avelox(TM), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Moxifloxacin should be used with caution when given concurrently with a tricyclic antidepressant.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CR Nefopam
1) Interaction Effect: an increased risk of seizures
2) Summary: Nefopam inhibits the neuronal uptake of norepinephrine and serotonin and increases the risk of seizures, especially in patients with a history of a convulsive disorder. Tricyclic antidepressants also lower the seizure threshold. Therefore, the manufacturer of nefopam advises caution in patients on concurrent tricyclic antidepressant therapy (Pillans & Woods, 1995).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Because of the increased risk of seizures, extreme caution should be exercised in patients receiving nefopam and a tricyclic antidepressant. An alternative analgesic may be considered.
7) Probable Mechanism: additive lowering of seizure threshold

3.5.1.CS Nialamide

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982m; Spigset et al, 1993n; Brodribb et al, 1994l; Neuvonen et al, 1993f). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991g). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971o; White & Simpson, 1984l).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965g; Winston, 1971g; Schuckit et al, 1971n; Spiker & Pugh, 1976g). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965g).

b) In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982l).

c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993m).

d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987g).

e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991f). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977g; Schuckit et al, 1971n; Ashcroft, 1975f).

3.5.1.CT Norepinephrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic

antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CU Octreotide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and octreotide have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Sandostatin(R), 1999; Marshall & Forker, 1982). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as octreotide, is not recommended (Prod Info Elavil (R), 1999).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of octreotide and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.CV Oxilofrine
1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia
2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.
7) Probable Mechanism: inhibition of norepinephrine reuptake
8) Literature Reports
a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.CW Pargyline
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982a; Spigset et al, 1993a; Brodribb et al, 1994; Neuvonen et al, 1993). Serotonin

syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991a). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971a; White & Simpson, 1984).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965; Winston, 1971; Schuckit et al, 1971; Spiker & Pugh, 1976). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982).
c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolescence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993).
d) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patients developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987).
e) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977; Schuckit et al, 1971; Ashcroft, 1975).

3.5.1.CX Paroxetine
1) Interaction Effect: doxepin toxicity (dry mouth, sedation, urinary retention)
2) Summary: Paroxetine coadministered with desipramine or imipramine produced higher serum concentrations of the tricyclic antidepressant (TCA) in some patients (Hartter et al, 1994; Brosen et al, 1993a). Although not reported specifically with doxepin, a similar interaction could be expected to occur. Paroxetine's effect on TCAs may resemble that of fluoxetine (another selective serotonin reuptake inhibitor), which is known to inhibit TCA metabolism (Aranow et al, 1989b; Vaughan, 1988; Goodnick, 1989b). With coadministration, monitor patients for doxepin toxicity. Doxepin doses may need to be reduced (Prod Info Paxil CR(TM), 2003).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: When doxepin is coadministered with paroxetine, monitor patients for signs and symptoms of doxepin toxicity (dry mouth, sedation, urinary retention, blurred vision). Doxepin doses may need to be reduced.
7) Probable Mechanism: decreased doxepin metabolism
8) Literature Reports
a) The effect of paroxetine on desipramine metabolism was studied in 9 extensive metabolizers (EM) and 8 poor metabolizers (PM) of desipramine. Subjects took a single oral dose of desipramine before starting paroxetine and a second dose after 11 days of paroxetine use. After the addition of paroxetine,

EMs experienced a 5-fold decrease in clearance of desipramine, indicating that paroxetine inhibits oxidation reactions catalyzed by CYP2D6. PMs had a slight increase in clearance of desipramine with paroxetine. With concurrent administration of desipramine and paroxetine, interaction of the two drugs may result in a need for dosage adjustments, especially in extensive metabolizers of desipramine (Brosen et al, 1993).

3.5.1.CY Pemoline

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.CZ Pentamidine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and pentamidine have been shown to prolong the QTc interval at the recommended therapeutic dose (Lindsay et al, 1990; Marshall & Forker, 1982i). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as pentamidine, is not recommended (Prod Info Elavil (R), 1999e).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of pentamidine and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.DA Pentobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.DB Phendimetrazine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports
a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little

advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.DC Phenelzine

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982k; Spigset et al, 1993l; Brodribb et al, 1994k; Neuvonen et al, 1993e). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991f). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971m; White & Simpson, 1984k).

3) Severity: major

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Concomitant use of a tricyclic antidepressant, such as doxepin, and a monoamine oxidase inhibitor (MAOI), such as phenelzine, should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine. If doxepin is replacing treatment with phenelzine, a minimum of 14 days should elapse after phenelzine is discontinued before doxepin therapy begins (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005). The manufacturer of phenelzine recommends a minimum of 10 days should elapse between discontinuing the tricyclic antidepressant therapy and initiating treatment with phenelzine (Prod Info NARDIL(R) Tablets, USP, 2005).

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965f; Brachfeld et al, 1963e; Winston, 1971f; Schuckit et al, 1971l; Sargent, 1965e; Spiker & Pugh, 1976f). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965f).

b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982j).

c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993k).

d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994j).

e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986d).

f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987f).

g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of

large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974d; Winston, 1971f; Schuckit et al, 1971l; White & Simpson, 1984j; Rom & Benner, 1972d). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991e). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991e). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977f; Schuckit et al, 1971l; Ashcroft, 1975e).

3.5.1.DD Phenindione

1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970e; Williams et al, 1976e). Considerable interindividual differences may be found (Pond et al, 1975e).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased phenindione metabolism; increased phenindione absorption
8) Literature Reports

a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975d). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970d). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976d). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.DE Phenmetrazine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.
7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission
8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).
b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info

DAYTRANA(TM) transdermal system, 2006).
c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).
d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).
e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.DF Phenobarbital
1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.DG Phenprocoumon
1) Interaction Effect: increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970g; Williams et al, 1976g). Considerable interindividual differences may be found (Pond et al, 1975g).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving tricyclic antidepressants and oral anticoagulant therapy, the prothrombin time ratio or INR (international normalized ratio) should be closely monitored with the addition and withdrawal of the antidepressant, and should be periodically reassessed during concurrent therapy. Achieving a stable drug regimen which produces the desired level of anticoagulation may be difficult in patients on this combination, and frequent adjustments of the anticoagulant dose may be required.
7) Probable Mechanism: decreased phenprocoumon metabolism; increased phenprocoumon absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975f). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after 8 days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in 6 healthy volunteers (Vesell et al, 1970f). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976f). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated

mechanism.

3.5.1.DH Phentermine

1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation

2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.DI Phenylephrine

1) Interaction Effect: hypertension, cardiac arrhythmias, and tachycardia

2) Summary: Clinical trials have demonstrated a 2- to 8-fold increase in the effects of intravenous infusions of alpha adrenergic drugs to volunteers on tricyclic antidepressants. Arrhythmias and other severe adverse effects have also been reported (Ghose, 1980; Avery, 1973a; Boakes et al, 1973a; Boakes, 1973; Mitchell et al, 1970; Stone et al, 1964). Local use (e.g., dental anesthesia) of epinephrine in concentrations of 1:100,000 or less is less likely to precipitate clinically significant hemodynamic changes (Steinberg & Block, 1971).

3) Severity: major

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: The vasoconstriction and other alpha-adrenergic effects of sympathomimetic drugs are substantially enhanced in the presence of tricyclic antidepressants (TCAs). Concomitant use should be avoided. If these drugs are given together, careful monitoring and a dose reduction of the sympathomimetic is required. Patients should be instructed to inform their doctor or dentist that they are taking a tricyclic antidepressant prior to any surgery or procedure.

7) Probable Mechanism: inhibition of norepinephrine reuptake

8) Literature Reports

a) Four healthy volunteers received intravenous infusions of various sympathomimetic amines (epinephrine, norepinephrine, phenylephrine, and isoproterenol) before and after imipramine (25 mg

three times daily for five days). They showed an increased pressor response to epinephrine (2- to 4-fold), norepinephrine (4- to 8-fold), and phenylephrine (2- to 3-fold) after imipramine, but no difference was observed in the response to isoproterenol. Thus, the increased pressor response appeared to occur only for alpha adrenergic effects. All four subjects demonstrated changes in cardiac rhythm with epinephrine and imipramine consisting of sinus arrhythmia in three subjects and multiple ectopic beats and a nodal rhythm in the fourth subject (Boakes et al, 1973).
b) A review of spontaneous reports of adverse reactions to vasoconstrictors in local anesthetics found that 15 patients receiving a local anesthetic with norepinephrine (1:25,000) had severe reactions (severe headaches, chest tightness, subarachnoid hemorrhage). The drug history was incomplete, but at least three had been taking a tricyclic antidepressant at the time (Anon, 1972).

3.5.1.DJ Phenytoin
1) Interaction Effect: an increased risk of phenytoin toxicity (ataxia, hyperreflexia, nystagmus, tremor)
2) Summary: A few case reports have indicated that imipramine inhibits phenytoin metabolism resulting in increased serum phenytoin. Tricyclic antidepressants (TCAs) may lower the seizure threshold in epileptic patients stabilized on anticonvulsants. Theoretically, because phenytoin is an enzyme inducer, the metabolism of antidepressants may be increased resulting in reduced TCA serum levels (Petti & Campbell, 1975a; Perucca & Richens, 1977a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor therapeutic efficacy of doxepin; an increased dose may be required. Serum phenytoin levels should be obtained when tricyclic antidepressant agents are added to therapy due to the potential for impaired phenytoin metabolism.
7) Probable Mechanism: inhibition of phenytoin metabolism

3.5.1.DK Pimozide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although citing no data, the manufacturer of pimozide states that concomitant use with other drugs which prolong the QT interval is contraindicated (Prod Info Orap(R), 1999a). Tricyclic antidepressants (TCAs) at therapeutic doses can cause QT prolongation (Prod Info Norpramin(R), 2000; Marshall & Forker, 1982z).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Because of the potential to prolong the QT interval, concurrent administration of a tricyclic antidepressant and pimozide is contraindicated.
7) Probable Mechanism: additive effects on QT interval
8) Literature Reports
a) Electrocardiogram (ECG) changes seen during clinical trials of pimozide in Tourette's syndrome and schizophrenia patients include prolongation of the QT interval, flattening, notching, and inversion of the T wave, and the appearance of U waves. Sudden, unexpected deaths have occurred at doses greater than 20 milligrams/day (Prod Info Orap(R) pimozide, 1999).

3.5.1.DL Pirmenol
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.
b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that

amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).
c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.DM Prajmaline

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.
b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).
c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.DN Primidone

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-

related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.DO Procainamide

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.

7) Probable Mechanism: additive cardiac effects

8) Literature Reports

a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.

b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).

c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.DP Procarbazine

1) Interaction Effect: neurotoxicity, seizures

2) Summary: Concomitant tricyclic antidepressant and more potent MAOI use has resulted in hyperpyrexia, convulsions, and death. Procarbazine has relatively weak MAOI actions, so while the potential for drug interactions between tricyclic antidepressants and procarbazine exists, clinical data are lacking at this time (Schuckit et al, 1971c; White & Simpson, 1984a). Concurrent use is not recommended (Prod Info Matulane (R), 1997).

3) Severity: major

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Concomitant use is not recommended and should probably be initiated only under close medical supervision, and then only if other antidepressant class agents have proven unsuccessful. With more potent MAOIs, recommendations for concurrent use of TCAs have included avoiding large doses of the TCA, using only oral tricyclics, and avoiding imipramine, clomipramine, and desipramine. Procarbazine therapy should not begin until seven days following discontinuation of tricyclic antidepressants and 14 days following the discontinuation of other MAO inhibitors.

7) Probable Mechanism: altered catecholamine uptake and metabolism

8) Literature Reports

a) Procarbazine is primarily used as an antineoplastic agent, but was originally investigated as a monoamine oxidase inhibitor (Gilman et al, 1985). Animal studies have indicated that procarbazine is a monoamine oxidase inhibitor (MAOI) (DeVita et al, 1965) but appears to be a relatively weak MAOI in man (Gilman et al, 1985). Hypertensive reactions may still result from concomitant administration of tricyclic antidepressants, sympathomimetics, and tyramine containing foods (Gilman et al, 1985; Ponto et al, 1977a).

b) Concomitant administration of monoamine oxidase (MAO) inhibitors with tricyclic antidepressants

has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965a; Brachfeld et al, 1963; Winston, 1971a; Schuckit et al, 1971b; Sargent, 1965; Spiker & Pugh, 1976a). Careful examination of such reports indicate unusual circumstances in most cases such as parenteral administration of a tricyclic. The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965a).
c) Procarbazine therapy should not begin until 7 days following discontinuation of tricyclic antidepressants and 14 days following the discontinuation of other MAO inhibitors (AMA Department of Drugs, 1992; Gilman et al, 1985).

3.5.1.DQ Prochlorperazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Compazine(R), 2002; Prod Info Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, though no reports are available. Tricyclic antidepressants (TCAs) at therapeutic doses can cause QT prolongation (Marshall & Forker, 1982ad). Case reports have described increased plasma levels and adverse effects when phenothiazines and tricyclic antidepressants were taken together, likely due to inhibition of their metabolism (Ghaemi & Kirkwood, 1998; Geller et al, 1985; Siris et al, 1982; Loga et al, 1981).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Concurrent administration of a phenothiazine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive effect on QT interval

3.5.1.DR Propafenone
1) Interaction Effect: doxepin toxicity (sedation, dry mouth)
2) Summary: A single case was reported in which coadministration of propafenone and desipramine in an elderly patient resulted in desipramine toxicity at a desipramine dosage which had previously produced levels in the therapeutic range (Katz, 1991a). Although not reported for doxepin, caution should be used with concomitant use of propafenone.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor for symptoms of tricyclic antidepressant toxicity.
7) Probable Mechanism: decreased doxepin metabolism
8) Literature Reports
a) A 68-year-old man suffering from agitated major depression was started on a dose of desipramine 125 mg daily which produced a subtherapeutic serum level of 442 nmol/L (therapeutic range 500 to 1000 nmol/L). An increased dose of 175 mg daily produced excellent clinical response with no side effects. He developed atrial fibrillation and flutter. Digoxin 0.25 mg daily was added to his therapy, and desipramine was discontinued. His arrhythmia was suppressed with the addition of propafenone 150 mg twice daily and 300 mg at bedtime. Desipramine 150 mg daily was again begun, at which point he experienced dry mouth, sedation, and shakiness; the desipramine serum level was measured at 2092 nmol/L. The desipramine was discontinued for five days, the side effects ceased, and desipramine therapy was resumed at 75 mg daily. The desipramine serum level was measured at 1130 nmol/L (Katz, 1991).

3.5.1.DS Propoxyphene
1) Interaction Effect: doxepin toxicity (sedation, lethargy, dry mouth, urinary retention)
2) Summary: Concomitant therapy with propoxyphene and doxepin has been reported to double steady state doxepin and desmethyldoxepin plasma concentrations and decrease cognitive function. This interaction is most likely related to inhibition of hepatic microsomal enzymes by propoxyphene (Abernethy et al, 1982).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for symptoms of tricyclic antidepressant toxicity such as sedation, dry mouth, and urinary retention. Serum doxepin levels may also be of value in predicting toxicity. An alternative analgesic agent such as acetaminophen with codeine might be considered if clinically appropriate.
7) Probable Mechanism: decreased doxepin metabolism

3.5.1.DT Propylhexedrine
1) Interaction Effect: hypertension, other cardiac effects, and CNS stimulation
2) Summary: Concomitant tricyclic antidepressant (TCA) and amphetamine administration has been

reported to result in enhanced amphetamine effects from the release of norepinephrine (Beaumont, 1973d; Raisfeld, 1972). A similar reaction might also occur with all drugs that have amphetamine-like effects. Acute elevations in blood pressure have been noted (Flemenbaum, 1971a). Some amphetamine-like drugs may inhibit the metabolism of TCAs, although most combinations have not been studied. When amphetamine analogs are being used to treat obesity, it should be noted that TCAs frequently lead to moderate weight gain (Russ & Ackerman, 1988). False positive urine tests for amphetamines have been reported during therapy with some TCAs (Merigian & Browning, 1993). Caution is advised when concurrent administration of amphetamine-like agents and TCAs is warranted. The patient should be closely monitored for increased cardiovascular effects (hypertension and dysrhythmias).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Coadministration of amphetamines and tricyclic antidepressants or other sympathomimetic agents could lead to hypertension, increased cardiovascular effects, or CNS stimulation (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006; Flemenbaum, 1972). Use caution if such therapy is warranted. Monitor the patient closely for hypertension and dysrhythmias.

7) Probable Mechanism: synergistic effects on noradrenergic neurotransmission

8) Literature Reports

a) Amphetamines may increase the activity of tricyclic antidepressants (TCA) or sympathomimetic agents. Additionally, coadministration of d-amphetamine with TCAs such as desipramine or protriptyline results in sustained increases in d-amphetamine concentration in the brain (Prod Info VYVANSE(TM) oral capsules, 2007; Prod Info DEXEDRINE(R) sustained-release oral capsules, oral tablets, 2006; Prod Info ADDERALL(R) oral tablets, 2006).

b) Human pharmacologic studies have demonstrated that methylphenidate may inhibit the metabolism of some tricyclic antidepressants, such as imipramine, clomipramine, or desipramine (Prod Info DAYTRANA(TM) transdermal system, 2006).

c) Concomitant administration of tricyclic antidepressants and methylphenidate can result in increases in blood pressure such that the hypotensive effects induced by TCAs may lead to blood pressures as high as 170/120 mmHg within one day of combined therapy. Discontinuation of the methylphenidate usually results in the blood pressure returning to normotensive levels; reinstitution of the methylphenidate resulted in further blood pressure elevation (Flemenbaum, 1971; Flemenbaum, 1972).

d) Fifteen patients with DSM-III major depression, who failed to respond to treatment with desipramine given for at least four weeks, were given fenfluramine 40 mg to 120 mg daily for two weeks but did not result in any transient or sustained clinical improvement. However, fenfluramine more than doubled steady-state plasma levels of desipramine (Price et al, 1990).

e) There have been claims based on uncontrolled studies that a better antidepressant response may occur with combined therapy (Garrettson et al, 1969). However, a systemic review of stimulants in the treatment of depression concluded that although uncontrolled studies were generally positive, the ten placebo-controlled studies of stimulant drugs in primary depression, with one exception, indicated little advantage of drug over placebo and did not appear to be as effective as the conventional antidepressants in primary depression (Satel & Nelson, 1989).

3.5.1.DU Quetiapine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.

7) Probable Mechanism: additive cardiac effects

8) Literature Reports

a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.DV Quinestrol

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension,

akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973c), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972c). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972c) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984c).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to four treatment groups. Ten patients received placebo, 10 received imipramine (150 mg daily) and placebo, five patients received imipramine (150 mg daily) and ethinyl estradiol (50 mcg daily), while five patients received imipramine (150 mg daily) and ethinyl estradiol (25 mcg daily). The 10 patients that received placebo did not improve over the six weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients taking imipramine alone. However, after two weeks, the five patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of two weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, five women received imipramine 150 mg and ethinyl estradiol 50 mcg daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor, and systolic hypotension (Prange, 1972b).
b) A case reported by (Khurana, 1972b) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 mg and imipramine 100 mg. The patient developed lethargy, tremors, and signs of depersonalization. After two years of therapy, the patient increased her estrogen dose to 5 mg and then 7.5 mg daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973b).
c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973a).
d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 mg at bedtime while 19 took clomipramine 25 mg at bedtime with oral contraceptives. Over the four-week study, three control patients (two due to side-effects) and five in the experimental group (two due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980a).
e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 mg daily for anorexia nervosa and conjugated estrogens 1.25 mg daily for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 mg was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogen 1.25 mg daily who was prescribed amitriptyline 50 mg daily for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogen 1.25 mg daily and amitriptyline 50 mg daily. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984b).
f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 mcg or less of ethinyl estradiol) from 27% to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984a).
g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980a). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation

of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983a).

3.5.1.DW Quinidine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Class Ia antiarrhythmics and tricyclic antidepressants have been shown to prolong the QTc interval at the recommended therapeutic dose. Even though no formal drug interaction studies have been done, the coadministration of Class Ia antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Prod Info Elavil(R), 1999g; Prod Info Quinaglute(R), 1999; Marshall & Forker, 1982m).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: The concurrent administration of a Class IA antiarrhythmic agent and a tricyclic antidepressant is not recommended.

7) Probable Mechanism: additive cardiac effects

8) Literature Reports

a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.

b) An increased incidence in sudden death was observed in six out of 53 patients with cardiac disease receiving amitriptyline, compared to 0 out of 53 in the control group. It was recommended that amitriptyline be avoided in patients with underlying cardiac disease except when depression was debilitating and no other drugs were helpful (Moir et al, 1972; Coull et al, 1970).

c) In a placebo controlled study, imipramine 3.5 mg/kg was administered daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine. The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity (Kantor et al, 1978).

3.5.1.DX Quinidine

1) Interaction Effect: doxepin toxicity (sedation, dry mouth, urinary retention) and an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Two studies have demonstrated that concomitant use of quinidine and imipramine or desipramine results in increased serum concentrations of these antidepressants (Brosen & Gram, 1989b; Steiner et al, 1987). A similar interaction may occur with other tricyclic antidepressants including doxepin. Due to their similar cardiac effects, the incidence of cardiotoxicity (increased PR interval, QRS complex, and QTc interval) may also be increased if tricyclic antidepressants are administered with Type I antiarrhythmics (Kantor et al, 1978b; Bigger et al, 1977).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Concurrent use of quinidine and doxepin is not recommended. Monitor for symptoms of tricyclic antidepressant toxicity; a decrease in doxepin dosage may be required. Also monitor the patient for signs and symptoms of additive cardiac effects, including any changes in the EKG.

7) Probable Mechanism: decreased doxepin metabolism, additive cardiac effects

8) Literature Reports

a) Quinidine is an inhibitor of the cytochrome P450 isoenzyme responsible for the 2-hydroxylation of imipramine and desipramine (Brosen & Gram, 1989a). Inhibition of this enzyme system can result in a 35% decrease in imipramine clearance and 85% decrease in desipramine clearance. Demethylation of imipramine by the cytochrome P450 system is unaffected by this interaction. Until more information is available, all patients having quinidine added to drug regimen containing imipramine or desipramine should be monitored for increased antidepressant serum concentrations and potential toxicity.

b) In a placebo controlled study, (Kantor et al, 1978a) administered imipramine 3.5 mg/kg daily for seven patients with severe depression and titrated doses to obtain therapeutic plasma concentrations. Two patients displayed premature atrial depolarizations and premature ventricular depolarizations before therapy. On patient had 33 premature atrial depolarizations (PAD) and 30 premature ventricular depolarizations (PVD) per hour, which decreased to 0.4 PAC and zero PVC per hour on imipramine.

The other patient had 12 PAD and 169 PVD per hour before treatment and 1.8 PAD and 28.1 PVD per hour on imipramine. The authors also cautioned that the incidence of cardiotoxicity may increase if tricyclic antidepressants are administered with Type I antiarrhythmics. It was also recommended that quinidine and procainamide not be used to treat the arrhythmias of a tricyclic overdose. The similarities between these agents may exacerbate the cardiotoxicity.

3.5.1.DY Rasagiline

1) Interaction Effect: severe CNS toxicity
2) Summary: Concomitant use of rasagiline and tricyclic antidepressants should be avoided. Concurrent administration or overlapping therapy with tricyclic antidepressants and non-selective MAOIs has been reported to cause serious, sometimes fatal, reactions; the mechanisms of these reactions are not fully understood. Signs and symptoms include severe CNS toxicity (behavioral and mental status changes, diaphoresis, muscular rigidity, hypertension, and syncope) associated with hyperpyrexia and death. Data from clinical studies, where rasagiline-treated patients (n=115) were concomitantly exposed to tricyclic antidepressants, are insufficient to rule out an interaction. At least 14 days should elapse after discontinuing rasagiline before initiating therapy with a tricyclic antidepressant (Prod Info AZILECT(R) oral tablets, 2006).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concurrent use of rasagiline and a tricyclic antidepressant is not recommended. Wait at least 14 days after discontinuing rasagiline before initiating therapy with a tricyclic antidepressant (Prod Info AZILECT(R) oral tablets, 2006).
7) Probable Mechanism: unknown

3.5.1.DZ Risperidone

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.EA S-Adenosylmethionine

1) Interaction Effect: an increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: A single case has been reported of serotonin syndrome likely resulting from the combination of S-adenosylmethionine (SAMe) and clomipramine (Iruela et al, 1993a). SAMe was shown to hasten the onset of therapeutic response of imipramine in a clinical trial involving 40 patients, without serotonergic side effects (Berlanga et al, 1992). If therapy is initiated with SAMe and a tricyclic antidepressant, the patient should be monitored closely for early signs of serotonin syndrome. Serotonin syndrome is a condition of serotonergic hyperstimulation and manifests as restlessness, myoclonus, changes in mental status, hyperreflexia, diaphoresis, shivering, and tremor. If the syndrome is not recognized and correctly treated, death can result (Sternbach, 1991).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: S-adenosylmethionine (SAMe) used concomitantly with imipramine was found to decrease depressive symptoms sooner than imipramine alone (Berlanga et al, 1992). One case has been reported of serotonin syndrome likely resulting from concomitant use of SAMe and clomipramine (Iruela et al, 1993). If SAMe and a tricyclic antidepressant are used together, use low doses of each and titrate upward slowly, while monitoring closely for early signs of serotonin syndrome such as increasing anxiety, confusion, and disorientation.
7) Probable Mechanism: additive pharmacologic effects resulting in excessive serotonergic stimulation

8) Literature Reports

a) A 71 year-old female was hospitalized with anxiety, agitation, confusion, and symptoms of serotonin syndrome. She had been taking S-adenosylmethionine 100 milligrams (mg) intramuscularly daily and clomipramine 25 mg daily for 10 days, which was then increased to 75 mg/day. Within 48-72 hours of the increased clomipramine dosage, she became progressively anxious, agitated, and confused. On admission she was verbally unresponsive and stuporous, with heart rate 130 beats/minute, respiratory rate 30 breaths/minute, temperature 40.5 degrees Celsius, diarrhea, myoclonus, generalized tremors, rigidity, hyperreflexia, shivering, diaphoresis, and dehydration. Temperature increased to 43 degrees Celsius during her hospital stay, with no documented infection. White blood cell count (WBC) was 13,040 mm3, lactic dehydrogenase was 662 units/liter (U/L), creatine phosphokinase was 8920 U/L, serum potassium 2.7 milliequivalents/liter (mEq/L), creatinine 1.1 mg/100 milliliter (mL) (laboratory reference values were not provided). A cranial computed tomography (CT) scan was normal. The patient was not taking neuroleptics. Serum benzodiazepine and tricyclic antidepressant levels were normal. Symptoms resolved gradually with 4 days of hydration and supportive care. The interaction was proposed to be a result of synergistic activity of S-adenosylmethionine and clomipramine (Iruela et al, 1993).

3.5.1.EB Salmeterol

1) Interaction Effect: an increased risk of cardiovascular excitation

2) Summary: Salmeterol should be administered with extreme caution to patients who are being treated with a tricyclic antidepressant, or within two weeks of the discontinuation of a tricyclic antidepressant (Prod Info SEREVENT(R) DISKUS(R) inhalation powder, 2006). Clinically significant changes in systolic and diastolic blood pressure, pulse rate, and electrocardiograms have been seen with the use of salmeterol, and these changes may be exacerbated by the use of a tricyclic antidepressant.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Close observation for adverse cardiovascular effects is warranted when these agents are administered concurrently or if salmeterol is given within two weeks of discontinuation of a tricyclic antidepressant.

7) Probable Mechanism: potentiation of vascular effects

3.5.1.EC Secobarbital

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects

2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.

7) Probable Mechanism: increased tricyclic antidepressant metabolism

8) Literature Reports

a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.ED Selegiline

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982i; Spigset et al, 1993j; Brodribb et al, 1994i; Neuvonen et al, 1993d). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991e). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971k; White & Simpson,

1984i).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of a tricyclic antidepressant, such as doxepin, and a monoamine oxidase inhibitor (MAOI), such as selegiline, should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine. A minimum of 14 days should elapse after selegiline is discontinued before doxepin therapy begins (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005). There is no specific washout period for doxepin when beginning treatment with selegiline. However, it is advisable to gradually taper the tricyclic antidepressant dosage before starting treatment with the MAOI (Remick, 2002).
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965e; Brachfeld et al, 1963d; Winston, 1971e; Schuckit et al, 1971j; Sargent, 1965d; Spiker & Pugh, 1976e). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965e).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982h).
c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993i).
d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994h).
e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986c).
f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987e).
g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974c; Winston, 1971e; Schuckit et al, 1971j; White & Simpson, 1984h; Rom & Benner, 1972c). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991d). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991d). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977e; Schuckit et al, 1971j; Ashcroft, 1975d).

3.5.1.EE Sematilide
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac

arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.EF Sertindole
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.EG Sertraline
1) Interaction Effect: modest elevations in doxepin serum levels or possible serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: There is limited evidence suggesting that sertraline may inhibit tricyclic antidepressant (TCA) metabolism resulting in higher TCA serum concentrations. Sertraline inhibits cytochrome P450 2D6 enzyme activity and may increase the plasma concentrations of coadministered drugs that are metabolized by this pathway, including the tricyclic antidepressants (Prod Info Zoloft(R), 2002; Preskorn et al, 1994c; Lydiard et al, 1993). Effects of the interaction may have little or no clinical impact, however. Increases in TCA serum levels associated with sertraline coadministration were modest compared with those found when fluoxetine (another selective serotonin reuptake inhibitor) was combined with desipramine (von Moltke et al, 1994). Monitor patients on doxepin-sertraline therapy for TCA toxicity (dry mouth, urinary retention, CNS depression). Doxepin doses may need to be reduced.
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The combined use of tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) may result in the inhibition of the TCA metabolism. A few cases of serotonin syndrome have also been reported with concurrent TCA and SSRI therapy. Caution should be observed when drugs in these two classes are used together.
7) Probable Mechanism: inhibition of doxepin metabolism
8) Literature Reports
a) Desipramine pharmacokinetics was studied in 18 healthy male volunteers. Study subjects received

only desipramine (50 mg daily) for 7 days followed by desipramine with sertraline (50 mg daily) for 21 days. When sertraline was added to desipramine therapy, the mean maximum concentration of desipramine increased by 34% and the area under the concentration-time curve increased by 26%. Trough concentrations of desipramine were close to baseline one week after sertraline was discontinued. The changes in desipramine concentrations were modest and the interaction may not be clinically significant (Preskorn et al, 1994b).

3.5.1.EH Sotalol

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).

3) Severity: major

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.

7) Probable Mechanism: additive QT prolongation

8) Literature Reports

a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).

b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.EI Sparfloxacin

1) Interaction Effect: prolongation of the QTc interval and/or torsades de pointes

2) Summary: Torsades de pointes has been reported in patients receiving sparfloxacin concomitantly with disopyramide and amiodarone. The use of sparfloxacin is contraindicated with drugs which produce an increase in the QTc interval and/or torsades de pointes, including tricyclic antidepressants. Sparfloxacin is also contraindicated in persons with known QTc prolongation (Prod Info Zagam(R), 1998a).

3) Severity: contraindicated

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Sparfloxacin is contraindicated in individuals with known QTc prolongation or in patients being treated concurrently with drugs that are known to increase the QTc interval and/or cause torsades de pointes.

7) Probable Mechanism: additive effects on QTc prolongation

8) Literature Reports

a) In clinical trials involving 1489 patients with a baseline QTc measurement, the mean prolongation of the QTc interval at sparfloxacin steady-state was 10 msec (2.5%). Of these subjects, 0.7% had a QTc interval greater than 500 msec at steady-state. However, no arrhythmic effects were seen in any of the patients. The magnitude of the QTc effect does not increase with repeated administration of sparfloxacin, and the QTc interval returns to baseline within 48 hours after discontinuation of sparfloxacin (Prod Info Zagam(R), 1998).

b) A case of sparfloxacin-induced torsades de pointes is described (Dupont et al, 1996). A 47-year old woman hospitalized for suppurative otitis media and mastoiditis was treated with sparfloxacin due to an allergy to betalactam antibiotics. On day six of treatment she felt dizzy and lost consciousness. This was attributed to torsades de pointes on the cardioscope and was followed by cardiac arrest which required cardiopulmonary resuscitation. Her pre-treatment electrocardiogram showed QT and QTc intervals of 0.34 and 0.46 seconds, respectively. An electrocardiogram post-arrest revealed QT and QTc intervals of 0.35 and 0.60 seconds, respectively. A 24-hour continuous electrocardiography confirmed numerous episodes of torsades de pointes occurring after episodes of sino-auricular block. Sparfloxacin was discontinued and the QTc returned to baseline within a week. Upon further testing, it was determined that the patient suffered from a mild idiopathic long QT syndrome. Due to the onset of symptoms with administration of sparfloxacin and the relief of symptoms following discontinuation of the drug, it is highly probable that sparfloxacin contributed to the torsades de pointes.

3.5.1.EJ Spiramycin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

2) Summary: Tricyclic antidepressants (TCAs) and spiramycin have been shown to prolong the QTc interval at the recommended therapeutic dose (Stramba-Badiale et al, 1997; Marshall & Forker, 1982b). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as spiramycin, is not recommended (Prod Info Elavil(R), 1999a).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of spiramycin and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.EK St John's Wort
1) Interaction Effect: an increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Theoretically, since St. John's Wort is thought to inhibit serotonin reuptake and may have mild monoamine oxidase inhibitory activity (Singer et al, 1999; Thiede & Walper, 1994), serotonin syndrome could result when St. John's Wort is taken along with a tricyclic antidepressant. This theoretical risk of serotonin syndrome is also based on case reports of serotonin syndrome resulting from concomitant use of selective serotonin reuptake inhibitors with tricyclic antidepressants (Alderman & Lee, 1996), as well as concomitant use of monoamine oxidase inhibitors with tricyclic antidepressants (Brodribb et al, 1994c; Spigset et al, 1993d; Tackley & Tregaskis, 1987b). Coadministration of amitriptyline and St. John's Wort decreased the area under the concentration-time curve of amitriptyline and its metabolite nortriptyline (Roots et al, 2000); if other tricyclic antidepressants are similarly affected by St. John's Wort, the risk of serotonin syndrome may be reduced, yet effectiveness of the tricyclic antidepressant may also be reduced. To maintain maximal effectiveness of the tricyclic antidepressant, as well as avoid any potential risk of serotonin syndrome, avoid concomitant use of St. John's Wort and tricyclic antidepressants.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of St. John's Wort with tricyclic antidepressants.
7) Probable Mechanism: additive pharmacologic effects resulting in excessive serotonergic stimulation

3.5.1.EL Sulfamethoxazole
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and cotrimoxazole have been shown to prolong the QTc interval at the recommended therapeutic dose (Lopez et al, 1987; Marshall & Forker, 1982q). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as cotrimoxazole, is not recommended (Prod Info Elavil (R), 1999i).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of cotrimoxazole and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.EM Sultopride
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is

prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.1.EN Tapentadol

1) Interaction Effect: increased risk of serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concurrent use of tapentadol and a tricyclic antidepressant may result in serotonin syndrome, which may be life-threatening. Symptoms of serotonin syndrome may include restlessness, hallucinations, loss of coordination, fast heart beat, rapid changes in blood pressure, increased body temperature, overreactive reflexes, nausea, vomiting, and diarrhea (Prod Info tapentadol immediate release oral tablets, 2008).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Coadministration of tapentadol and a tricyclic antidepressant may result in a life-threatening condition called serotonin syndrome. If these agents are used together, monitor the patient closely for symptoms of serotonin syndrome (restlessness, hyperthermia, hyperreflexia, incoordination), especially during treatment initiation and dose increases (Prod Info tapentadol immediate release oral tablets, 2008).
7) Probable Mechanism: additive serotonergic effect

3.5.1.EO Tedisamil

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Cases of QTc prolongation and/or torsades de pointes have been reported with all Class III antiarrhythmic agents, including acecainide (Chow et al, 1984), amiodarone (Faggiano et al, 1996), azimilide (Corey et al, 1999), bretylium (Gilman et al, 1985a), ibutilide (Rodriguez et al, 2001), sematilide (Singh, 1996), dofetilide (Allen et al, 2002), and sotalol (Marill & Runge, 2001). Even though no formal drug interaction studies have been done, the coadministration of Class III antiarrhythmics and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is not recommended (Yamreudeewong et al, 2003a; Prod Info Corvert(R), 2000).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a Class III antiarrhythmic and a tricyclic antidepressant (TCA) is not recommended.
7) Probable Mechanism: additive QT prolongation
8) Literature Reports
a) EKG effects reported in patients receiving therapeutic doses of tricyclic antidepressants include increased heart rate, prolonged PR interval, intraventricular conduction delays, increased corrected QT interval (QTc) and flattened T waves (Marshall & Forker, 1982y).
b) Concurrent use of Class III antiarrhythmic agents, and other drugs that can prolong the QT interval, such as tricyclic antidepressants, is not recommended. Dofetilide should be stopped for at least 2 days before any interacting drug is initiated. If concurrent use cannot be avoided, cautious dosing and telemetric monitoring is advised (Yamreudeewong et al, 2003).

3.5.1.EP Telithromycin

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Telithromycin may prolong the QT interval in some patients (Owens, 2001d). Because tricyclic antidepressants may also prolong the QT interval and increase the risk of arrhythmias, the concurrent administration of telithromycin and tricyclic antidepressants is not recommended (Marshall & Forker, 1982ac).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Because of the potential for additive QT interval prolongation, the concurrent administration of telithromycin and a tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.EQ Terfenadine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) have been shown to prolong the QTc interval at the recommended therapeutic dose (Marshall & Forker, 1982ab). Even though no formal drug interaction studies have been done, the coadministration of terfenadine and other drugs known to prolong the QTc interval, including tricyclic antidepressants, is contraindicated (Prod Info Elavil(R), 1999j; Anon, 1997).
3) Severity: contraindicated

4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of terfenadine with any drug that prolongs the QT interval, such as tricyclic antidepressants, is contraindicated.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.ER Thiopental

1) Interaction Effect: possible decreased tricyclic antidepressant serum concentrations and possible additive adverse effects
2) Summary: Concomitant barbiturate and tricyclic antidepressant (TCA) therapy may result in increased metabolism of the TCA. There have been scattered reports of individuals with decreased serum levels of TCAs in the presence of a barbiturate (Moody et al, 1977; Silverman & Braithwaite, 1972; Burrows & Davies, 1971). In addition, TCAs can worsen seizure control by reducing the seizure threshold (Brodie, 1992). These drugs also have additive CNS and respiratory depressant effects.
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for efficacy of antidepressant effect. Increases in tricyclic antidepressant dosages may be required. Additionally, monitor for toxicity when either drug is added to or withdrawn from therapy. Serum concentrations may be of value in determining appropriate dosage.
7) Probable Mechanism: increased tricyclic antidepressant metabolism
8) Literature Reports
a) The pharmacokinetics of a single oral dose of desipramine (100 mg) were studied in eight epileptic patients chronically treated with phenobarbital and in eight drug-free healthy controls (Spina et al, 1996). All subjects were extensive metabolizers with respect to the genetically determined CYP2D6-related metabolic polymorphism. Compared with controls, epileptic patients exhibited lower peak plasma desipramine concentrations (74 nmol/L vs. 107 nmol/L), smaller desipramine area under the concentration-time curve values (1943 nmol/L/h vs. 3234 nmol/L/h), and shorter desipramine elimination half-lives (15.1 h vs. 20.6 h). All barbiturates are believed to have similar effects leading to induction of hepatic enzymes and the 2D6 isozyme is believed to be important in the metabolism of most or all TCAs. Thus, similar effects should be expected with any combination of TCA and barbiturate.

3.5.1.ES Thioridazine

1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Although citing no data, the manufacturer of thioridazine states that concomitant use with other drugs which prolong the QT interval is contraindicated (Prod Info Mellaril(R), 2001). Tricyclic antidepressants (TCAs) at therapeutic doses can cause QT prolongation (Marshall & Forker, 1982k).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concurrent administration of a tricyclic antidepressant and thioridazine is contraindicated.
7) Probable Mechanism: additive effect on QT interval

3.5.1.ET Tibolone

1) Interaction Effect: attenuation of antidepressant effectiveness; tricyclic toxicity (drowsiness, hypotension, akathisia)
2) Summary: In isolated cases, the pharmacologic effects of tricyclic antidepressants may be increased or decreased by estrogens (Somani & Khurana, 1973m), with paradoxical loss of antidepressant effect yet tricyclic toxicity being manifested simultaneously (Prange, 1972m). The effects of the interaction appear to be estrogen dose-related (Khurana, 1972m) and may be of clinical importance primarily in patients previously stabilized on tricyclic therapy who are being started on estrogen therapy (Krishnan et al, 1984m).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If signs or symptoms of altered tricyclic response are noted, dose adjustment downward of either the estrogen or tricyclic component may be successful in restoring effectiveness or resolving toxicity. However, drug withdrawal may be required.
7) Probable Mechanism: possible estrogen-enhanced hepatic metabolism of the tricyclic
8) Literature Reports
a) Some studies evaluated the qualitative effects of concomitant administration of estrogen and TCAs. In one trial, 30 depressed female prisoners were randomly assigned to 4 treatment groups. Ten patients received placebo, 10 received imipramine (150 milligrams/day) and placebo, 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (50 micrograms/day), while 5 patients received imipramine (150 milligrams/day) and ethinyl estradiol (25 micrograms/day). The 10 patients that received placebo did not improve over the 6 weeks of the study. The 10 patients taking estrogen and imipramine demonstrated a significantly greater improvement in symptoms than did the 10 patients

taking imipramine alone. However, after 2 weeks, the 5 patients that received imipramine and high-dose estrogen had not improved as much as the patients receiving imipramine and low-dose estrogen. The only side-effect reported was drowsiness, which only affected the patients taking imipramine. Following the discontinuation of ethinyl estradiol, a time period of 2 weeks was required for the high-dose estrogen group to do as well as the low-dose group. This effect was attributed to the presence of residual estrogen in the high-dose group. In another group, 5 women received imipramine 150 milligrams and ethinyl estradiol 50 micrograms daily did not improve as much as 10 patients receiving only imipramine. Also, the patients on the combination had severe side-effects including lethargy, coarse tremor and systolic hypotension (Prange, 1972l).

b) A case reported by (Khurana, 1972l) demonstrated an interaction in a 32-year-old female taking conjugated estrogens 2.5 milligrams and imipramine 100 milligrams. The patient developed lethargy, tremors, and signs of depersonalization. After 2 years of therapy, the patient increased her estrogen dose to 5 milligrams and then 7.5 milligrams daily. The patient became nauseated, had constant headaches, and low normal blood pressure. All lab work was normal. Upon discontinuing the estrogen, the side-effects abated. Some investigators have proposed that the side effects resulted from enhanced TCA effects secondary to estrogen inhibition of hepatic microsomal enzymes (Somani & Khurana, 1973l).

c) In a study women received clomipramine and oral contraceptives or clomipramine alone. At the beginning of the study there were 30 women taking the combination, but 12 subsequently dropped out. The 18 patients on the combination were matched with 18 patients taking clomipramine alone. No significant difference was noted in the patients' responses to clomipramine. It was proposed that there was no significant difference in side-effects between the groups; however, the groups were matched after patients had dropped out of the study. Had the patients been matched prior to the study, different conclusions may have been drawn (Beaumont, 1973g).

d) The effect of oral contraceptives on clomipramine was studied in 42 women between the ages of 18 and 40. Twenty-three women took clomipramine 25 milligrams at bedtime while 19 took clomipramine 25 milligrams at bedtime with oral contraceptives. Over the 4-week study, 3 control patients (2 due to side-effects) and 5 in the experimental group (2 due to side-effects) dropped out. Venous blood samples were drawn at weekly intervals for measurement of serum clomipramine concentrations. No difference in serum concentrations was noted between the groups. However, this result may be partially due to the low dose of clomipramine given (Luscombe & John, 1980f).

e) The onset of akathisia was reported in 3 patients receiving conjugated estrogens and tricyclic antidepressants concurrently. A 24-year-old patient receiving clomipramine 120 milligrams/day for anorexia nervosa and conjugated estrogens 1.25 milligrams/day for amenorrhea developed restless legs and a constant desire to move continuously. Estrogen was discontinued and benztropine 2 milligrams was administered, resulting in marked reduction and resolution within 48 hours. Akathisia and disorientation developed in a 55-year-old patient on conjugated estrogens 1.25 milligrams/day who was prescribed amitriptyline 50 milligrams/day for depression. Within hours of amitriptyline, the patient was confused, restless, and possessed an inner desire to move continuously. Symptoms disappeared after discontinuing amitriptyline. Positive rechallenge at one week with doxepin 100 milligrams, with resolution following discontinuation of doxepin. A third case of akathisia was reported in a 35-year-old patient who received conjugated estrogens 1.25 milligrams/day and amitriptyline 50 milligrams/day. Akathisia developed within a few hours after taking the first dose of amitriptyline and resolved within 48 hours following discontinuation of the antidepressant (Krishnan et al, 1984l).

f) The absolute bioavailability of imipramine increased in women who received low-dose oral contraceptives (50 micrograms or less of ethinyl estradiol) from 27 to 44% (p less than 0.05) as evident by an increase in the area under the plasma concentration time curve (Abernethy et al, 1984f).

g) Estrogens may inhibit the oxidation of TCAs by affecting hepatic microsomal enzymes (John et al, 1980f). Many TCAs are metabolized via oxidation and conjugation pathways. Inhibition of the oxidation of TCAs could result in accumulation and toxicity due to decreased clearance. Estrogens are suspected of possessing other effects on the central nervous system resulting in an antidepressant effect (Oppenheim, 1983f).

3.5.1.EU Toloxatone

1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)

2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982p; Spigset et al, 1993q; Brodribb et al, 1994o; Neuvonen et al, 1993h). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991i). If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971s; White & Simpson, 1984n).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Concomitant use of a tricyclic antidepressant (TCA) and a monoamine oxidase

inhibitor (MAOI) should be done only with close monitoring and where the clinical benefit outweighs the potential risk. Other antidepressant therapy should first be considered. If deemed clinically necessary, avoid large doses and use agents other than imipramine, clomipramine, desipramine, and tranylcypromine.
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past. Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965i; Winston, 1971i; Schuckit et al, 1971r; Spiker & Pugh, 1976i). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965i).
b) There is minimal risk of a clinically significant pharmacokinetic interaction between amitriptyline and toloxatone, a MAOI-A (Vandel et al, 1993). Seventeen inpatients being treated for major depressive illness were administered amitriptyline 125 mg once daily for two weeks, and the following two weeks they received amitriptyline 125 mg daily and toloxatone 600 mg daily. With combined therapy there was a small, nonsignificant increase in amitriptyline plasma levels. The availability and urinary excretion of amitriptyline and its metabolites were not significantly affected.
c) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991h). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977i; Schuckit et al, 1971r; Ashcroft, 1975h).
d) Serotonin syndrome has been reported with the use of moclobemide, a reversible inhibitor of monoamine oxidase, and a TCA. A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994n).

3.5.1.EV Tramadol
1) Interaction Effect: an increased risk of seizures
2) Summary: Seizures have been reported in patients using tramadol. Some medications, including tricyclic antidepressants (TCAs), are known to reduce the seizure threshold. The risk of seizures may be enhanced when doxepin and tramadol therapy are combined (Prod Info Ultram(R), 1998).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Caution should be used if tramadol is to be administered to patients receiving concomitant TCA therapy. If possible, avoid this combination, especially in patients with underlying conditions that might predispose to seizures.
7) Probable Mechanism: unknown

3.5.1.EW Tranylcypromine
1) Interaction Effect: neurotoxicity, seizures, or serotonin syndrome (hypertension, hyperthermia, myoclonus, mental status changes)
2) Summary: Concomitant TCA and MAOI use has resulted in hyperpyrexia, convulsions, and death. Concurrent use of MAOIs and TCAs has also been reported to result in a condition termed serotonin syndrome (Insel et al, 1982g; Spigset et al, 1993h; Brodribb et al, 1994g; Neuvonen et al, 1993c). Serotonin syndrome is a rare but potentially fatal condition of serotonergic hyperstimulation characterized by hypertension, hyperthermia, myoclonus, and changes in mental status (Sternbach, 1991d). Consequently, coadministration of TCAs and MAOIs is contraindicated in most cases. If TCAs and MAOIs must be used concurrently, avoid large doses, use only oral TCAs, avoid imipramine, clomipramine, desipramine, and tranylcypromine, and monitor patients closely (Schuckit et al, 1971i; White & Simpson, 1984g).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of doxepin with a monoamine oxidase inhibitor (MAOI), such as tranylcypromine is contraindicated (Prod Info Parnate(R), 2001). If doxepin is replacing treatment with tranylcypromine, a minimum of 14 days should elapse after tranylcypromine is discontinued before therapy with doxepin begins (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005). The manufacturer of tranylcypromine recommends that at least 7 days should elapse before tranylcypromine therapy is replaced by doxepin. Similarly, if doxepin therapy is substituted by tranylcypromine, there should be a 7 day washout period. Tranylcypromine should then be given using half the normal starting dosage for, minimally, the first

week of therapy (Prod Info Parnate(R), 2001).
7) Probable Mechanism: altered catecholamine uptake and metabolism
8) Literature Reports
a) Concomitant administration of monoamine oxidase inhibitors (MAOIs) with tricyclic antidepressants (TCAs) has been considered an absolute contraindication in the past and still is listed as such by the manufacturers (Prod Info Parnate(R), 2001). Reports of excitation, hyperpyrexia, convulsions, and possible death have been attributed to the combination (Lockett & Milner, 1965d; Brachfeld et al, 1963c; Winston, 1971d; Schuckit et al, 1971h; Sargent, 1965c; Spiker & Pugh, 1976d). The mechanism may relate to the combined inhibition of catecholamine reuptake into the central nervous system and inhibition of catecholamine metabolism (Sjoqvist, 1965d).
b) Administration of a TCA after MAOI therapy may result in the development of serotonin syndrome. In a double-blind, crossover study examining the effects of clorgyline and clomipramine for the treatment of obsessive-compulsive disorder, two subjects developed severe reactions characteristic of serotonin syndrome. During the study, patients had received clorgyline therapy, followed by a washout period of approximately four weeks and subsequent clomipramine therapy. After taking the first 100 mg dose of clomipramine, one patient developed coarse myoclonic jerking in both legs, hyperreflexia, diaphoresis, and arrhythmia. Another patient developed a similar reaction after the first dose, with upper motor neuron symptoms, myoclonic movements, and cardiac irritability. Both patient's symptoms resolved several hours later, and both patients were later treated successfully with clomipramine without adverse effects (Insel et al, 1982f).
c) A drug interaction occurred in a 76-year old woman who had been taking clomipramine 50 mg daily for several months prior to switching to moclobemide 300 mg daily. The patient experienced somnolence, confusion, and fever which then progressed to further mental impairment, muscle stiffness, myoclonus, and convulsive attacks. The patient's symptoms were described as fulfilling the diagnostic criteria for serotonin syndrome and were resolved a few days later after discontinuing all antidepressant medications (Spigset et al, 1993g).
d) A 39-year old woman with bipolar disorder developed serotonin syndrome after imipramine was added to moclobemide. The patient was taking moclobemide 300 mg twice daily when imipramine was started at 50 mg daily, followed by two dosage increases of imipramine to 200 mg and a reduction of moclobemide dosage to 150 mg twice daily. Five days after the increase in imipramine to 200 mg per day, the patient developed symptoms of serotonin syndrome, including sweating, shivering, confusion, fever, and spasms in the extremities. The patient was treated with chlorpromazine and symptoms resolved over the next few days without further complications (Brodribb et al, 1994f).
e) Three patients with bipolar disorder developed manic symptoms while undergoing concurrent therapy with isocarboxazid and amitriptyline. In all three cases the patients had been given MAOIs and TCAs alone without complications. It was only when the drugs were used in combination that symptoms of mania emerged, suggesting a synergistic effect (de la Fuente et al, 1986b).
f) In one case, clomipramine 10 mg twice daily was added to a stable regimen of tranylcypromine in a physically healthy 34-year old man. After taking several doses, the patient developed symptoms of nausea and profuse sweating, followed by pyrexia, dyspnea, and agitation. The hyperpyrexical state led to disseminated intravascular coagulation and eventual death (Tackley & Tregaskis, 1987d).
g) There is evidence that MAOIs and TCAs can be given concomitantly in patients previously unresponsive to the MAOI or TCA alone. A few precautions must be followed including: a) avoidance of large doses (no more than 150 mg amitriptyline or its equivalent, 45 mg phenelzine, or 60 mg isocarboxazid) b) oral administration c) avoidance of clomipramine, imipramine, desipramine, and tranylcypromine in any combination, and d) close monitoring of patients (Kline, 1974b; Winston, 1971d; Schuckit et al, 1971h; White & Simpson, 1984f; Rom & Benner, 1972b). The combination may be utilized in one of two ways. Most frequently, the recommendation is to stop all previous antidepressants (five to ten days for TCAs and 14 days for MAOIs); the combination is then simultaneously started (Perry et al, 1991c). Alternatively, in a patient previously receiving a TCA, small doses of the MAOI may be slowly added (Schoonover, 1983). Some sources suggest that the combination of amitriptyline and isocarboxazid is preferred (Perry et al, 1991c). Numerous studies in patients with refractory depression or phobic anxiety states have successfully used the combination of MAOIs and TCAs (Ponto et al, 1977d; Schuckit et al, 1971h; Ashcroft, 1975c).

3.5.1.EX Trifluoperazine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Q and T wave distortions have been observed in patients taking phenothiazines (Prod Info Compazine(R), 2002; Prod Info Stelazine(R), 2002; Prod Info Thorazine(R), 2002). Other phenothiazines may have similar effects, though no reports are available. Tricyclic antidepressants (TCAs) at therapeutic doses can cause QT prolongation (Marshall & Forker, 1982ad). Case reports have described increased plasma levels and adverse effects when phenothiazines and tricyclic antidepressants were taken together, likely due to inhibition of their metabolism (Ghaemi & Kirkwood, 1998; Geller et al, 1985; Siris et al, 1982; Loga et al, 1981).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable

6) Clinical Management: Concurrent administration of a phenothiazine and a tricyclic antidepressant is not recommended.
7) Probable Mechanism: additive effect on QT interval

3.5.1.EY Trimethoprim
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and cotrimoxazole have been shown to prolong the QTc interval at the recommended therapeutic dose (Lopez et al, 1987; Marshall & Forker, 1982q). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as cotrimoxazole, is not recommended (Prod Info Elavil (R), 1999i).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: The concurrent administration of cotrimoxazole and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.EZ Vasopressin
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants and vasopressin have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Vivactil(R), 1999; McCue et al, 1989; Munger & Effron, 1988; Mauro et al, 1988; Marshall & Forker, 1982j; Goldstein & Claghorn, 1980; Buckhardt et al, 1978; Pinder et al, 1977a; Thorstrand, 1976; Singh, 1972). Even though no formal drug interaction studies have been done, the coadministration of drugs known to prolong the QTc interval is not recommended.
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of drugs that prolong the QT interval, such as tricyclic antidepressants and vasopressin, is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.FA Venlafaxine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest) and adverse effects of both drugs
2) Summary: Tricyclic antidepressants (TCAs) and venlafaxine have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Effexor(R) XR, 2003; Marshall & Forker, 1982d). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as venlafaxine, is not recommended (Prod Info Elavil(R), 1999c). In addition, venlafaxine and tricyclic antidepressants (TCAs) may competitively inhibit each other's metabolism which may increase side effects of both drugs (Perry, 2000; Prod Info Effexor(R) XR, 2003; Ellingrod & Perry, 1994). Venlafaxine increased the AUC, Cmax, and Cmin of desipramine by approximately 35%. The AUCs of 2-OH-desipramine increased by 2.5 and 4.5 fold when administered with venlafaxine 37.5 mg and 75 mg every 12 hours, respectively. The pharmacokinetics of imipramine and the 2-hydroxy metabolite were not affected (Prod Info venlafaxine extended release oral tablets, 2008).
3) Severity: major
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Due to the potential for additive effects on the QT interval, the concurrent administration of venlafaxine and tricyclic antidepressants is not recommended.
7) Probable Mechanism: decreased TCA and venlafaxine metabolism; additive effects on QT prolongation
8) Literature Reports
a) When administered with imipramine, the pharmacokinetics of imipramine and the 2-hydroxy metabolite were not affected. Venlafaxine increased the area under the concentration-time curve (AUC), maximum concentration (Cmax), and minimum concentration (Cmin) of desipramine by approximately 35%. The 2-OH-desipramine AUCs increased by 2.5-fold (venlafaxine 37.5 mg every 12 hours) and by 4.5-fold (venlafaxine 75 mg every 12 hours). The clinical significance of this finding is unknown (Prod Info venlafaxine extended release oral tablets, 2008).

3.5.1.FB Warfarin
1) Interaction Effect: an increased risk of bleeding
2) Summary: Tricyclic antidepressants (TCAs) may increase the half-life and bioavailability of oral anticoagulants (Vesell et al, 1970a; Williams et al, 1976a). Considerable interindividual differences may be found (Pond et al, 1975a).
3) Severity: moderate

4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving doxepin and warfarin concurrently, the prothrombin time ratio or international normalized ratio (INR) should be closely monitored for stability of the anticoagulant response. Adjustment of the warfarin dosage may be required to maintain the desired level of anticoagulation.
7) Probable Mechanism: decreased warfarin metabolism; increased warfarin absorption
8) Literature Reports
a) In a study of healthy volunteers, the concurrent use of nortriptyline or amitriptyline resulted in an increase of dicumarol levels and an increase in the plasma half-life of dicumarol, although the effect was not consistent in all subjects (Pond et al, 1975). This effect was not observed with warfarin.
b) A single oral dose of bishydroxycoumarin after eight days of nortriptyline resulted in a significantly prolonged half-life and decreased volume of distribution of the coumarin anticoagulant in six healthy volunteers (Vesell et al, 1970). The mechanism of action was suggested to be reduced bishydroxycoumarin metabolism and/or altered coumarin absorption.
c) Drug dosing was studied in 16 patients on long-term anticoagulant therapy who used concurrent TCAs (Williams et al, 1976). TCAs affected the stability of anticoagulant control leading to frequent changes in the doses of anticoagulants. Inhibition of coumarin metabolism was the postulated mechanism.

3.5.1.FC Ziprasidone
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Ziprasidone use is associated with dose-related prolongation of the QTc interval. Even though no formal drug interaction studies have been done, it is recommended that concurrent use with other agents that may prolong QTc interval be avoided (Prod Info GEODON(R) oral capsules, IM injection, 2007; Marshall & Forker, 1982ae).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Due to the potential for additive QTc interval prolongation, avoid the concurrent administration of ziprasidone and agents that can prolong the QTc interval (Prod Info GEODON(R) oral capsules, IM injection, 2007).
7) Probable Mechanism: additive cardiac effects

3.5.1.FD Zolmitriptan
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Tricyclic antidepressants (TCAs) and zolmitriptan have been shown to prolong the QTc interval at the recommended therapeutic dose (Prod Info Zomig(R), 2001; Marshall & Forker, 1982l). Even though no formal drug interaction studies have been done, the coadministration of tricyclic antidepressants and other drugs known to prolong the QTc interval, such as zolmitriptan, is not recommended (Prod Info Elavil(R), 1999f).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of zolmitriptan and tricyclic antidepressants is not recommended.
7) Probable Mechanism: additive effects on QT prolongation

3.5.1.FE Zotepine
1) Interaction Effect: an increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)
2) Summary: Several antipsychotic agents have demonstrated QT prolongation including amisulpride (Prod Info Solian(R), 1999), haloperidol (O'Brien et al, 1999), risperidone (Duenas-Laita et al, 1999), sertindole (Agelink et al, 2001), quetiapine (Owens, 2001b), sultopride (Lande et al, 1992), and zotepine (Sweetman, 2003). Even though no formal drug interaction studies have been done, the coadministration of a tricyclic antidepressant and an antipsychotic is not recommended (Prod Info Pamelor(R), 2001; Marshall & Forker, 1982p).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of a tricyclic antidepressant and an antipsychotic is not recommended.
7) Probable Mechanism: additive cardiac effects
8) Literature Reports
a) Electrocardiographic changes that have occurred during clinical trials with pimozide have included prolongation of the corrected QT interval, flattening, notching, and inversion of the T wave and the

appearance of U waves. In experimental studies, sudden, unexpected deaths have occurred while patients were receiving pimozide doses of 1 mg/kg. The proposed mechanism for these deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmias (Prod Info Orap(R), 1999).

3.5.2 Drug-Food Combinations

3.5.2.A Ethanol

1) Interaction Effect: enhanced drowsiness; impairment of motor skills
2) Summary: Ethanol in combination with antidepressants may alter behavior, with the predominant effect being enhanced impairment in psychomotor performance. Almost all studies to date have evaluated the effects of the combination on motor skills, driving behavior and psychomotor skills (Landauer et al, 1969; Patman et al, 1969; Milner & Landauer, 1973a; Seppala et al, 1975; Seppala, 1977). There are no studies evaluating respiratory response with the combination.
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Encourage abstention from alcohol during at least the first few weeks of tricyclic administration to allow patient accommodation to potential CNS depressant effects of the tricyclic.
7) Probable Mechanism: additive CNS depressant activity; impaired hepatic metabolism of the tricyclic antidepressant
8) Literature Reports
a) The studies available indicate that the interaction between amitriptyline (and other antidepressants) in combination with ethanol is unpredictable. They indicate that antidepressants may enhance, prevent, or not affect the CNS depressant actions of ethanol. The most significant effect reported is enhanced CNS depression. However, there are reports that tricyclic antidepressants may actually antagonize the sedative effects of ethanol (Milner & Landauer, 1973).
b) The propensity for interaction may be related to the inherent CNS depressant action of the tricyclic antidepressant, listed in one series in descending order as amitriptyline, doxepin, imipramine, nortriptyline, desipramine, and protriptyline (Marco & Randels, 1981).
c) Imipramine and amitriptyline are the best documented examples of disruptions of metabolism. Clearance of imipramine was 3-fold higher in alcoholics compared with healthy volunteers (Ciraulo et al, 1988).
d) Individual case reports have documented "blackouts" following modest amounts of alcohol in combination with either amitriptyline or imipramine (Hudson, 1981), and reversible extrapyramidal effects (parkinsonian effects, akathisia) with amoxapine (Shen, 1984).

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

Comparative Efficacy / Evaluation With Other Therapies

4.1 Monitoring Parameters

A) Doxepin Hydrochloride
1) Therapeutic
a) Laboratory Parameters
1) Urinary MHPG
a) Elevations of urinary MHPG (3-methoxy-4-hydroxyphenethylene glycol) before treatment were reported to correlate with pain relief with doxepin treatment, but not improvement in depression (Ward et al, 1983).
b) Physical Findings
1) Relief of symptoms of depression
2) Improvement of mood
3) Relief of anxiety
a) ANXIETY AND DEPRESSION ASSOCIATED WITH ALCOHOLISM

1) Reduction or resolution of palpitations, tachycardia, chest pain or tightness, shortness of breath, hyperventilation, or depressed mood.

b) ANOREXIA NERVOSA

1) Reduction and resolution of signs/symptoms associated with anorexia nervosa (ie, calorie restriction, excess energy or exercise, disturbed sleep, sense of personal ineffectiveness, amenorrhea, social withdrawal, emaciated appearance, dry-cracked skin, fine downy hair, vomiting, malnutrition, and associated medical complications.

c) DEPRESSION

1) The following target symptoms should be monitored (depressed mood, suicidal thoughts or intent, change in appetite (increased/decreased), lack of energy, change in sleep patterns (hypersomnia/insomnia), lack of pleasure/interest in usual activities, feeling of excessive guilt/worthlessness, psychomotor retardation or agitation, difficulties in thinking/concentration/memory).

d) DETRUSOR OVERACTIVITY

1) Reduction or resolution of nocturnal micturition and incontinence.

e) INSOMNIA

1) Patients should be monitored for improvement in the signs/symptoms consistent with insomnia (delay in sleep onset, frequent nocturnal awakenings, the subjective feeling of not feeling rested, and disturbances in daytime functioning, such as decreased concentration, fatigue, myalgias).

f) CHRONIC PAIN

1) Reduction or resolution of pain perception, depression, sleep disturbances, anxiety, and irritability.

2) Improve or maintain patient's level of functioning, decreasing the rate of physical deterioration, improve sense of well being, improve family and social relationships.

g) PREMENSTRUAL SYNDROME

1) Reduction or resolution of signs/symptoms associated with premenstrual syndrome (ie, tension, irritability, dysphoria, fatigue, anxiety, crying, depression, restlessness, cravings for sweet/salty foods, binge eating, headache).

h) POSTTRAUMATIC STRESS DISORDER

1) Reduction or resolution of flashbacks, recollections, and dreams associated with a traumatic event.

2) Reduction or resolution of sleep disturbances, outbursts of anger, hypervigilance, emotional numbing, guilt, inability to concentrate, and the physiological reaction (ie, sweating) upon re-exposure to the event (ie, nightmare).

i) TOBACCO CESSATION

1) Reduction or resolution of irritability, craving, anxiety/nervousness, difficulty with concentration, restlessness, headaches, drowsiness, changes in sleep patterns, increase in appetite and weight, and gastrointestinal upset.

j) URTICARIA

1) Reduction or resolution of erythema, wheal, swelling, angioedema, itching, and lesions.

2) Toxic

a) Laboratory Parameters

1) Complete blood cell count

2) Liver function tests

b) Physical Findings

1) Blood pressure for hypotension and pulse

2) Seizures have developed during therapy

3) Sexual dysfunction (ejaculatory dysfunction) or priapism

4) Monitor patients receiving antidepressants for worsening of depression, suicidality, or unusual changes in behavior, especially at the initiation of therapy or when the dose increases or decreases. Such monitoring should include at least weekly face-to-face contact with patients or their family members or caregivers during the initial 4 weeks of treatment, then visits every other week for the next 4 weeks, then at 12 weeks, and then as clinically indicated beyond 12 weeks. Families and caregivers should be advised of the need for close observation (ie, daily observation) of patients and communication with the prescriber (Anon, 2004).

5) Patients who experience symptoms of anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, akathisia, hypomania, or mania may be at an increased risk for worsening depression or suicidality. If these symptoms are observed, therapy should be re-evaluated and it may be necessary to discontinue medications when symptoms are severe, sudden in onset, or were not part of the patient's initial symptoms (Anon, 2004).

4.2 Patient Instructions

A) Doxepin (By mouth)

Doxepin

Treats depression, anxiety, and sleep disorders. This medicine is a tricyclic antidepressant.

When This Medicine Should Not Be Used:
You should not use this medicine if you have ever had an allergic reaction to doxepin or other tricyclic antidepressants (such as Elavil® or Tofranil®), maprotiline (Ludiomil®), or trazodone (Desyrel®). Do not use this medicine if you have glaucoma or if you are unable to pass urine.

How to Use This Medicine:
Capsule, Liquid, Tablet
- Your doctor will tell you how much of this medicine to use and how often. Do not use more medicine or use it more often than your doctor tells you to.
- You may take this medicine with or without food.
- Measure the oral liquid with a marked dropper that comes with the medicine.
- The oral liquid must be mixed with one-half glass of water, milk, or fruit juice before you drink it. Do not use grape juice or carbonated beverages (soda pop). Mix the medicine just before taking the dose. Do not prepare ahead of time.
- If you are using this medicine once a day, you may take it at bedtime.
- This medicine should come with a Medication Guide. Read and follow these instructions carefully. Ask your doctor or pharmacist if you have any questions. Ask your pharmacist for the Medication Guide if you do not have one. Your doctor might ask you to sign some forms to show that you understand this information.

If a Dose is Missed:
- If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next dose, wait until then to use the medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.
- If you use only one dose at bedtime, skip the missed dose. Wait until the next night. You should not use two doses at the same time.

How to Store and Dispose of This Medicine:
- Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
- Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after you have finished your treatment. You will also need to throw away old medicine after the expiration date has passed.
- Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, and herbal products.
- Make sure your doctor knows if you are using disulfiram (Antabuse®), cimetidine (Tagamet®), tolazamide (Tolinase®), or certain medicine for heart rhythm problems (such as flecainide, propafenone, quinidine, Cardioquin®, Quinaglute®, Rythmol®, or Tambocor®).
- You must wait at least 5 weeks between using this medicine and other medicine to treat depression (such as citalopram, escitalopram, fluoxetine, paroxetine, sertraline, Celexa®, Lexapro™, Paxil®, Prozac®, or Zoloft®). Do not use this medicine if you have used an MAO inhibitor (MAOI) such as Eldepryl®, Marplan®, Nardil®, or Parnate® within the past 14 days.
- Do not drink alcohol while you are using this medicine.
- Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and allergy medicine, narcotic pain relievers, and sedatives.

Warnings While Using This Medicine:
- Make sure your doctor knows if you are pregnant or breastfeeding, or if you have heart disease, epilepsy, or stomach problems.
- For some children, teenagers, and young adults, this medicine can increase thoughts of suicide. Tell your doctor or your child's doctor right away if you or your child start to feel more depressed and have thoughts about hurting yourselves. Report any unusual thoughts or behaviors that trouble you or your child, especially if they are new or are getting worse quickly. Make sure the doctor knows if you or your child have trouble sleeping, get upset easily, have a big increase in energy, or start to act reckless. Also tell the doctor if you or your child have sudden or strong feelings, such as feeling nervous, angry, restless, violent, or scared. Let the doctor know if you, your child, or anyone in your family has bipolar disorder (manic-depressive) or has tried to commit suicide.
- If you are using this medicine for depression, it may take 2 to 3 weeks before you start to feel better.
- Do not stop using this medicine suddenly without asking your doctor. You may need to slowly decrease your dose before stopping it completely.
- This medicine may make you drowsy. Avoid driving, using machines, or doing anything else that could be dangerous if you are not alert.

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
- Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, chest tightness, trouble breathing.

Changes in behavior, or thoughts of hurting yourself or others.
Fast or uneven heartbeat.
Feeling nervous, restless, anxious, agitated, or excited for no reason.
Jerky muscle movement you cannot control (often in your face, tongue, or jaw).
Lightheadedness or fainting.
Numbness, tingling, or burning pain in your hands, arms, legs, or feet.
Problems with balance or walking.
Problems with urination.
Ringing, buzzing, or other unexplained noise in ears.
Seizures or tremors.
Severe confusion, or seeing or hearing things that are not there.
Swelling in your hands, ankles, or feet.
Trouble sleeping.
Twitching or muscle movements you cannot control.
Unexplained fever, chills, or sweating.
Unusual bleeding or bruising.
Unusual tiredness or weakness.
Yellowing of your skin or the whites of your eyes.

If you notice these less serious side effects, talk with your doctor:
Blurred vision.
Change in taste.
Constipation, diarrhea, nausea, vomiting, or upset stomach.
Drowsiness or dizziness.
Dry mouth or mouth sores.
Hair loss.
Headache.
Problems having sex.
Sensitivity to sunlight.
Skin rash or itching.
Swelling in scrotum or testicles.
Swelling of the breasts or breast soreness in both females and males.
Warmth or redness in your face, neck, arms, or upper chest.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

B) Doxepin (On the skin)

Doxepin

Reduces itching caused by skin diseases such as atopic dermatitis or lichen simplex chronicus.

When This Medicine Should Not Be Used:
You should not use this medicine if you have had an allergic reaction to doxepin, or if you have glaucoma or problems urinating.

How to Use This Medicine:
Cream
Apply a thin layer to the affected area. Rub it in gently.
Apply a thin layer of this medicine each time you use it.
Wash your hands with soap and water before and after using this medicine.
Do not cover the treated area with a bandage unless your doctor has told you to.

If a Dose is Missed:
If you miss a dose or forget to use your medicine, apply it as soon as you can. If it is almost time for your next dose, wait until then to apply the medicine and skip the missed dose. Do not apply extra medicine to make up for a missed dose.

How to Store and Dispose of This Medicine:
Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of the used medicine container and any leftover medicine after you have finished your treatment. You will also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, and herbal products.
Make sure your doctor knows if you are using MAO inhibitors such as Eldepryl®, Marplan®, Nardil®, or Parnate®, or allergy medicines.

Make sure your doctor knows if you are using medicine for depression such as trazadone, Clexa®, Prozac®, Paxil®, or Zoloft®, or amitriptyline, Norpramin®, or Vivactil®.
There are many other drugs that can interact with doxepin. Make sure your doctor knows about all other medicines you are using.
Tell your doctor if you are using any medicines that make you sleepy. These include sleeping pills, cold and allergy medicine, narcotic pain relievers, and sedatives.
Do not drink alcohol while you are using this medicine.

Warnings While Using This Medicine:
Make sure your doctor knows if you are pregnant or breast feeding.
This medicine may make you dizzy or drowsy. Avoid driving, using machines, or doing anything else that could be dangerous if you are not alert.

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, chest tightness, trouble breathing.
Confusion, hallucinations, severe weakness, vomiting, muscle stiffness.
Drowsiness or lightheadedness or fainting.
Irregular heartbeat
Swelling in your feet, arms, or body.

If you notice these less serious side effects, talk with your doctor:
Burning or stinging of your skin where the medicine in applied.
Change in taste or dryness of your mouth.
Headache or tiredness.
Nervousness, anxiety.
Numbness in your tongue.
Redness, pain, swelling, or itching on site of cream application.
Worsening of you skin condition.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) Depression is a complicated disorder and consequently treatment regimens are diverse. The two most prevalent diagnostic syndromes among affective disorders are major depression and bipolar disorders. The tricyclic antidepressants (TCAs) serotonin reuptake inhibitors (SSRIs) and the monoamine oxidase inhibitors (MAOIs) are considered the most effective agents for treating major depression. For treating bipolar disorders, lithium is considered the standard of therapy over TCAs, MAOIs, SSRIs, and other agents such as carbamazepine or levothyroxine.

B) Doxepin is effective for the treatment of endogenous or typical depression. Doxepin has similar efficacy and adverse effects as the other TCAs, but possesses some distinguishing characteristics. Doxepin inhibits histamine release and has been used topically to treat pruritus and systemically for peptic ulcer disease. Doxepin has also been used for treating anxiety-depression states and depression-induced insomnia. Cardiac effects of doxepin are considered mild compared to those of the other TCAs.

C) Doxepin does have a place in therapy for the treatment of unipolar depression, but should be considered secondary to imipramine and amitriptyline. Because of anxiolytic properties, antihistamine action, sedative effects and fewer cardiac effects, doxepin may be useful for treating depressed patients with coanxiety, peptic ulcer disease, associated insomnia, or who are elderly. Doxepin should be considered an alternative agent and formulary considerations should be based primarily on cost.

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) Doxepin has similar pharmacologic properties to other tricyclic antidepressants (amitriptyline and imipramine). Doxepin has a pronounced sedative effect similar to amitriptyline but probably less than that of imipramine. Doxepin is particularly effective in depression associated with anxiety or in mixed anxiety depression syndromes (Pinder et al, 1977b).

2) Doxepin may be more effective than imipramine in patients with depression associated with sleep disturbances but it is not superior to other tricyclic antidepressants for severe endogenous depression (Pinder et al, 1977b).

3) Doxepin has been shown to exert a significant antihistamine effect. In 8 subjects administered a dose of 25 mg, the amount of histamine required to cause an urticarial reaction increased 82-fold (Sullivan, 1982).

B) REVIEW ARTICLES

1) A review of the other uses of antidepressant agents, including enuresis, bulimia, anorexia nervosa, panic disorder, chronic pain, migraine headache, and peptic ulcer disease is available (Orsulak & Waller, 1989).

2) Drug-interactions of antidepressants are reviewed in German language (Zapotoczky & Simhandl, 1995).

4.5 Therapeutic Uses

Doxepin

Doxepin Hydrochloride

4.5.A Doxepin

4.5.A.1 Anorexia nervosa
See Drug Consult reference: ANOREXIA NERVOSA - DRUG THERAPY

4.5.B Doxepin Hydrochloride

Alcoholism - Anxiety - Depression

Anxiety - Depression

Anxiety - Depression - Psychoneurotic personality disorder

Cancer pain; Adjunct

Chronic pain

Cocaine-induced anxiety disorder

Complex regional pain syndrome

Cyclical vomiting syndrome

Depression - Opioid dependence

Detrusor instability of bladder

Disorder of gastrointestinal tract

Disorder of oral mucous membrane - Pain

Insomnia

Nicotine dependence

Peptic ulcer disease

Post-prandial hypoglycemia

Posttraumatic stress disorder

Pruritus (Moderate), Due to atopic dermatitis or lichen simplex chronicus

Psychogenic headache

Urticaria

4.5.B.1 Alcoholism - Anxiety - Depression
FDA Labeled Indication
a) Overview
FDA Approval: Adult, yes; Pediatric, yes (12 years and older)
Efficacy: Adult, Effective

Recommendation: Adult, Class IIa
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Indicated for controlling the anxiety and/or depression associated with alcoholism

c) Adult:

1) GENERAL INFORMATION

a) The most effective dose of DOXEPIN for mild-to-moderate anxiety or depression ranges between 75 and 150 milligrams/day. A starting dose of DOXEPIN 25 milligrams 3 times daily is recommended, but the entire daily dose up to 150 milligrams may be administered at bedtime without altering efficacy. For more severe anxiety and depression, DOXEPIN 50 milligrams 3 times daily may be administered and the dose increased to a maximum of 300 milligrams/day. The antidepressant effect of DOXEPIN may take 2 or 3 weeks to achieve, but the antianxiety effect usually occurs rapidly (Prod Info Adapin(R), 1995a).

4.5.B.2 Anxiety - Depression

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, yes (12 years and older)
Efficacy: Adult, Effective; Pediatric, Effective
Recommendation: Adult, Class IIa; Pediatric, Class IIa
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Indicated for the treatment of depression and/or anxiety associated with organic disease
Also indicated for PSYCHOTIC DEPRESSIVE DISORDERS with associated anxiety including involutional depression and manic-depressive disorders

c) Adult:

1) GENERAL INFORMATION

a) DOXEPIN is an effective agent in the treatment of ENDOGENOUS DEPRESSION (Grof et al, 1974; Burrows et al, 1972; Bianchi et al, 1971a) and NEUROTIC DEPRESSION (Mendels & Schless, 1975; Solis et al, 1970a). Clinical trials have shown that DOXEPIN has less marked mood elevating activities than IMIPRAMINE but similar to that of AMITRIPTYLINE. DOXEPIN has been shown to be most effective in agitated depressed patients and less effective in retarded depressive patients. In addition, DOXEPIN is shown to be more effective than IMIPRAMINE in neurotic-type depression and less effective than IMIPRAMINE in endogenous depression (Pinder et al, 1977e).

2) In the absence of severe impairment of myocardial performance, depressed patients with pre-existing heart disease were treated effectively with IMIPRAMINE or DOXEPIN without an adverse effect on ventricular rhythm or hemodynamic function (Veith et al, 1982a). In a double-blind, randomized trial involving 24 depressed patients with heart disease treated with IMIPRAMINE or DOXEPIN 50 milligrams (mg) at bedtime or placebo. Doses were gradually increased every 3 days until side effects or a dose of 150 mg given at bedtime was achieved. No evidence of cardiovascular adverse effects were seen. As measured by radionuclide ventriculograms, tricyclic antidepressants had no effect on left ventricular ejection fraction at rest or during maximal exercise. The incidence of premature ventricular contractions was reduced in patients treated with IMIPRAMINE; however, no consistent change was observed in patients receiving DOXEPIN or placebo. IMIPRAMINE- and DOXEPIN-treated patients showed a significant improvement (p less than 0.001) in depression when compared with placebo-treated patients. Further evaluation of the tricyclics and their effect on cardiovascular function is required.

3) DOXEPIN has produced a more favorable response than AMITRIPTYLINE in patients with depression associated with anxiety or the MIXED DEPRESSION ANXIETY syndrome, and it is possible that DOXEPIN may have more prominent sedative effects than AMITRIPTYLINE (Pinder et al, 1977e).

4) Several studies have reported the benefits of doxepin in patients with mixed ANXIETY and depression (Goldberg et al, 1974; Goldstein et al, 1973).

5) Doxepin titrated in a conventional manor (beginning with 50 milligrams daily and titrating upwards to 250 mg daily over 1 week) was more effective than using pulse dosing (250 mg every 6 days) (Deuschle et al, 1997). Depressed patients were randomly assigned to receive either conventional dosing (n=10) or pulse dosing (n=9) over 39 days. In the pulse dosing group, scores on the Hamilton Depression Rating (HAM-D) scale differed from baseline after day 36 (p less than 0.03) while in the conventional dosing group, they differed after only 2 days (p less than 0.02). Starting on day 25, significantly lower HAM-D scores were seen in the conventional dosing group versus the pulse dosing group (p less than 0.05) and this continued through day 39 (p less than 0.01).

4.5.B.3 Anxiety - Depression - Psychoneurotic personality disorder

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, yes (12 years and older)
Efficacy: Adult, Evidence favors efficacy

Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Indicated for the treatment of psychoneurotic patients with depression and/or anxiety (Prod Info SINEQUAN(R) capsule, oral concentrate, 2005)

4.5.B.4 Cancer pain; Adjunct

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Case reports have described the use of doxepin in terminal cancer patients who are unresponsive to narcotic analgesics

c) Adult:
1) Four severely debilitated cancer patients with neuropathic pain were reported to be more comfortable following rectal administration of unmodified DOXEPIN capsules. Serum concentrations of N-desmethyldoxepin after two to five days of treatment with a constant dose of DOXEPIN were 573 micrograms/milliliter (mcg/mL) and 403 mcg/mL (with 50 milligrams (mg) three times/day), 204 mcg/mL (with 50 mg twice a day), and less than 25 mcg/mL (with 25 mg every day) (Storey & Trumble, 1992).
2) The combination of PIROXICAM (60 to 120 milligrams orally daily, given with SUCRALFATE 1 to 2 g daily) plus DOXEPIN (25 to 225 mg daily) was reported effective in the treatment of advanced cancer pain (Cohn et al, 1988). SUCRALFATE given concurrently with PIROXICAM was effective in preventing severe gastrointestinal (GI) toxicity. However, several patients did not administer sucralfate concurrently with PIROXICAM and developed GI symptoms (GI hemorrhage, gastric ulcer or perforation). It is recommended that PIROXICAM and DOXEPIN therapy (with adjunctive SUCRALFATE administration) be considered in patients with terminal cancer who are unresponsive to narcotic analgesics.

4.5.B.5 Chronic pain

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Patients with chronic pain have experienced some relief with doxepin therapy
A review of doxepin as adjunctive therapy for chronic pain has been published by the Boston Pain Center (Aronoff & Evans, 1982)

c) Adult:
1) DOXEPIN (up to 3 milligrams/kilogram/day (mg/kg)) for pain relief was better than placebo in 60 patients with chronic low back or cervical pain and depression (Hameroff et al, 1984). Relative to the percent of time the pain was felt, effect of pain on sleep, and muscle tension, DOXEPIN was slightly better than placebo at 1 week, and significantly better at 6 weeks. Benefit was most consistently derived when the daily dose was at least 2.5 mg/kg, and the combined DOXEPIN/desmethyldoxepin plasma level exceeded 70 ng/mL. The proposed mechanism, as demonstrated by the laboratory, was enhanced enkephalin activity.

4.5.B.6 Cocaine-induced anxiety disorder

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Ineffective
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Not effective in the treatment of panic attacks associated with cocaine abuse

c) Adult:
1) The use of tricyclic antidepressant therapy in 10 patients with cocaine-induced panic attacks resulted in extreme anxiety and had to be discontinued (Louie et al, 1989). One patient improved after doxepin 50 milligrams/day (mg/day) but, at higher doses, became severely confused and panicky and had to be hospitalized. Another patient had a partial response to trazodone 150 mg/day and did not want to be switched to another agent. Other agents used in this patient population included amitriptyline, desipramine, and nortriptyline. Thus, heterocyclic antidepressants were not well tolerated except for trazodone and low doses of doxepin, two medications with relatively high serotonergic re-uptake

blockade.

4.5.B.7 Complex regional pain syndrome

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Topical doxepin reduced the symptoms of complex regional pain syndrome CRPS, including pain, discoloration, and thermal and mechanical allodynia

c) Adult:

1) A 32-year-old woman attained relief of symptoms of complex regional pain syndrome (CRPS) with topical application of doxepin 5% cream (Xepin(R)). After a fall on her left wrist, the woman developed the symptoms of CRPS, although the wrist was not broken. In addition to burning dermatomal pain, she showed blue discoloration, hyperhidrosis, and mechanical and thermal allodynia. A stellate ganglion block on the left side gave significant reduction in symptoms for 4 weeks. A second block provided similar relief. Topical application of doxepin cream twice daily reduced her symptoms significantly after 2 weeks. Each time she omitted using the cream for more than 5 days, her symptoms returned. In addition to reducing the pain, it decreased the thermal and mechanical allodynia and the discoloration (McCleane, 2002).

4.5.B.8 Cyclical vomiting syndrome

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Tricyclic antidepressant therapy, including DOXEPIN, may be beneficial in treating CYCLIC VOMITING SYNDROME

c) Adult:

1) In a retrospective case series (n=17), adults with CYCLIC VOMITING SYNDROME (CVS) were shown to derive benefit from treatment with low-dose tricyclic antidepressants (open-label), including DOXEPIN (median dose 50 milligrams (mg) daily; range 25 to 150 mg). However, a comparison group of 37 patients with usual functional nausea and vomiting had superior results from tricyclic-antidepressant therapy compared with those with CVS. Of the 17 patients with CVS, 3 (17.6%) achieved complete remission, and 10 (58.8%) attained partial response (decreased intensity of symptoms, decreased cycle frequency, or shortening of cycles). Of 7 patients who used doxepin, 6 experienced remission or improvement -- the same response as 7 patients given amitriptyline. No patient responded to desipramine (0 of 3) or imipramine (0 of 1), with 4 of 4 responding to nortriptyline. Of the patients with functional nausea and vomiting treated with tricyclic antidepressants, 19 of 37 (51.4%) achieved complete remission and 12 (32.4%) showed partial response. The authors suggest that the pathophysiology of CVS might be similar to that of migraine headache (Prakash & Clouse, 1999).

4.5.B.9 Depression - Opioid dependence

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

DOXEPIN reduced the craving for HEROIN, nervousness, and the use of amphetamines

c) Adult:

1) Doxepin was superior in the treatment of depression when compared with placebo in a 5-week trial as adjunctive treatment in a methadone maintenance program. Only 46 of 76 patients completed the study. Relative to several depression parameters, doxepin was shown better than placebo. Doxepin did not significantly increase the incidence or severity of adverse effects to methadone (Titievsky et al, 1982)

2) DOXEPIN was efficacious in HEROIN addicts with associated anxiety and depression. Doses of 100 to 150 mg daily for periods of longer than 4 weeks significantly decreased symptoms of anxiety and depression as measured by the Hamilton depression rating scale (Woody et al, 1975).

4.5.B.10 Detrusor instability of bladder

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Effective in the treatment of detrusor overactivity in women

c) Adult:
1) DOXEPIN caused a significant decrease in the nighttime micturition frequency and the nighttime incontinence episodes. Cystometric parameters improved significantly during treatment with DOXEPIN. The authors concluded that DOXEPIN seems to offer a new alternative in the pharmacological treatment of detrusor overactivity and associated symptoms (Lose et al, 1989).
2) In this randomized, double-blind, placebo-controlled study of DOXEPIN, 19 females with detrusor overactivity and associated symptoms who had failed to respond to conventional pharmacotherapy, obtained relief ascribed to the ability of DOXEPIN to improve storage failure by decreasing bladder contractility and/or decreasing sensory input (Lose et al, 1989). DOXEPIN caused a significant decrease in the nighttime micturition frequency and the nighttime incontinence episodes (p less than 0.05). Cystometric parameters improved significantly during treatment with DOXEPIN. The authors concluded that DOXEPIN seems to offer a new alternative in the pharmacological treatment of detrusor overactivity and associated symptoms.

4.5.B.11 Disorder of gastrointestinal tract

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category A
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
An effective alternative in treating IRRITABLE BOWEL SYNDROME
Other types of epigastric distress have also reportedly responded to therapy

c) Adult:
1) A meta-analysis of controlled clinical trials related to the use of antidepressants for the treatment of functional gastrointestinal (GI) disorders concluded that this type of therapy (primarily tricyclic antidepressants) is efficacious in some patients. Included were 11 trials published between 1978 and 1998 focused on antidepressant therapy in irritable bowel syndrome (8) and dyspepsia (non-ulcer) (2); one study included patients with either disorder. Among the medications studied were amitriptyline (3), trimipramine (3), desipramine (2), DOXEPIN (1), mianserin (1), and either clomipramine or mianserin (1). All of the trials compared the treatment drug against placebo. In 8 studies using a dichotomous outcome measure, ie, response to treatment, the odds ratio for improvement with therapy was 4.2. In 7 studies using a continuous variable of pain scores, the standardized mean improvement in pain averaged 0.9 standard deviation (SD) (means for the treatment and control groups divided by the SD). Pooling of the risk difference indicated that 3.2 patients needed to be treated for 1 to experience symptom improvement. The authors were uncertain if the improvement in GI symptoms was an independent action of the drugs or if the improvement reflected the effects of the drugs on the psychological outlook of the recipients (Jackson et al, 2000).
2) A nondepressed patient obtained relief from irritable bowel syndrome, resistant to other therapies, while receiving DOXEPIN 150 milligrams/day (Gartrell & Mosbacher, 1982). Another similar case with similar results was reported (Pies, 1983).
3) Doxepin relieved 2 cases of epigastric distress (Shen et al, 1983). A 77-year-old man with an 8-year history of severe, unremitting epigastric distress experienced significant relief on DOXEPIN 100 milligrams/day. Similar results were observed in a 55-year-old man after initiation of DOXEPIN 125 milligrams/day.

4.5.B.12 Disorder of oral mucous membrane - Pain

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Mucosal local doxepin rinse relieved mucosal pain caused by cancer or cancer treatment for more than 3 hours

c) Adult:
1) An oral rinse of doxepin solution gave relief of pain to patients with oral mucosal damage. In an single-dose, open trial, 41 patients with oral mucosal pain resulting from cancer or cancer treatment

rinsed their mouths for 1 minute with 5 milliliters (mL) of doxepin suspension 5 milligrams/mL. At 15 minutes post- rinsing, mean pain reduction was 60% (p less than 0.01), and at 3 hours, 25% (p less than 0.05). By 24 hours, pain had returned to pre-rinse levels. Thirty-five percent of patients reported absence of fatigue, 13% mild fatigue, 20% moderate, 16% moderate-to-severe, and 16% severe (Epstein et al, 2001).

4.5.B.13 Insomnia

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Used as a sedative-hypnotic, however, benzodiazepines are usually recommended for patients with sleep disturbances

c) Adult:

1) GENERAL INFORMATION

a) Doxepin has been promoted as a sedative-hypnotic for all patients, whether they have underlying symptoms of anxiety and depression or not. One manufacturer has indicated that doxepin is recommended for sleep disturbances that accompany anxiety neurosis and depression, but not for patients with INSOMNIA as the only disorder (Prod Info Sinequan(R), 1989). Doxepin does have marked sedative effects, similar to those of amitriptyline (Hollister, 1972; Ayd, 1969), and studies have shown that somnolence occurs in up to 19% of those on chronic treatment (Pitts, 1969a); (Belsasso, 1969; Gallant, 1969). These studies have most likely prompted the use of the drug as a sedative hypnotic. Indeed, some have recommended the drug be administered at bedtime because of its noticeable sedative and hypnotic properties, but this advice was referred to patients with emotional disorders or depression (Belasso et al, 1969). Doxepin also has been reported to produce insomnia, excitement, restlessness, agitation, euphoria, and anxiety which are certainly not the most desirable effects of a sedative (Pitts, 1969a).

2) In a randomized, double-blind, placebo-controlled trial, doxepin improved sleep and working ability in patients with chronic primary insomnia more than did placebo but was associated with more rebound insomnia upon discontinuation. Patients with DSM-IV primary insomnia (mean duration 11 years) were treated either with placebo (n=20) or doxepin 25 to 50 milligrams/night for 4 weeks. Polysomnographic measures showed improved sleep efficiency, increased total sleep time, and decreased time of wake-after- sleep-onset (WASO) with doxepin (relative to baseline and to values of placebo-treated patients, p less than 0.01 or better for all comparisons) at the first night of treatment. Improvements persisted at day 28 of treatment. Sleep efficiency with doxepin was 89% at day 1 and throughout treatment (compared to 78% at baseline). Average total sleep time with doxepin at day 28 was 7.1 hours (vs 6.3 hours at baseline). With discontinuation of treatment, the number of doxepin-treated patients experiencing rebound on 3 or more sleep parameters was significantly greater than the number of placebo-treated patients experiencing rebound (p less than 0.05) for the 3 nights of acute withdrawal. At night 42 (2 weeks without treatment), some sleep parameters in the doxepin group were better than at baseline (sleep efficiency, p less than 0.05; WASO, p less than 0.01), and none was worse. Frequency of adverse events did not differ significantly for the 2 groups. Dry mouth, dizziness, and somnolence tended to be more pronounced in the doxepin group, and diarrhea, dyspepsia, anorexia, sweating, and common colds more frequent in the placebo group. Sleep improvements with doxepin were rated slight or moderate by the authors (Hajak et al, 2001).

3) In June, 1971, three separate studies concerning the treatment of nondepressed insomniacs with doxepin were presented at the First International Congress, The Association for Psychophysiological Study of Sleep. Baseline sleep patterns, established while the patients received a placebo, were compared with sleep patterns recorded while receiving doxepin 25 or 50 milligrams at bedtime for 2 weeks. Each investigator reported a decrease in all the patient's REM sleep and awake time while receiving doxepin. During the placebo withdrawal administration, each patient experienced REM rebound. The authors did note a slight decrease of doxepin's effectiveness as the trials continued, however, they concluded that tolerance to drowsiness did not develop (Pers Comm, 1989). Because drug exposure lasted only 14 days, surmising that tolerance does not develop to doxepin therapy seems premature. No studies could be found indicating that tolerance occurs to the sedative effects. Tolerance to the drowsiness has been reported by Roerig, one manufacturer of doxepin, thus until proven otherwise tolerance to the sedative effects is assumed to occur (Prod Info Sinequan(R), 1999).

4) DOXEPIN had a positive effect on sleep disturbances in 9 patients with depression accompanied by disorders of sleep. DOXEPIN 75 and 150 milligrams/day improved sleep efficiency as evidenced by decreased sleep latency and increased total sleep time (Roth et al, 1982).

5) One study reported using doxepin 100 milligrams for treating insomnia in heroin addicts receiving clonidine to alleviate withdrawal symptoms. The investigators did not report the success rate for treating insomnia, however, doxepin seem to be beneficial for inhibiting the peripheral hypotensive actions of clonidine (Schanda et al, 1983).

6) Long-term side effects of doxepin were assessed in 1706 patients who received the drug for periods

of a few weeks to 22 months (mean 3.3 months) in doses ranging from 25 to 600 milligrams daily. The most common side effects (greater than 2%) consisted of: drowsiness (17.4%), anticholinergic effects, mostly dry mouth (22.9%), extrapyramidal symptoms, usually in high doses (6.3%), dizziness (5.9%), hypotension (2.8%), tachycardia (2.6%), gastrointestinal effects (3.7%), and insomnia (2.1%). No abnormalities in WBC, Hgb, Hct or evidence of BLOOD DYSCRASIAS were reported in the more than 800 patients for whom blood tests were done. AST, ALT, and ALKALINE PHOSPHATASE values were abnormal in only a few of the patients tested (less than 1%) (Pitts, 1969a).

4.5.B.14 Nicotine dependence

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Doxepin may be a useful adjunct in smoking cessation

c) Adult:

1) DOXEPIN was efficacious in the treatment of NICOTINE WITHDRAWAL (Edwards et al, 1990). DOXEPIN was given to 8 patients prior to smoking cessation with the following regimen: 25 milligrams at bedtime initially and titrated in increments of 25 milligrams every third day to reach a target dose of 150 milligrams. When 150 milligrams/day was maintained for 1 week, patients were instructed to terminate smoking. Twenty-one patients were instructed to begin smoking cessation after the initial visit. Dropouts were more frequent in the patients that did not receive DOXEPIN (72% compared with 50% in the DOXEPIN patients). DOXEPIN significantly suppressed symptom frequency during the first and second week as compared with the patients who did not receive DOXEPIN.

2) A 5-week pilot study revealed that DOXEPIN therapy was useful in nicotine withdrawal (Whelan & Davis, 1990). Of the original 8 subjects treated with DOXEPIN and 21 controls, only 4 of the DOXEPIN group and 6 controls finished the study. DOXEPIN reduced the severity of symptoms during the first 2 weeks but there was no significant difference in the last 3 weeks.

3) DOXEPIN was reported effective in achieving smoking cessation in a small double-blind study involving 19 adults (Murphy et al, 1990; Edwards et al, 1989). Prior to smoking cessation, the DOXEPIN (or placebo) was given in doses of 50 milligrams daily for 3 days, then 100 milligrams daily on days 4 through 6, followed by 150 milligrams daily from day 7 to 21. On day 22, subjects stopped smoking and DOXEPIN 150 milligrams daily or placebo was continued for an additional 4 weeks. The study medication was given at bedtime. Smoking cessation was achieved in all of the 9 subjects treated with DOXEPIN 7 days after stopping smoking and was maintained in 7 of the subjects at 9 weeks; only 1 of 10 placebo subjects reported cessation. A precessation DOXEPIN serum level higher than 10 ng/mL was associated with cessation of smoking in this study. In the 2 DOXEPIN subjects reporting relapse, DOXEPIN levels were less than 10 ng/mL. DOXEPIN appeared to reduce the intensity of cigarette craving (2.8 +/- 1.7 for DOXEPIN users versus 5.1 +/- 0.8 for placebo). Substantial weight gain was observed in subjects treated with DOXEPIN who were able to stop smoking (mean, 11.7 pounds). It is suggested that the weight gain attributable to cessation of smoking was most likely compounded by weight gain secondary to DOXEPIN use. This small study suggests that DOXEPIN may have a role in assisting smoking cessation.

4.5.B.15 Peptic ulcer disease

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Effective in the treatment of peptic ulcer disease due to its histamine blocking activity

c) Adult:

1) Tricyclic antidepressants have anti-histamine blocking properties, however, standard H2 antagonists are recommended for the treatment of peptic ulcer disease. For peptic ulcer disease, doxepin has been as effective as cimetidine (Shrivastava et al, 1985a; Ruud et al, 1982; Hoff et al, 1981) and doxepin was effective in patients who had failed cimetidine (Shrivastava et al, 1985a; Mangla & Pereira, 1982).

2) Doxepin was superior to placebo in a study of the effect of doxepin on gastric acid and salivary secretion in patients with asymptomatic, chronic duodenal ulcer disease. Seven patients received either 50 or 100 milligrams doxepin or placebo, and were evaluated at 3.5, 5.5, 7.5, and 9.5 hours after drug administration. Both gastric acid and salivary secretion were decreased significantly more by doxepin than placebo, but no statistically significant differences were seen between the 2 doses of doxepin (Brown-Cartwright et al, 1986).

4.5.B.16 Post-prandial hypoglycemia

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class III
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Has reduced symptoms of postprandial symptomatic hypoglycemic.

c) Adult:
1) DOXEPIN reduced symptoms of postprandial symptomatic hypoglycemic in 32 subjects (Lechin et al, 1991). There was a 4-week baseline period followed by an 8-week study with DOXEPIN 25 milligrams being substituted for placebo. During the placebo period, all patients showed hypoglycemia, hyperinsulinemia, and disorders of plasma neurotransmitters during the oral glucose tolerance test when compared with control subjects. The subjects were divided into 3 separate groups according to different blood levels of neurotransmitters. Groups I and II showed low basal noradrenalin/adrenalin ratios and low serotonin levels. Group III had a high noradrenalin/adrenalin ratio with a raised serotonin level and all subjects showed severe dysthymic depression. The symptoms of postprandial hypoglycemia did not correlate with a low glucose level but rather an imbalance in the neurotransmitter levels. Serotonin and noradrenalin stimulate hypothalamic activity which reduces pituitary-adrenocortical functioning. This in turn reduces the adrenaline level and causes hypoglycemia. All 32 subjects showed pituitary-adrenocortical hyperactivity before treatment. After treatment with DOXEPIN they were all asymptomatic.

4.5.B.17 Posttraumatic stress disorder

a) Overview
FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Tricyclic antidepressant therapy including doxepin has been reported beneficial in the treatment of posttraumatic stress disorder in COMBAT VETERANS (Falcon et al, 1985)

c) Adult:
1) Posttraumatic stress disorder due to trauma, burns, rape, and other noncombat physical insults have been treated with antidepressants. A 36-year-old male suffered posttraumatic stress disorder several months after receiving second and third degree burns in a truck fire. The patient responded well to DOXEPIN (daily doses of 50 milligrams (mg) to start, increasing to 300 mg, then tapering to 50 mg) over a period of 1 year (Blake, 1986).

4.5.B.18 Pruritus (Moderate), Due to atopic dermatitis or lichen simplex chronicus

FDA Labeled Indication

a) Overview
FDA Approval: Adult, yes (5% cream); Pediatric, no
Efficacy: Adult, Effective; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIa; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category C
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
DOXEPIN cream reduces the pruritus associated with atopic dermatitis and lichen simplex chronicus
Topical DOXEPIN combined with corticosteroids improves treatment results
Topical doxepin reduced erythema and itching in chronically pruritic burn wounds
Eliminated recalcitrant lichen simplex in a child (Thomson & Highet, 2001)

c) Adult:
1) GENERAL INFORMATION
a) Doxepin cream 5% is indicated for the short-term treatment (up to 8 days) of moderate pruritus in adult patients with atopic dermatitis or lichen simplex chronicus. The use of doxepin cream in children is not recommended (Prod Info Zonalon(R), 2004). In two multi-center, double-blind, placebo-controlled studies, atopic dermatitis, lichen simplex chronicus, and other eczemas were successfully treated with doxepin cream in 559 adults (Tech Info Zonalon(R), 1994).
2) MONOTHERAPY
a) Topical doxepin therapy effectively reduced erythema and itching in chronically pruritic burn wounds. In a prospective, randomized study, thirty-one patients reporting itch in healed burns 4 to 12 months of age (mean, 7 months) received either ongoing standard care with oral antihistamines (ie, diphenhydramine, hydroxyzine) or topical 5% doxepin cream applied 4 times daily to affected area(s) for 3 months. Both groups used a skin moisturizer two to three times daily during the study. Patients rated itch and erythema daily using a visual analog scale. Patients in the doxepin

treatment group had significantly greater reductions in itching and erythema at 1, 8, and 12 weeks as compared with the standard care group. Itching completely stopped in 75% of doxepin-treated patients compared to only 20% of standard care patients. Mild to moderate somnolence was reported in both groups (Demling & DeSanti, 2003).

b) Doxepin cream 5% was superior to placebo (ie, vehicle only) in 270 patients with moderate to severe atopic dermatitis with pruritus in a double-blind, randomized, vehicle-controlled trial lasting seven days. Eighty-five percent of patients receiving the active cream reported relief of pruritus, compared with 57% using the vehicle only. Localized stinging and burning requiring discontinuation in 37 doxepin and 3 placebo patients, were the only significant side effects (Drake et al, 1994).

c) In two multicenter, double-blind, placebo-controlled studies, atopic dermatitis, lichen simplex chronicus, and other eczemas, were successfully treated by DOXEPIN cream in 559 adults (Tech Info Zonalon(R), 1994).

d) Oral DOXEPIN has been effectively used to treat chronic urticaria in numerous clinical trials (Gupta et al, 1987; Goldsobel et al, 1986; Harto et al, 1985); (Greene et al, 1985)(Neittaanmaki et al, 1984a), however, few trials using topical preparations have been published. In one double-blind study, 40 subjects were injected with 8 different dilutions of histamine. Sixty-eight percent showed relief from itching with a 5% topical solution of DOXEPIN, compared to 53% with DIPHENHYDRAMINE and 25% with vehicle alone (Bernstein et al, 1981).

3) COMBINATION THERAPY

a) Patients with pruritic atopic dermatitis responded more promptly and their symptoms improved to a significantly greater extent when topical DOXEPIN was added to HYDROCORTISONE or TRIAMCINOLONE therapy compared with topical corticosteroid monotherapy. In a randomized, double-blind, multi-center trial, cream was applied 4 times daily for 8 days: hydrocortisone 2.5% (HC, n=83); triamcinolone 0.1% (TR, n=90); doxepin 5% plus HC 2.5% (n=86); and doxepin 5% plus TR 0.1% (n=90). Patient-rated visual analog scores for pruritus severity had declined by 8% and 10.7% for HC- and TR-treated patients at 12 hours after initiation of therapy. At the same time, mean reductions in the doxepin-HC and doxepin-TR groups were 31.6% and 22.4%, respectively (p less than 0.001; p=0.07). On day 2, pruritus relief was noted in 46.7%, 66.7%, 70.4%, and 79.1%, respectively, for groups receiving HC, TR, doxepin-HC, and doxepin-TR, according to physician ratings (p=0.01 doxepin-HC vs monotherapy; p=0.027, doxepin-TR vs monotherapy). Common side effects of the corticosteroids were local stinging or burning (not improved by doxepin). Mild and transient drowsiness occurred in 38% and 10% of patients using doxepin plus HC or TR, respectively; rates were 9% and 5% with single-agent corticosteroid therapy (Berberian et al, 1999).

d) Pediatric:

1) Recalcitrant lichen simplex in a 3-year-old boy was resolved by application of 5% doxepin cream. At age 1 year, the boy had intense pruritus of the lower left leg. With persistent scratching, the area developed lichen simplex, which was effectively treated with emollients. At 2 years of age, he had a recurrence, which did not respond to potent topical preparations and occlusive wraps, including mometasone ointment, hydrocolloid dressings, tar bandages, and clobetasol propionate, because the child would remove the dressings. At age 3 years, the boy was treated with 5% doxepin cream in an attempt to break the "itch- scratch cycle." Within 24 hours of doxepin application, scratching stopped, and at 14 days, there was complete resolution. No side effects were observed. In particular, there was no sedation (the principal side effect observed with topical doxepin) (Thomson & Highet, 2001).

4.5.B.19 Psychogenic headache

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence is inconclusive
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category C

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Beneficial results of DOXEPIN have been reported in patients with PSYCHOGENIC HEADACHE

c) Adult:

1) Beneficial results of DOXEPIN were reported in patients with PSYCHOGENIC HEADACHE following anxiety/depressive illnesses (Okasha et al, 1973). Doses of 10 milligrams three times/day were administered and dosage increased when required by 2 mg daily after 2 weeks at weekly intervals. The study lasted 8 weeks, and by the fourth week the majority of patients noticed marked improvement. When compared with AMITRIPTYLINE and DIAZEPAM, DOXEPIN was the only drug with a highly significant effect on headache, anxiety, and depression. The investigators speculate that superiority of DOXEPIN may be attributed to its effect as an antianxiety agent, antidepressant, and central muscle relaxant.

4.5.B.20 Urticaria

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy

Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:
Effective in the treatment of urticaria

c) Adult:
1) Oral DOXEPIN 10 to 30 milligrams daily has been effective in the treatment of IDIOPATHIC COLD URTICARIA, effectively suppressing the wheal and itching responses and shortening the duration of the wheal response in the ice cube test (Neittaanmaki et al, 1984a).
2) Oral DOXEPIN 5 milligrams twice a day was effective in the treatment of chronic idiopathic URTICARIA in a controlled study. Oral MEQUITAZINE (a phenothiazine antihistamine) 5 mg twice a day was equally effective (Harto et al, 1985; Ledo et al, 1985).
3) Oral DOXEPIN 25 milligrams three times a day was effective in the treatment of CHRONIC IDIOPATHIC URTICARIA in a placebo-controlled trial involving 16 adult patients (Goldsobel et al, 1986). Patients were randomly assigned to receive either DOXEPIN or placebo for 4 weeks; each group was then crossed over for the next 4 weeks. DOXEPIN was associated with fewer waking hours with lesions, and less angioedema and swelling as compared to placebo-treated patients. Daily antihistamine use was less in patients treated with DOXEPIN. Lethargy was observed during DOXEPIN therapy but decreased with continued use of the drug; dry mouth and constipation were also reported.

4.6 Comparative Efficacy / Evaluation With Other Therapies

Amitriptyline

Amitriptylinoxide

Amoxapine

Bupropion

Capsaicin

Chlordiazepoxide

Cimetidine

Cinnarizine

Clomipramine

Clovoxamine

Desipramine

Diazepam

Diphenhydramine

Dothiepin

Fluoxetine

Imipramine

Loxapine

Maprotiline

Mianserin

Nomifensine

Opipramol

Paroxetine

Perphenazine/Amitriptyline Hydrochloride

Trazodone

Trimipramine

4.6.A Amitriptyline

4.6.A.1 Depression

a) Clinical studies have shown that doxepin and amitriptyline are of comparable efficacy in depression; side effects have occurred with greater frequency in patients receiving amitriptyline (Toru et al, 1972; Bianchi et al, 1971; Solis et al, 1970).

b) In one study, amitriptyline-perphenazine produced significantly greater improvement than doxepin on several measures of psychiatric tests. The combination also produced a greater incidence of sedation and anticholinergic side effects (Rickels et al, 1982a). Doxepin 100 to 150 milligrams/day was compared with a combination of amitriptyline 100 to 150 milligrams/day plus perphenazine 8 to 12 milligrams/day in 130 depressed, nonpsychotic outpatients over a period of 4 weeks.

c) Four antidepressants were used in a group of 116 private practice patients suffering from depression associated with chronic or recurrent pain. Dosage range was 150 to 300 milligrams/day, and the antidepressant was changed if necessary to get an adequate response. The response to the 4 antidepressants was not statistically significantly different: doxepin 17 of 22 (77%); imipramine 33 of 44 (75%); amitriptyline 21 of 25 (84%); and desipramine 34 of 44 (75%). A significant response was a 50% reduction in pain judged subjectively (Lindsay & Wyckoff, 1981).

d) Doxepin was compared with amitriptyline in acutely depressed patients using cortical evoked potentials as the measurement of success (Friedman et al, 1980). Many depressed patients have a magnified perception of intervisity to a stimulus; thus, often they complain of pain which to others might be described as discomfort. In 33 patients, baseline potentials were measured after 1 week of placebo therapy, then they received 150 milligrams/day of either doxepin or amitriptyline. Five visual and 5 auditory evoked potentials were recorded. Doxepin reduced the amplitudes of the evoked potentials significantly. Amitriptyline had a similar, but insignificant effect.

e) One author reported that doxepin showed faster pharmacologic activity and greater antidepressive and anxiolytic effects than amitriptyline (Solis et al, 1970).

4.6.B Amitriptylinoxide

4.6.B.1 Depression

a) Doxepin and amitriptylinoxide, in doses of 180 to 360 milligrams/day, had a similar efficacy in a four-week study involving 44 inpatients with severe depression. Efficacy was judged on several rating scales. The two drugs showed comparable efficacy and there were no significant differences in adverse effects (Konig et al, 1994).

4.6.C Amoxapine

4.6.C.1 Mixed anxiety and depressive disorder

a) Amoxapine 160 milligrams/day (maximum dose) was compared with doxepin 130 milligrams/day (maximum dose) in the treatment of mixed anxiety/depression in 142 patients. Twenty-four to 31 of amoxapine-treated subjects (n=71) and 16 to 24 of doxepin-treated subjects (n=71) receiving doxepin were identified as improved after 4 weeks. Amoxapine achieved a more rapid response. Side effects between the 2 treatments were comparable; however, doxepin caused more constipation (Hekimian et al, 1983).

4.6.D Bupropion

4.6.D.1 Depression

a) Bupropion 300 to 450 milligrams daily was reported similar in efficacy to doxepin 100 to 225 milligrams daily in the treatment of major depressive disorder in a double-blind study involving 147 outpatients (Feighner et al, 1986). Doxepin, however, improved sleep better than bupropion; anticholinergic side effects were more frequent with doxepin as compared with bupropion, as was increased appetite and weight gain.

4.6.E Capsaicin

4.6.E.1 Chronic pain - Neuropathic pain

a) Topical doxepin hydrochloride, topical capsaicin, or the combination of the 2 all provided analgesia in chronic human neuropathic pain (CNP), in contrast to placebo. In a randomized, double-blind, placebo-controlled trial, 200 patients with CNP were given placebo cream, 3.3% doxepin hydrochloride cream, 0.25% capsaicin cream, or a cream containing 3.3% doxepin and 0.25% capsaicin. Patients were to apply a volume of cream approximately equal in size to a grain of rice 3 times daily to the painful area for 4 weeks. Overall pain was unchanged in the placebo group. In the other 3 groups, overall pain decreased from approximately 7 to approximately 6 on a pain scale ranging from 0 to 10 (p less than 0.001 for all drug groups). Scores for burning pain were unchanged in the placebo group but increased in all 3 drug groups at week 1 and, though diminishing somewhat thereafter, remained significantly above that of the placebo group. Sensitivity was unchanged by placebo and doxepin but declined significantly, beginning in the first week, with both capsaicin (p less than 0.001) and doxepin/capsaicin (p less than 0.01) treatments. Shooting pain was reduced by the capsaicin treatments but not by doxepin or placebo. Ten percent of patients in the doxepin group and 5% in the doxepin/capsaicin group complained of drowsiness, suggesting the systemic absorption of doxepin. A burning sensation was reported by 81% of those in the capsaicin and by 61% of those in the doxepin/capsaicin group (McCleane, 2000).

4.6.F Chlordiazepoxide

4.6.F.1 Anxiety

a) Most clinical studies to date have indicated that doxepin has proven as useful as chlordiazepoxide in patients with anxiety neurosis (Simeon et al, 1970; Kingstone et al, 1970; Johnstone & Claghorn, 1968). At this point doxepin can not be recommended over chlordiazepoxide or other benzodiazepines in neurotic anxiety but is recommended as the drug of choice in patients with mixed anxiety-depression states (Pinder et al, 1977c).

4.6.G Cimetidine

4.6.G.1 Duodenal ulcer disease

a) In a double-blind randomized study of 21 patients, doxepin (50 milligrams at bedtime for 1 week, followed by 100 milligrams at bedtime) was comparable with cimetidine 300 milligrams four times a day for the treatment of duodenal ulcers (Shrivastava et al, 1985). After 6 weeks, the average ulcer size decreased by 97% in both groups. Interestingly, doxepin was significantly more effective in women than in men, while cimetidine was more effective in men than in women. Further large studies are needed to confirm whether there truly exists a sex-related difference in ulcer healing, especially with doxepin.

4.6.H Cinnarizine

4.6.H.1 Urticaria

a) A randomized, double-blind, crossover trial in 10 patients with primary acquired idiopathic cold urticaria compared the effects of cinnarizine 10 milligrams (mg) three times daily with doxepin 10 mg three times daily and placebo. Each arm of therapy lasted two weeks. Eight patients considered doxepin superior to cinnarizine. Cinnarizine provided some symptom relief in five patients, and was ineffective in four. One patient discontinued cinnarizine therapy due to excessive fatigue. Placebo produced no symptom relief (Neittaanmaki et al, 1984).

4.6.I Clomipramine

4.6.I.1 Dysthymia

a) Results were equivocal in a study that compared clomipramine and doxepin (75 milligrams/day of either) in a group of 66 patients with neurotic depression. Patient-rated measures did not show a superior agent. Clomipramine was rated better by physician-rated measures. There were no significant differences in side effects (Kornhaber & Horwitz, 1984).

b) Doxepin (25 milligrams three times a day) and clomipramine (25 milligrams three times a day), were more effective than L-tryptophan (500 mg three times a day) in 42 neurotically-depressed patients. The findings of the study were that doxepin and clomipramine resulted in more responses than L-tryptophan, therapeutic blood levels of clomipramine and doxepin were much smaller than those found in endogenously depressed patients, that responders had a significantly higher blood level of the two than non-responders at 21 days, and that the response to clomipramine, but not doxepin, parallelled its accumulation in the blood. (Linnoila et al, 1980).

4.6.J Clovoxamine

4.6.J.1 Depression

a) SUMMARY: Clovoxamine offered no clinical advantage over doxepin in the treatment of major depression in one small double-blind study.

b) In a small, double-blind study (n=34), clovoxamine 150 to 300 milligrams daily was generally comparable in efficacy with doxepin 75 to 150 milligrams daily in the treatment of major depression (Lodge & Freeman, 1986). However, doxepin was statistically superior to clovoxamine with regard to improvement of the anxiety/somatization component of Hamilton Rating Scale for Depression (HAM-D) during the first week of treatment. In addition, patient assessments of the response to treatment were highly in favor of doxepin; 97% of doxepin-treated patients indicated they had improved significantly compared to only 50% in the clovoxamine group. Adverse effects were similar in each group, although headache, sweating, and anticholinergic symptoms tended to occur more frequently with clovoxamine. Analysis of pretreatment data in this study indicated more severe depression in the clovoxamine group, which may have influenced results reported. However, several patients with severe psychotic depression were also treated effectively with clovoxamine, suggesting efficacy of the drug in this subgroup. A larger and placebo-controlled study comparing these agents is needed.

4.6.K Desipramine

Chronic pain

Endogenous depression

4.6.K.1 Chronic pain

a) Desipramine and doxepin had similar efficacy in treating depression and doxepin was more effective than desipramine in the treatment of pain severity in one study (Ward et al, 1984). Desipramine (mean dose 173 milligrams/day) was compared with doxepin (mean dose 188 milligrams/day) in 36 patients with depression and chronic back pain. Both drugs produced equal responses in depression ratings. Pain severity showed a better response to doxepin.

b) Four antidepressants had similar efficacy in a group of 116 private practice patients suffering from depression associated with chronic or recurrent pain. Dosage range was 150 to 300 milligrams/day, and the antidepressant was changed if necessary to get an adequate response. The response to the 4 antidepressants was not significantly different: doxepin 17 of 22 (77%); imipramine 33 of 44 (75%); amitriptyline 21 of 25 (84%); and desipramine 34 of 44 (75%). A significant response was a 50% reduction in pain subjectively judged (Lindsay & Wyckoff, 1981a).

4.6.K.2 Endogenous depression

a) Doxepin and desipramine were equally effective in a group of 38 patients with a diagnosis of primary affective disorder, endogenous depression. Both drugs had equal efficacy, but doxepin had a more rapid onset (Amsterdam et al, 1982).

4.6.K.3 Efficacy

a) A prospective study compared oral doses and corresponding plasma levels of doxepin with desipramine (as standard reference compound) for 31 patients (19 females, 12 males), mean age 76 (range, 66 to 86). The results in eight doxepin-treated patients (25 to 100 milligrams/day) showed zero levels of doxepin or its metabolite, desmethyldoxepin, in their plasma. The authors believed that doxepin's reputation for having fewer side effects may reflect the low plasma levels achieved at commonly prescribed doses and that at more appropriate doses, the side-effect profile may be more in line with standard tricyclics. The authors recommend routine monitoring of doxepin levels in the elderly and question poor bioavailability or absorption of this tricyclic antidepressant in some patients (Gosselin et al, 1989).

b) Desipramine suppressed wheal response for 2 days and flare for one day, whereas doxepin suppressed the wheal for 4 days and flare for 6 days in a double-blind, single dose, noncrossover study. Thirty-three healthy adult volunteers (32 males, 1 female) received a single, oral 25-milligram dose of desipramine or doxepin. The duration of H1-receptor blockade by these two tricyclic antidepressants were compared. Results showed significant differences in the suppression of the wheal-and-flare responses to histamine between the two drugs (Rao et al, 1988). These results suggest that doxepin should be withheld for at least 7 days before allergy skin testing.

4.6.L Diazepam

4.6.L.1 Anxiety

a) No significant difference has been observed in clinical trials in patients with anxiety (with or without depression) between doxepin and diazepam (d'Elia et al, 1974; Fielding et al, 1969; Kasich, 1969).

b) A double-blind, placebo-controlled study of 61 outpatients compared doxepin and diazepam in the treatment of anxious and anxious-depressive syndromes (Haskell et al, 1978). After the first week, an enhanced sense of well-being was associated with diazepam. By the end of 6 weeks, there was no significant difference for altering mood and symptomatology with either drug. Objective evaluation rated diazepam more effective than doxepin among anxious patients. Drowsiness was the most common side effect. Significant weight gain occurred with doxepin. Possible biases may have been induced by the sampling technique, population characteristics, and consequent drop-out rate.

4.6.M Diphenhydramine

4.6.M.1 Urticaria

a) Oral doxepin 10 milligrams three times a day was reported significantly superior to oral diphenhydramine 25 milligrams three times a day in the treatment chronic idiopathic urticaria in a controlled study involving 50 patients (Greene et al, 1985). Clearing of pruritus and urticarial lesions was observed in 5% and 43% of diphenhydramine and doxepin-treated patients, respectively; partial or total control pruritus and hives occurred in 10% and 74% of patients, respectively. Doxepin was also associated with significantly less sedation than diphenhydramine.

4.6.N Dothiepin

4.6.N.1 Depression

a) Dothiepin and doxepin were similarly effective when administered in single daily doses of 150 milligrams in a ten-week, placebo-controlled, double-blind study of 579 outpatients with major depressive disorder with psychotic features. Efficacy was judged by several rating scales. Only 341 patients completed the trial. Both drug groups were significantly superior to placebo and there were no significant differences between the two groups. Dothiepin was superior to doxepin relative to the incidence and severity of adverse events (Ferguson et al, 1994).

4.6.O Fluoxetine

4.6.O.1 Depression

a) Doxepin and fluoxetine had similar efficacy in a comparative study involving 80 depressed patients (61 outpatients, 19 inpatients) diagnosed as having major depressive disorder. The patients received either fluoxetine 20 to 60 milligrams/day (mean, 28.9 mg/day) or doxepin 100 to 200 milligrams/day (mean, 146.8 mg/day). Both treatment groups showed improvement over time, with no difference between fluoxetine and doxepin at study termination. The most common side effects of fluoxetine (headache, nausea, and insomnia) were in contrast to the pronounced anticholinergic side effects of doxepin (dry mouth, fatigue, constipation). Moreover, the significant weight gain associated with doxepin therapy was not seen with fluoxetine treatment (Remick et al, 1989).

b) Fluoxetine 20 to 80 milligrams daily (once daily or divided twice a day) and doxepin 50 to 200 milligrams daily (once daily or divided twice a day or three times a day) had comparable efficacy in the treatment of depression in geriatric patients (at least 64 years of age). Each drug was administered in increasing doses over the first two weeks of the study, with maintenance doses (up to 80 mg daily of fluoxetine and 200 mg daily of doxepin) being determined by the third week; this maintenance dose was given for three more weeks (total, six weeks). Both drugs were considered equally effective using the following parameters: Hamilton Psychiatric Rating Scale for Depression (HAM-D), Raskin Severity of Depression Scale, Covi Anxiety Scale, Clinical Global Impressions severity and improvement, Patient Global Improvement, and SCL-58 scales. Both drugs produced significant improvement compared to baseline scores. Fluoxetine was associated with a lower degree of drowsiness/sedation, dry mouth, constipation and vision disturbances. However, nervousness/anxiety, insomnia, sweating, dyspepsia, and nausea occurred to a greater degree with fluoxetine. Body weight decreased with fluoxetine and increased with doxepin (Feighner & Cohn, 1985).

c) In one study comparing fluoxetine and doxepin, both drugs were effective in major depressive disorder in geriatric patients, with a lower incidence of side effects being observed with fluoxetine (Feighner & Cohn, 1985). Weight loss occurred with fluoxetine, as compared to weight gain with doxepin, which was statistically significant. Heart rate was shown to increase in doxepin-treated patients as compared to decreases in fluoxetine-treated patients; this was also a statistically significant difference. Significant improvement in depressive symptoms was further demonstrated in a group (n=33) of geropsychiatric patients. Although this study only followed patients for a period of one month, significant side effects such as nausea, weight loss, and agitation were not noted. Doses of fluoxetine used were 20 mg every other day to 20 mg daily (Orengo et al, 1996).

4.6.P Imipramine

4.6.P.1 Depression

a) Imipramine may be slightly more effective than doxepin in the treatment of depression. Ninety-nine patients with neurotic depression received imipramine 100 to 200 milligrams/day or doxepin 100 to 200 milligrams/day for 4 weeks in a double-blind study. Imipramine was superior in 24 of 27 parameters. Imipramine was shown to be superior to doxepin in improving the symptoms of anxiety/depression; global evaluations showed improvement in 39 of 48 (81%) of imipramine patients and 34 and 49 (69%) of doxepin patients (Finnerty et al, 1978).

b) In a study involving 79 patients, a higher socioeconomic status and shorter duration of illness were indicative of a favorable response to imipramine, whereas a higher response rate to doxepin was found in male patients (Finnerty & Goldberg, 1981).

c) Amitriptyline was superior to imipramine and doxepin in relation to their effects on interpersonal learning in 50 depressed inpatients (Gillis, 1981). All subjects performed better, according to quantitative indices of

learning tasks, than patients who received antipsychotic or neuroleptic drugs but no antidepressants. Amitriptyline patients scored significantly higher than either imipramine or doxepin patients.
d) No significant differences in overall efficacy of the 2 drugs was reported in one study (Kimura, 1972), but doxepin 30 to 150 mg daily was superior to imipramine 150 mg daily in neurotic depression, whereas imipramine appeared to be superior to doxepin in endogenous depression (Pinder et al, 1977d).
e) Similar antidepressant effects of doxepin and imipramine were reported; however, imipramine had a more rapid onset of action. Doxepin appeared to have more sustained effects (Hasan & Akhtar, 1971).

4.6.P.2 Efficacy

a) In elderly patients doxepin produces less orthostatic effects than imipramine (10.5 mmHg vs 25.9 mmHg). The orthostatic effect observed with imipramine was weakly related to dose and did not correlate with pretreatment orthostatic hypotension or with duration of treatment (Neshkes et al, 1985).

4.6.Q Loxapine

4.6.Q.1 Anxiety

a) No significant differences were reported between doxepin and loxapine succinate in patients with anxiety neurosis (Charlalampous et al, 1974).

4.6.R Maprotiline

4.6.R.1 Depression

a) Single nightly doses of doxepin and maprotiline, 75 to 150 milligrams orally for 6 weeks produced moderate to marked improvement in depression in a majority of 47 depressed patients. Both drugs were rated equally effective in this double-blind study. Side effects were not significantly different (Anon, 1978).
b) Maprotiline and doxepin were equally effective in a double-blind, multicenter trial in 95 depressed (neurotic and psychotic) inpatients/outpatients who were randomized into 2 equal groups (Vaisanen et al, 1978). A dose of 75 milligrams daily of either maprotiline or doxepin was given initially; the dose was doubled if needed. Seventy-eight patients completed the three-to-four week trial. The dropout group included six due to unwanted effects (2 maprotiline, 4 doxepin), one from each group due to lack of efficacy and nine for other reasons (non-cooperation/noncompliance). Almost one-half of the patients in the study received additional psychoactive medication including sedatives, neuroleptics, and tranquilizers which were not thought to influence the trial. Overall assessment using a five point scale of target symptoms and a visual analogue scale showed no statistically significant difference between the two treatment groups. The most common side effects in both groups were dry mouth and fatigue. Fourteen patients continued treatment with maprotiline after the trial for a mean of 13 weeks (five received maprotiline for 30 weeks) with no pathological changes in laboratory values except for a slight rise in liver enzyme levels in two patients during initial therapy.

4.6.S Mianserin

4.6.S.1 Mixed anxiety and depressive disorder

a) Mianserin 60 milligrams/day and doxepin 150 milligrams/day had similar efficacy in 60 patients with mixed anxiety/depression. After 4 weeks of treatment, there was no consistent difference in efficacy, but a higher incidence of side effects occurred in the doxepin group (Khan et al, 1983).

4.6.T Nomifensine

4.6.T.1 Depression

a) Doxepin 186 mg daily was more effective than nomifensine 196 mg daily in treatment of endogenous and neurotic depression (Anderson, 1977). Fatigue and dizziness occurred more often with doxepin than nomifensine.

4.6.U Opipramol

4.6.U.1 Depression

a) In a randomized double-blind 5-week trial, doxepin was found to be more effective overall than opipramol. Patients were diagnosed with one of the following types of depression: neurotic depression, psychotic depression, involutional melancholia and senile depression. Eighteen patients were in the opipramol group and 22 in the doxepin group. The average dose of doxepin was between 10 and 20 milligrams (mg)/day and opipramol was between 50 and 100 mg/day. Effects of the drugs were viewed from three standpoints: nosologic classification, syndrome classification and individual symptoms. From the nosological standpoint, doxepin was significantly more effective; although opipramol was very effective in treating patients with involutional melancholia. From the syndrome classification standpoint, doxepin was once again better overall. From the individual symptoms standpoint, doxepin was more effective in relieving depressive mood, fear, suicidal thoughts, feeling of insufficiency, guilt, insomnia, vegetative symptoms and psychomotor disturbances than was opipramol. Drowsiness was the only adverse effect reported with either drug (Terzani, 1972).

4.6.V Paroxetine

4.6.V.1 Depression

a) Paroxetine was at least as effective as doxepin in the treatment of major depression in 272 geriatric patients in a double-blind, randomized trial. After a washout-period of 4 to 14 days, patients over 60 years of age received either paroxetine 10 to 40 milligrams (mg) (mean 23.4 mg) as a single daily dose or doxepin (up to 200 milligrams (mg), mean 105.2 mg/day) divided in two doses. Therapy continued for 42 days. Paroxetine was as effective as doxepin by several measures and more effective by others. Doxepin caused more sedation, confusion, and anticholinergic effects, and less nausea and headache compared with paroxetine (Dunner et al, 1992).

4.6.W Perphenazine/Amitriptyline Hydrochloride

4.6.W.1 Depression

a) Doxepin (100 to 150 milligrams/day) was not as effective as amitriptyline/perphenazine (100/8 to 150/12 milligrams/day) in 130 nonpsychotic depressed outpatients over 4 weeks. Amitriptyline/perphenazine produced greater improvement based on several rating scales. The combination also showed a greater incidence of anticholinergic and sedative side effects (Rickels et al, 1982).

4.6.X Trazodone

4.6.X.1 Depression

a) No significant difference in safety or efficacy was seen in a comparison of trazodone (mean daily dose during weeks 1, 3, and 6 was 125 milligrams (mg), 221 mg, and 246 mg) with doxepin (mean daily dose during weeks 1, 3, and 6 was 58 mg, 105 mg, and 127 mg) in 30 outpatients with major depressive disorder in a 6-week, double-blind, parallel study (Himmelhoch, 1986).

b) No significant difference was reported in a double-blind study of 101 patients, on the efficacy of trazodone and doxepin in the treatment of depression (Murphy & Ankier, 1980).

4.6.Y Trimipramine

4.6.Y.1 Depression

a) The therapeutic efficacy and cardiac safety of trimipramine and doxepin were comparable in 37 patients with major depressive disorder. Patients received one week of placebo followed by five weeks of either trimipramine or doxepin in doses up to 200 milligrams/day. Based on ECG and psychiatric and cognitive function tests, the drugs were concluded to be equally safe and efficacious in this group of patients (Nair et al, 1993).

b) Trimipramine was superior to doxepin in safety and efficacy in a 4-week study. Trimipramine and doxepin (150 milligrams/day of each) were compared in 25 depressed hospitalized patients. Comparisons of efficacy favored trimipramine over doxepin. Doxepin had a higher incidence of side effects (Assalian et al, 1985).

531. Product Information: BROVANA(TM) inhalation solution, arformoterol tartrate inhalation solution. Sepracor,Inc, Marlborough, MA, 2006.
532. Product Information: Biaxin(R), clarithromycin. Abbott Laboratories, North Chicago, IL, 2002.
533. Product Information: CYMBALTA(R) delayed-release oral capsules, duloxetine hcl delayed-release oral capsules. Eli Lilly and Company, Indianapolis, IN, 2008.
534. Product Information: Catapres(R), clonidine. Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT, 1996.
535. Product Information: Cerebyx(R), fosphenytoin sodium injection. Parke-Davis, Division of Warner-Lambert, Morris Plains, NJ, 1999.
536. Product Information: Compazine(R), prochlorperazine maleate spansule. GlaxoSmithKline, Research Triangle Park, NC, 2002.
537. Product Information: Corvert(R), ibutilide fumarate injection. Pharmacia & Upjohn Company, Kalamazoo, MI, 2000.
538. Product Information: DAYTRANA(TM) transdermal system, methylphenidate transdermal system. Shire US Inc., Wayne, PA, 2006.
539. Product Information: DEXEDRINE(R) sustained-release oral capsules, oral tablets, dextroamphetamine sulfate sustained-release oral capsules, oral tablets. GlaxoSmithKline, Research Triangle Park, NC, 2006.
540. Product Information: DynaCirc(R), isradipine. Novartis Pharmaceuticals Corporation, East Hanover, NJ, 2000.
541. Product Information: Effexor(R) XR, venlafaxine hydrochloride extended-release. Wyeth Laboratories, Philadelphia, PA, 2003.
542. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999.
543. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999a.
544. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999b.
545. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999c.
546. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999d.
547. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999e.
548. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999f.
549. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999g.
550. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999h.
551. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999i.
552. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999j.
553. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999k.
554. Product Information: Elavil(R), amitriptyline. Merck & Co, Inc, West Point, PA, 1999l.
555. Product Information: FORADIL(R) AEROLIZER(R) inhalation powder, formoterol fumarate inhalation powder. Schering Corporation, Kenilworth, NJ, 2006.
556. Product Information: Factive(R), gemifloxacin mesylate tablets. LG Life Sciences, Ltd., Seoul, Korea, 2003.
557. Product Information: Foscavir(R), foscarnet. AstraZeneca, Inc., Alexandria, VA, 1998.
558. Product Information: GEODON(R) oral capsules, IM injection, ziprasidone hcl oral capsules, ziprasidone mesylate IM injection. Pfizer,Inc, New York, NY, 2007.
559. Product Information: GenESA(R), arbutamine hydrochloride. Gensia Automedics, Inc., San Diego, CA, 1997.
560. Product Information: Halfan(R), halofantrine hydrochloride. Research Triangle Park, NC, 1998.

561. Product Information: Hismanal(R), astemizole. Janssen Pharmaceutica, Inc., Titusville, NJ, 1996.
562. Product Information: Hylorel(R), guanadrel. Fisons Corporation, Rochester, NY, 1995.
563. Product Information: Inapsine(R), droperidol. Akorn, Inc., Decatur, IL, 2002.
564. Product Information: LEXIVA(R) oral solution, oral tablets, fosamprenavir calcium oral solution, oral tablets. GlaxoSmithKline, Research Triangle Park, NC, 2009.
565. Product Information: Manerix(R), Moclobemide. Hoffmann-La Roche Limited, Mississauga, Ontario, Canada, 2001.
566. Product Information: Marplan(R), isocarboxazid. Roche Laboratories Inc., Nutley, NJ, 1998.
567. Product Information: Matulane(R), procarbazine. Roche Laboratories Inc., Nutley, NJ, 1997.
568. Product Information: Mellaril(R), thioridazine. Novartis Pharmaceuticals Corporation, East Hanover, New Jersey, 2001.
569. Product Information: NARDIL(R) Tablets, USP, phenelzine sulfate tablets, USP. Parke-Davis, New York, NY, 2005.
570. Product Information: Norpramin(R), desipramine hydrochloride tablets. Aventis Pharmaceuticals Inc., Kansas City, MO, 2000.
571. Product Information: Orap(R) pimozide. TEVA Pharmaceuticals, Sellersville, PA, 1999.
572. Product Information: Orap(R), pimozide. Gate Pharmaceuticals, Sellersville, PA, 1999.
573. Product Information: Orap(R), pimozide. Gate Pharmaceuticals, Sellersville, PA, 1999a.
574. Product Information: Orlaam(R), levomethadyl acetate. Roxane Laboratories, Columbus, OH, 2001.
575. Product Information: PCE(R), erythromycin particles in tablets. Abbott Laboratories, North Chicago, IL, 1997.
576. Product Information: Pamelor(R), nortriptyline. Mallinkroft Inc., St. Louis, MO, 2001.
577. Product Information: Parnate(R), tranylcypromine sulfate tablets. GlaxoSmithKline, Research Triangle Park, NC, 2001.
578. Product Information: Paxil CR(TM), paroxetine. GlaxoSmithKline, Research Triangle Park, NC, 2003.
579. Product Information: Propulsid(R), cisapride. Janssen Pharmaceutica Inc., Titusville, NJ, 2000.
580. Product Information: Prozac(R), fluoxetine. Eli Lilly and Company, Indianapolis, IN, 2001.
581. Product Information: Quinaglute(R), quinidine gluconate. Berlex Laboratories, Inc., Wayne, NJ, 1999.
582. Product Information: Raxar(R), grepafloxacin hydrochloride. Glaxo Wellcome Inc., Research Triangle Park, NC, 1999.
583. Product Information: SEREVENT(R) DISKUS(R) inhalation powder, salmeterol xinafoate inhalation powder. GlaxoSmithKline, Research Triangle Park, NC, 2006.
584. Product Information: SINEQUAN(R) capsule, oral concentrate, doxepin HCl capsule, oral concentrate. Pfizer Roerig, New York, NY, 2005.
585. Product Information: SINEQUAN(R) oral capsule, doxepin hydrochloride oral capsule. Roerig Division, New York, NY, 2005.
586. Product Information: SINEQUAN(R) oral capsules, doxepin hcl oral capsules. Pfizer, 2007.
587. Product Information: Sandostatin(R), octreotide. Novartis Pharmaceuticals, East Hanover, NJ, 1999.
588. Product Information: Serentil(R), mesoridazine. Novartis Pharmaceuticals Corporation, East Hanover, NJ, 2001.
589. Product Information: Sinequan(R), doxepin hydrochloride capsules and oral concentrate. Physicians' Desk Reference (electronic version), MICROMEDEX, Inc, Englewood, CO, USA, 1999.
590. Product Information: Solian(R), amisulpride tablets. Lorex Synthelabo, Maidenhead, Berkshire, UK, 1999.
591. Product Information: Stelazine(R), trifluoperazine hydrochloride. GlaxoSmithKline, Research Triangle Park, NC, 2002.
592. Product Information: Strattera(TM), atomoxetine. Eli Lilly and Company, Indianapolis, IN, 2002.
593. Product Information: Tequin(TM), gatifloxacin. Bristol-Myers Squibb Company, Princeton, NJ, 1999.
594. Product Information: Thorazine(R), chlorpromazine. Smithkline Beecham Pharmaceuticals, Philadelphia, PA, 2002.
595. Product Information: Trisenox(R), arsenic trioxide. Cell Therapeutics, Inc., Seattle, WA, 2000.
596. Product Information: Trisenox(R), arsenic trioxide. Cell Therapeutics, Inc., Seattle, WA, 2000a.
597. Product Information: Ultram(R), tramadol hydrochloride. Ortho-McNeil Pharmaceutical, Raritan, NJ, 1998.
598. Product Information: VYVANSE(TM) oral capsules, lisdexamfetamine dimesylate oral capsules. New River Pharmaceuticals,Inc, Blacksburg, VA, 2007.
599. Product Information: Vascor(R), bepridil hydrochloride. Ortho-McNeil Pharmaceuticals, Raritan, NJ, 2000.
600. Product Information: Vivactil(R), protriptyline. Merck & Co Inc, Westpoint, PA, 1999.
601. Product Information: ZONALON(R) cream, doxepin hcl cream. Doak Dermatologics, Fairfield, NJ, 2005.
602. Product Information: ZONALON(R) topical cream, 5%, doxepin hydrochloride topical cream. Bioglan Pharma, Inc , Malvern, PA, 2002.
603. Product Information: ZYVOX(R) IV injection, oral tablets, oral suspension, linezolid IV injection, oral tablets, oral suspension. Pharmacia & Upjohn Company, New York, NY, 2008.
604. Product Information: Zagam(R), sparfloxacin. Rhone-Poulenc Rorer Pharmaceuticals Inc, Collegeville, PA, 1998.
605. Product Information: Zagam(R), sparfloxacin. Rhone-Poulenc Rorer Pharmaceuticals Inc, Collegeville, PA, 1998a.
606. Product Information: Zoloft(R), sertraline hydrochloride. Roerig Division of Pfizer Inc, New York, NY, 2002.
607. Product Information: Zomig(R), zolmitriptan tablets. AstraZeneca Pharmaceuticals, Wilmington, DE, 2001.
608. Product Information: Zonalon(R) cream, doxepin hydrochloride cream. GenDerm Corporation, Lincolnshire, IL, 1997.
609. Product Information: Zonalon(R), doxepin hydrochloride cream. Physicians' Desk Reference (electronic version), MICROMEDEX, Inc, Englewood, CO, USA, 1999.
610. Product Information: Zonalon. GenDerm, US, 94.

611. Product Information: tapentadol immediate release oral tablets, tapentadol immediate release oral tablets. Ortho-McNeil-Janssen Pharmaceuticals Inc, Raritan, NJ, 2008.
612. Product Information: venlafaxine extended release oral tablets, venlafaxine extended release oral tablets. Upstate Pharma,LLC, Rochester, NY, 2008.

DRUGDEX® Evaluations

ATOMOXETINE

0.0 Overview

1) Class
- **a)** This drug is a member of the following class(es):
  - Central Nervous System Agent
  - Norepinephrine Reuptake Inhibitor

2) Dosing Information
- **a)** Atomoxetine Hydrochloride
  - **1)** Adult
    - **a)** Attention deficit hyperactivity disorder
      - **1)** 40 mg/day ORALLY; increase after a minimum of 3 days to a target dose of approximately 80 mg/day; MAX dosage of 100 mg/day may be considered after 2 to 4 additional weeks in patients who have not achieved adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008)
  - **2)** Pediatric
    - **a)** safety and effectiveness not established in children less than 6 years of age (Prod Info STRATTERA(R) oral capsules, 2008)
      - **1)** Attention deficit hyperactivity disorder
        - **a)** acute treatment: (weight of 70 kg or less) 0.5 mg/kg/day ORALLY; increase after a minimum of 3 days to a target dose of 1.2 mg/kg/day; MAX dosage is 1.4 mg/kg/day or 100 mg/day (whichever is less) (Prod Info STRATTERA(R) oral capsules, 2008)
        - **b)** acute treatment: (weight greater than 70 kg) 40 mg/day ORALLY; increase after a minimum of 3 days to a target dose of approximately 80 mg/day; MAX dosage of 100 mg/day may be considered after 2 to 4 additional weeks in patients who have not achieved adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008)
        - **c)** maintenance: 1.2 to 1.8 mg/kg/day ORALLY has been studied in 1 clinical trial; MAX dosage is 1.4 mg/kg/day or 100 mg/day, whichever is less (weight of 70 kg or less) OR 100 mg/day (weight greater than 70 kg) (Prod Info STRATTERA(R) oral capsules, 2008)

3) Contraindications
- **a)** Atomoxetine Hydrochloride
  - **1)** hypersensitivity to atomoxetine or to other components of the product (Prod Info STRATTERA(R) oral capsules, 2009)
  - **2)** MAO inhibitor use; do not administer atomoxetine during therapy with or within 2 weeks of discontinuing an MAO inhibitor (Prod Info STRATTERA(R) oral capsules, 2009)
  - **3)** narrow angle glaucoma; increased risk of mydriasis (Prod Info STRATTERA(R) oral capsules, 2009)

4) Serious Adverse Effects
- **a)** Atomoxetine Hydrochloride
  - **1)** Angioedema
  - **2)** Cerebrovascular accident
  - **3)** Dyskinesia
  - **4)** Injury of liver (Severe)
  - **5)** Mania
  - **6)** Myocardial infarction
  - **7)** Priapism
  - **8)** Prolonged QT interval
  - **9)** Psychotic disorder
  - **10)** Seizure
  - **11)** Sudden cardiac death
  - **12)** Suicidal thoughts

5) Clinical Applications
- **a)** Atomoxetine Hydrochloride
  - **1)** FDA Approved Indications
    - **a)** Attention deficit hyperactivity disorder

1.0 Dosing Information

Drug Properties

Storage and Stability

Adult Dosage

Pediatric Dosage

1.1 Drug Properties

A) Information on specific products and dosage forms can be obtained by referring to the Tradename List (Product Index)

B) Synonyms

Atomoxetine
Atomoxetine HCl
Atomoxetine Hydrochloride
Tomoxetine

C) Physicochemical Properties

1) Molecular Weight

a) 291.82 (Prod Info Strattera(R), 2004)

2) Solubility

a) 27.8 mg/mL in water (Prod Info Strattera(R), 2004)

1.2 Storage and Stability

A) Atomoxetine Hydrochloride

1) Preparation

a) Oral route

1) Atomoxetine hydrochloride (HCl) may be taken with or without food. Swallow capsules whole, and do not open (Prod Info STRATTERA(R) oral capsules, 2008).

1.3 Adult Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage in Other Disease States

1.3.1 Normal Dosage

1.3.1.A Atomoxetine Hydrochloride

1.3.1.A.1 Oral route

1.3.1.A.1.a Attention deficit hyperactivity disorder

1) The recommended starting dose of atomoxetine hydrochloride (HCl) in adult patients with attention-deficit hyperactivity disorder is 40 milligrams (mg)/day orally. The dose may be increased after a minimum of 3 days to a target dose of approximately 80 mg/day, given as a single daily dose (in the morning) or as 2 divided doses (in the morning and late afternoon/early evening). The maximum dose of atomoxetine 100 mg/day may be given after 2 to 4 additional weeks in patients who have not achieved an adequate response on lower doses. Tapering of the dose is not required upon therapy discontinuation (Prod Info STRATTERA(R) oral capsules, 2008).

2) Concomitant CYP2D6 Inhibitors

a) Atomoxetine hydrochloride should be initiated at 40 milligrams (mg)/day in adult patients receiving concomitant strong CYP2D6 inhibitors, such as paroxetine, fluoxetine, or quinidine. Patients should only be titrated to the maximum dose of 80 mg/day after 4 weeks if they have tolerated the initial dose but did not achieve an adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008).

1.3.2 Dosage in Renal Failure

A) Atomoxetine Hydrochloride

1) No dose adjustment of atomoxetine hydrochloride is necessary in patients with renal insufficiency (Prod Info STRATTERA(R) oral capsules, 2008).

1.3.3 Dosage in Hepatic Insufficiency

A) Atomoxetine Hydrochloride

1) Atomoxetine hydrochloride (HCl) is metabolized in the liver, and dose adjustments are necessary in patients with hepatic impairment. Starting and target doses of atomoxetine HCl should be reduced by 50%

of the normal dose in patients with moderate hepatic insufficiency (Child-Pugh Class B) and reduced to 25% of the normal dose in patients with severe hepatic insufficiency (Child-Pugh Class C) (Prod Info STRATTERA(R) oral capsules, 2008).

1.3.6 Dosage in Other Disease States

A) Atomoxetine Hydrochloride

1) CYP2D6 Poor Metabolizers

a) In patients who are known poor metabolizers of CYP2D6, atomoxetine hydrochloride should be initiated at 40 milligrams/day (mg/day). Patients should only be titrated to the target dose of 80 mg/day after 4 weeks if they have tolerated the initial dose but did not achieve an adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008).

1.4 Pediatric Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage in Other Disease States

1.4.1 Normal Dosage

1.4.1.A Atomoxetine Hydrochloride

1.4.1.A.1 Oral route

1.4.1.A.1.a Attention deficit hyperactivity disorder

1) Acute Therapy

a) Patients Weighing 70 Kilograms or Less

1) The recommended starting dose of atomoxetine hydrochloride (HCl) in children and adolescent patients with attention-deficit hyperactivity disorder who weigh 70 kilograms (kg) or less is approximately 0.5 milligrams (mg)/kg/day orally. The dose may be increased after a minimum of 3 days to a target dose of approximately 1.2 mg/kg/day, given as a single daily dose (in the morning) or as 2 divided doses (in the morning and late afternoon/early evening). Although no additional benefits were observed in clinical studies with doses higher than 1.2 mg/kg/day, the maximum dose in children and adolescents is atomoxetine 1.4 mg/kg/day or 100 mg/day, whichever is less. Tapering of the dose is not required upon therapy discontinuation (Prod Info STRATTERA(R) oral capsules, 2008).

2) Concomitant CYP2D6 Inhibitors

a) Atomoxetine hydrochloride should be initiated at 0.5 milligrams/kilogram/day (mg/kg/day) in patients receiving concomitant strong CYP2D6 inhibitors, such as paroxetine, fluoxetine, or quinidine. Patients should only be titrated to the maximum dose of 1.2 mg/kg/day after 4 weeks if they have tolerated the initial dose but did not achieve an adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008).

b) Patients Weighing Greater than 70 Kilograms

1) The recommended starting dose of atomoxetine hydrochloride (HCl) in children and adolescent patients with attention-deficit hyperactivity disorder who weigh greater than 70 kilograms is 40 milligrams (mg)/day orally. The dose may be increased after a minimum of 3 days to a target dose of approximately 80 mg/day, given as a single daily dose (in the morning) or as 2 divided doses (in the morning and late afternoon/early evening). The maximum dose of atomoxetine 100 mg/day may be given after 2 to 4 additional weeks in patients who have not achieved an adequate response on lower doses. Tapering of the dose is not required upon therapy discontinuation (Prod Info STRATTERA(R) oral capsules, 2008).

2) Concomitant CYP2D6 Inhibitors

a) Atomoxetine hydrochloride should be initiated at 40 milligrams (mg)/day in patients receiving concomitant strong CYP2D6 inhibitors, such as paroxetine, fluoxetine, or quinidine. Patients should only be titrated to the maximum dose of 80 mg/day after 4 weeks if they have tolerated the initial dose but did not achieve an adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008).

c) The safety of single doses exceeding 120 mg or total daily doses exceeding 150 mg has not been evaluated (Prod Info STRATTERA(R) oral capsules, 2008).

2) Maintenance Therapy

a) In one study, pediatric patients (ages 6 to 15 years) with attention-deficit hyperactivity disorder continued on atomoxetine hydrochloride (HCl) 1.2 to 1.8 milligrams (mg)/kilogram (kg)/day after achieving a continuous response during an initial 10-week, open-label treatment phase. The maximum recommended total daily dose is 1.4 mg/kg/day or 100 mg/day (whichever is less) in patients weighing 70 kg or less, and 100 milligrams/day in patients weighing over 70 kg. Tapering of the dose is not required upon therapy discontinuation. Patients who receive atomoxetine HCl for extended time periods should be periodically reassessed to verify drug effectiveness (Prod Info STRATTERA(R) oral capsules, 2008).

b) The safety of single doses exceeding 120 mg or total daily doses exceeding 150 mg has not been evaluated (Prod Info STRATTERA(R) oral capsules, 2008).

2) The safety and effectiveness of atomoxetine hydrochloride have not been evaluated in pediatric patients less than 6 years of age (Prod Info STRATTERA(R) oral capsules, 2008).

1.4.2 Dosage in Renal Failure

A) Atomoxetine Hydrochloride

1) No dose adjustment of atomoxetine hydrochloride is necessary in patients with renal insufficiency (Prod Info STRATTERA(R) oral capsules, 2008).

1.4.3 Dosage in Hepatic Insufficiency

A) Atomoxetine Hydrochloride

1) Atomoxetine hydrochloride (HCl) is metabolized in the liver, and dose adjustments are necessary in patients with hepatic impairment. Starting and target doses of atomoxetine HCl should be reduced by 50% of the normal dose in patients with moderate hepatic insufficiency (Child-Pugh Class B) and reduced to 25% of the normal dose in patients with severe hepatic insufficiency (Child-Pugh Class C) (Prod Info STRATTERA(R) oral capsules, 2008).

1.4.5 Dosage in Other Disease States

A) Atomoxetine Hydrochloride

1) CYP2D6 Poor Metabolizers

a) In patients who are known poor metabolizers of CYP2D6, atomoxetine hydrochloride should be initiated at 0.5 milligrams/kilogram/day (mg/kg/day). Patients should only be titrated to the target dose of 1.2 mg/kg/day after 4 weeks if they have tolerated the initial dose but did not achieve an adequate response on lower doses (Prod Info STRATTERA(R) oral capsules, 2008).

2.0 Pharmacokinetics

Onset and Duration

Drug Concentration Levels

ADME

2.1 Onset and Duration

A) Onset

1) Initial Response

a) ATTENTION-DEFICIT/HYPERACTIVITY DISORDER, ORAL: 1 week (Spencer et al, 2001).

1) Based on data from children with ADHD in an open study (twice-daily dosing).

2) In adults with ADHD, a significant reduction in symptoms versus placebo was seen after 2 weeks of treatment (Spencer et al, 1998).

b) MAJOR DEPRESSION, ORAL: within one week (Chouinard et al, 1985).

1) Based on limited patient data from an open study.

2.2 Drug Concentration Levels

A) Therapeutic Drug Concentration

1) Not established in any indication.

B) Time to Peak Concentration

1) ORAL: 1 to 2 hours (Farid et al, 1985); (Prod Info Strattera(R), 2002).

a) In children ages 7 to 14 years with attention deficit hyperactivity disorder and classified as extensive metabolizers, maximal concentration was achieved in 2 hours after either a single dose of atomoxetine 10 milligrams (mg) or steady-state dosing (20 to 45 mg twice daily) (Witcher et al, 2003).

b) Following single 90-mg oral doses in healthy subjects (extensive metabolizers), peak plasma levels of atomoxetine varied considerably, ranging from 315 to 1231 ng/mL. Plasma levels fell to undetectable levels

at 36 hours postdosing. In poor metabolizers, peak levels tended to be higher, and occurred later (based on two subjects) (Farid et al, 1985).

c) With administration of 20 and 40 mg twice daily for 7 days in extensive metabolizers (healthy subjects), peak levels on day 1 were approximately 100 and 250 ng/mL, respectively; there was no significant accumulation on days 2 through 7. Plasma concentrations of the metabolite, noratomoxetine, were low in these subjects (less than 10 ng/mL). In subjects who were poor metabolizers in this study (n=2), significant accumulation of both atomoxetine and noratomoxetine was observed during repeat dosing (Farid et al, 1985).

C) Area Under the Curve

1) mean 2766 ng x hr/mL after 90-mg single dose (extensive metabolizers) (Farid et al, 1985).

a) In children ages 7 to 14 years with attention deficit disorder and classified as extensive metabolizers, plasma concentrations of the active metabolite 4-hydroxyatomoxetine were 26 to 35 times less than those for atomoxetine (Witcher et al, 2003).

b) During repeat dosing in extensive metabolizers (healthy subjects), AUC data indicated no significant accumulation of atomoxetine; in subjects receiving 20 mg and 40 mg twice daily for one week, AUC(0-24) values at steady-state (last dose) were 975 to 1126 ng x hr/mL and 2460 to 3710 ng x hr/mL, respectively. In poor metabolizers receiving these doses, accumulation was significant, with corresponding values of 10,490 ng x hr/mL and 29,330 ng x hr/mL (based on data from two subjects) (Farid et al, 1985).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

2.3.1 Absorption

A) Bioavailability

1) ORAL: 63% in extensive metabolizers; 94% in poor metabolizers (Prod Info Strattera(TM), 2002t).

B) Effects of Food

1) extent of absorption unaffected (Prod Info Strattera(TM), 2002t).

a) The rate of absorption is reduced when given with food in adults (by 37%) and time to peak levels prolonged (by about 3 hours); however, AUC is unaffected (Prod Info Strattera(TM), 2002t).

2.3.2 Distribution

A) Distribution Sites

1) Protein Binding

a) 98% (albumin) (Prod Info Strattera(TM), 2002t).

B) Distribution Kinetics

1) Volume of Distribution

a) Approximately 74 to 250 liters (extensive metabolizers) (Witcher et al, 2003; Farid et al, 1985).

1) Volume of distribution was similar (74 to 328 liters) between single oral doses (10 to 90 milligrams (mg)), and repeat dosing (20 to 45 mg twice daily) in extensive metabolizers (healthy subjects). In poor metabolizers (data limited), a slightly lower volume of distribution was reported (about 90 L) (Witcher et al, 2003; Farid et al, 1985).

2.3.3 Metabolism

A) Metabolism Sites and Kinetics

1) LIVER, extensive (Michelson et al, 2001; Farid et al, 1985).

a) Cytochrome P450 (CYP)-2D6 is involved in the metabolism of atomoxetine (Michelson et al, 2001). An active metabolite, 4-hydroxyatomoxetine, undergoes significant glucuronidation and renal excretion (Michelson et al, 2001).

b) Some patients are poor metabolizers of atomoxetine and will have significantly higher AUC values (10-fold) and plasma levels compared to extensive metabolizers; lab tests are available to identify poor metabolizers (Prod Info Strattera(TM), 2002t).

B) Metabolites

1) 4-Hydroxyatomoxetine (active) (Michelson et al, 2001; Farid et al, 1985).

a) Equipotent to the parent compound as a norepinephrine transporter inhibitor; however, it is present in low concentrations in plasma relative to the parent compound (about 1%) (Prod Info Strattera(TM),

2002t). Its contribution to clinical effects is unknown.
2) Noratomoxetine (inactive) (Farid et al, 1985).
3) N-desmethylatomoxetine (inactive) (Witcher et al, 2003).

2.3.4 Excretion
A) Kidney
1) Renal Excretion (%)
a) less than 3% unchanged (Prod Info Strattera(TM), 2002t).
1) Most of an oral dose of atomoxetine is excreted in the urine as 4-hydroxyatomoxetine-O-glucuronide (80%) (Prod Info Strattera(TM), 2002t; Michelson et al, 2001).
B) Total Body Clearance
1) 0.3 to 0.5 L/hr/kg (extensive metabolizers) (Farid et al, 1985; Prod Info Strattera(TM), 2002t).
a) Clearance is about 10-fold lower in poor metabolizers (0.03 to 0.04 L/hr/kg) (Farid et al, 1985; Prod Info Strattera(TM), 2002t).
b) Plasma clearance was similar (17 to 62 liters/hour; average, 36 to 40 liters/ hour) between single oral doses (10 to 90 mg) and repeat dosing (20 to 45 mg twice daily) in extensive metabolizers (healthy subjects); there was no evidence of dose-dependency. In poor metabolizers receiving repeat doses, a substantially lower clearance was observed (about 3 L/hr) (Witcher et al, 2003; Farid et al, 1985).
C) Other
1) OTHER EXCRETION
a) FECES
1) Less than 17% of a dose is excreted in feces as 4-hydroxyatomoxetine-O-glucuronide (Prod Info Strattera(TM), 2002t).

2.3.5 Elimination Half-life
A) Parent Compound
1) ELIMINATION HALF-LIFE
a) 4 to 5 hours (in extensive metabolizers; 22 hours in poor metabolizers (Farid et al, 1985; Michelson et al, 2001; Prod Info Strattera(TM), 2002).
1) Half-life was similar (3 to 6 hours) between single oral doses (10 to 90 milligrams (mg)), and repeat dosing (20 to 45 mg twice daily) in extensive metabolizers (healthy subjects); there was no evidence of dose-dependency. In poor metabolizers receiving the same repeat doses, a substantially longer half-life was observed (17 to 21 hours) (Witcher et al, 2003; Farid et al, 1985).

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING
1) Atomoxetine Hydrochloride
a) Oral (Capsule)
Suicidal Ideation in Children and Adolescents:
Atomoxetine increased the risk of suicidal ideation in short-term studies in children or adolescents with Attention-Deficit/Hyperactivity Disorder (ADHD). Anyone considering the use of atomoxetine in a child or adolescent must balance this risk with the clinical need. Co-morbidities occurring with ADHD may be associated with an increase in the risk of suicidal ideation and/or behavior. Patients who are started on therapy should be monitored closely for suicidality (suicidal thinking and behavior), clinical worsening, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber. Atomoxetine is approved for ADHD in pediatric and adult patients. Atomoxetine is not approved for major depressive disorder.
Pooled analyses of short-term (6 to 18 weeks) placebo-controlled trials of atomoxetine in children and adolescents (a total of 12 trials involving over 2200 patients, including 11 trials in ADHD and 1 trial in enuresis) have revealed a greater risk of suicidal ideation early during treatment in those receiving atomoxetine compared to placebo. The average risk of suicidal ideation in patients receiving atomoxetine was 0.4% (5/1357 patients), compared to none in placebo-treated patients (851 patients). No suicides occurred in these trials (Prod Info STRATTERA(R) oral capsules, 2009).

3.1 Contraindications

A) Atomoxetine Hydrochloride

1) hypersensitivity to atomoxetine or to other components of the product (Prod Info STRATTERA(R) oral capsules, 2009)

2) MAO inhibitor use; do not administer atomoxetine during therapy with or within 2 weeks of discontinuing an MAO inhibitor (Prod Info STRATTERA(R) oral capsules, 2009)

3) narrow angle glaucoma; increased risk of mydriasis (Prod Info STRATTERA(R) oral capsules, 2009)

3.2 Precautions

A) Atomoxetine Hydrochloride

1) suicidal ideation has occurred; increased risk in children and adolescents during the first few months of therapy or following a dosage adjustment; monitoring for signs of suicidality, clinical worsening, and unusual changes in behavior (eg, agitation, irritability) recommended; discontinuation may be necessary (Prod Info STRATTERA(R) oral capsules, 2009; US Food and Drug Administration, 2005)

2) bipolar disorder; mixed/manic episode may be induced; screening recommended prior to therapy for patients with comorbid depressive symptoms (Prod Info STRATTERA(R) oral capsules, 2009)

3) cardiovascular disease, cerebrovascular disease, hypertension, tachycardia; risk of increased blood pressure and heart rate; monitoring recommended (Prod Info STRATTERA(R) oral capsules, 2009)

4) liver injury has been reported rarely; if signs of liver injury occur (eg, elevated liver enzymes, jaundice, pruritus, dark urine, right upper quadrant tenderness), discontinue use and do not restart (Prod Info STRATTERA (R) oral capsules, 2009)

5) orthostatic hypotension and syncope have been reported; use cautiously in conditions predisposing to hypotension or associated with abrupt heart rate or blood pressure changes (Prod Info STRATTERA(R) oral capsules, 2009)

6) priapism has been reported rarely in children and adults; seek prompt medical attention (Prod Info STRATTERA(R) oral capsules, 2009)

7) psychotic or manic symptoms, hallucinations, delusional thinking or mania may occur in children and adolescents without a prior history of psychotic illness or mania at usual doses; discontinuation may be necessary (Prod Info STRATTERA(R) oral capsules, 2009)

8) structural cardiac abnormalities; risk of sudden death at usual doses; should not be used in adult or pediatric patients with known structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious heart problems (Prod Info STRATTERA(R) oral capsules, 2009)

3.3.1 Cardiovascular Effects

3.3.1.A Atomoxetine Hydrochloride

Increased diastolic arterial pressure

Increased systolic arterial pressure

Myocardial infarction

Orthostatic hypotension

Palpitations

Prolonged QT interval

Raynaud's phenomenon

Sudden cardiac death

Syncope

Tachycardia

3.3.1.A.1 Increased diastolic arterial pressure

a) Incidence: pediatrics, 3.5% to 4% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In clinical studies, increased diastolic blood pressure (mean increase of 1 and 2.4 mmHg in adults and pediatric patients, respectively, compared to placebo) has been reported in atomoxetine-treated patients with attention-deficit hyperactivity disorder (ADHD). Use caution in patients receiving atomoxetine who have preexisting hypertension, tachycardia, or cardiovascular or cerebrovascular disease due to the risk of heart rate and blood pressure elevation in these patients. Pulse and blood pressure monitoring is recommended at baseline, following dose increases, and periodically during therapy (Prod Info STRATTERA(R) oral capsules, 2008). In addition, greater increases in heart rate and systolic pressure have been reported among cytochrome P450 2D6 poor metabolizers (Michelson et al, 2001a; Chouinard et al, 1985a).

c) In placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), diastolic blood pressures of 105 mm Hg or greater were reported in 0% of patients who received atomoxetine (n=0 of 510) compared to 0.3% of patients who received placebo (n=1 of 393). No patients had a high diastolic blood pressure documented on more than one occasion (Prod Info STRATTERA(R) oral capsules, 2008).

d) In pediatric placebo-controlled trials, high diastolic blood pressures were reported in 4% of atomoxetine-treated patients (n=50 of 1262) compared to 1.1% of placebo-treated patients (n=8 of 759) at the final study visit. Additionally, high systolic blood pressures were reported on 2 or more occasions in 3.5% (n=44 of 1262) of pediatric patients treated with atomoxetine and 0.5% (n=4 of 759) treated with placebo during the study (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.2 Increased systolic arterial pressure

a) Incidence: pediatrics, 4.4% to 4.8% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In clinical studies, increased systolic blood pressure (mean increase of 2 and 1.6 mmHg in adults and pediatric patients, respectively, compared to placebo) has been reported in atomoxetine-treated patients with attention-deficit hyperactivity disorder (ADHD). Use caution in patients receiving atomoxetine who have preexisting hypertension, tachycardia, or cardiovascular or cerebrovascular disease due to the risk of heart rate and blood pressure elevation in these patients. Pulse and blood pressure monitoring is recommended at baseline, following dose increases, and periodically during therapy (Prod Info STRATTERA(R) oral capsules, 2008). In addition, greater increases in heart rate and systolic pressure have been reported among cytochrome P450 2D6 poor metabolizers (Michelson et al, 2001a; Chouinard et al, 1985a).

c) In placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), systolic blood pressures of 180 mm Hg or greater were not reported in patients taking atomoxetine (n=510) or placebo (n=393). No patients had a high systolic blood pressure documented on more than one occasion (Prod Info STRATTERA(R) oral capsules, 2008).

d) In pediatric placebo-controlled trials, high systolic blood pressures were reported in 4.8% of atomoxetine-treated patients (n=59 of 1226) compared to 3.5% of placebo-treated patients (n=26 of 748) at the final study visit. Additionally, high systolic blood pressures were reported on 2 or more occasions in 4.4% (n=54 of 1226) of pediatric patients treated with atomoxetine and 1.9% (n=14 of 748) treated with placebo during the study (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.3 Myocardial infarction

a) Myocardial infarction has occurred in adult patients receiving atomoxetine at usual doses. Consider not using atomoxetine in adult patients with clinically significant cardiac abnormalities (eg, coronary artery disease, serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, other serious cardiac problems) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.4 Orthostatic hypotension

a) Incidence: pediatric, up to 1.8% (Prod Info STRATTERA(R) oral capsules, 2008)

b) Orthostatic hypotension has been reported in 0.2% of atomoxetine-treated child and adolescent patients (n=12 of 5596). Additionally, in child and adolescent patients with attention-deficit hyperactivity disorder (ADHD), orthostatic hypotension occurred in 1.8% of patients who received atomoxetine (n=6 of 340) compared to 0.5% of patients who received placebo (n=1 of 207) in short-term, placebo-controlled studies. Patients with any condition that may predispose them to hypotension should use atomoxetine with caution (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.5 Palpitations

a) Incidence: adults, 3% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), palpitations were reported in 3% of patients who received atomoxetine (n=540) compared to 1% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.6 Prolonged QT interval

a) There have been spontaneous postmarketing reports of QT prolongation with atomoxetine use (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.7 Raynaud's phenomenon

a) New onset and exacerbation of preexisting Raynaud's phenomenon have been reported in spontaneous postmarketing accounts (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.8 Sudden cardiac death

a) Sudden death has occurred in adult patients receiving atomoxetine at usual doses and in children and adolescent patients with structural cardiac abnormalities or other serious heart problems who were receiving atomoxetine at usual doses. Therefore, consider not using atomoxetine in adult patients with clinically significant cardiac abnormalities (eg, coronary artery disease, serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, other serious cardiac problems). Additionally, use of atomoxetine is not recommended in pediatric patients with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, or other serious cardiac problems. Patients should be assessed prior to starting atomoxetine therapy for a family history of sudden death or ventricular arrhythmia and should receive a physical exam to look for signs of cardiac disease. Furthermore, a prompt cardiac evaluation should be performed in patients who develop symptoms suggesting cardiac disease (eg, exertional chest pain, unexplained syncope) during atomoxetine therapy (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.9 Syncope

a) Incidence: pediatric, 0.8% (Prod Info STRATTERA(R) oral capsules, 2008)

b) Syncope has been reported in 0.8% of atomoxetine-treated child and adolescent patients (n=46 of 5596) and there have been spontaneous postmarketing reports of syncope; however, syncope has not been reported with atomoxetine use in child and adolescent patients with attention-deficit hyperactivity disorder (ADHD) during short-term, placebo-controlled studies. Patients with any condition that may predispose them to hypotension should use atomoxetine with caution (Prod Info STRATTERA(R) oral capsules, 2008).

c) Reports of syncope were significantly higher in patients classified as poor metabolizers of CYP2D6 drugs than those classified as extensive metabolizers (3% and 1%, respectively) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.1.A.10 Tachycardia

a) Incidence: adults, 1.5%; pediatrics, 0.3% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In clinical studies, tachycardia has been reported in atomoxetine-treated patients with attention-deficit hyperactivity disorder (ADHD). Use caution in patients receiving atomoxetine who have preexisting hypertension, tachycardia, or cardiovascular or cerebrovascular disease due to the risk of heart rate and blood pressure elevation in these patients. Pulse and blood pressure monitoring is recommended at baseline, following dose increases, and periodically during therapy (Prod Info STRATTERA(R) oral capsules, 2008). In addition, greater increases in heart rate and systolic pressure have been reported among cytochrome P450 2D6 poor metabolizers (Michelson et al, 2001a; Chouinard et al, 1985a).

c) In placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD),

tachycardia was reported more frequently in patients taking atomoxetine (1.5%; n=8 of 540) than placebo (0.5%; n=2 of 402). Compared to placebo, mean increases in heart rate of 5 beats/minute were reported for atomoxetine-treated patients (Prod Info STRATTERA(R) oral capsules, 2008).
d) In pediatric placebo-controlled trials, tachycardia was reported in 0.3% of atomoxetine-treated patients (n=5 of 1597) compared to 0% of placebo-treated patients (n=0 of 934). At the final study visit, heart rates greater than or equal to 110 beats/minute with increases of at least 25 beats/minute were reported for 2.5% of patients taking atomoxetine (n=36 of 1434) compared to 0.2% receiving placebo (n=2 of 850). Heart rates of at least 110 beats/minute with increases of at least 25 beats/minute were reported on more than one occasion in 1.1% (n=15 of 1417) of pediatric patients treated with atomoxetine during the study. Additionally, patients identified as extensive metabolizers had reported increases in mean heart rate of 5 beats/minute while poor metabolizers had increases of 9.4 beats/minute (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.2 Dermatologic Effects

3.3.2.A Atomoxetine Hydrochloride

Rash

Urticaria

3.3.2.A.1 Rash
a) Incidence: adults, 2%; pediatrics, 2% (Prod Info STRATTERA(R) oral capsules, 2008)
b) Allergic reactions, including rash, have been reported with atomoxetine use (Prod Info STRATTERA (R) oral capsules, 2008).
c) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), rash was reported in 2% of patients who received atomoxetine (n=540) compared to 1% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).
d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), rash was reported in 2% of atomoxetine-treated patients (n=1597) compared to 1% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.2.A.2 Urticaria
a) Allergic reactions, including urticaria, have been reported with atomoxetine use (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.3 Endocrine/Metabolic Effects

3.3.3.A Atomoxetine Hydrochloride

Abnormal height in relation to growth / age standard

Hyponatremia

Weight loss

3.3.3.A.1 Abnormal height in relation to growth / age standard
a) The weight and height gains in atomoxetine-treated pediatric patients lags behind the normative population for the first 9 to 12 months of therapy and rebounds at about 3 years of treatment regardless of pubertal status at the time of treatment initiation. After approximately 12 months of atomoxetine therapy, gain in height stabilizes and at 3 years pediatric patients gain 19.4 cm on average, which is 0.4 cm less than predicted by baseline data. Poor metabolizers of CYP2D6 treated for at least 2 years gained an average of 1.1 cm less than predicted and extensive metabolizers of CYP2D6 gained an average of 0.4 cm less than predicted. In short-term controlled 9 week studies atomoxetine-treated patients gained an average of 0.9 cm compared to 1.1 cm in placebo (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.3.A.2 Hyponatremia
a) A 32-year-old man receiving atomoxetine hydrochloride (HCl) for attention deficit hyperactivity disorder (ADHD) experienced hyponatremia which resolved upon drug withdrawal. After taking atomoxetine 60 milligrams daily for 2 months with good results, the patient presented to his outpatient psychiatrist with a few week history of nausea and fatigue. He reported no psychiatric symptoms or

other medical problems and was not taking any other medications. A laboratory workup revealed a low serum sodium level of 122 millimole/liter (mmol/L), which was decreased from a sodium level of 141 mmol/L obtained 1-year previously. All other laboratory results were reported as normal. Hyponatremia due to medication-induced syndrome of inappropriate antidiuretic hormone (SIADH) was suspected by the patient's primary care physician who did not find any other cause for the low sodium level; therefore, atomoxetine HCl was discontinued. Sodium levels obtained 1 and 2 weeks later were 130 mmol/L and 140 mmol/L, respectively. Two weeks after discontinuing atomoxetine HCl, the patient initiated amphetamine/dextroamphetamine (Adderall XR(R)) for the treatment of his ADHD. Consider monitoring serum sodium and other signs and symptoms of hyponatremia and SIADH in patients receiving atomoxetine HCl (Singh, 2007).

3.3.3.A.3 Weight loss

a) Incidence: pediatrics, 7.1% to 29.1% (Prod Info STRATTERA(R) oral capsules, 2008)
b) The weight and height gains in atomoxetine-treated pediatric patients lags behind the normative population for the first 9 to 12 months of therapy and rebounds at about 3 years (17.9 kg on average, 0.5 kg more than predicted from baseline data) of treatment regardless of pubertal status at the time of treatment initiation. In short-term controlled 9 week studies atomoxetine-treated patients lost an average of 0.4 kg compared to a gain of 1.5 kg in the placebo group. Poor metabolizers of CYP2D6 treated for at least 2 years gained an average 2.4 kg less than predicted and extensive metabolizers of CYP2D6 gained an average of 0.2 kg less than predicted. Additionally, in a fixed-dose controlled trial patients lost at least 3.5% of their body weight in the atomoxetine-treated patients in 7.1% (0.5 mg/kg day dose), 19.3% (1.2 mg/kg day dose), and 29.1% (1.8 mg/kg day dose) of patients compared with 1.3% in the placebo group (Prod Info STRATTERA(R) oral capsules, 2008).
c) Weight loss and anorexia have been reported more often with atomoxetine than placebo in limited controlled studies (Michelson et al, 2001a; Zerbe et al, 1985a; Spencer et al, 1998a). Both effects are dose-related, and were also observed in open studies. The magnitude of weight loss was similar to that observed during methylphenidate therapy in ADHD patients in an unpublished study (Michelson et al, 2001a).

3.3.4 Gastrointestinal Effects

3.3.4.A Atomoxetine Hydrochloride

Abdominal pain

Constipation

Decrease in appetite

Indigestion

Loss of appetite

Nausea

Sialolithiasis

Vomiting

Xerostomia

3.3.4.A.1 Abdominal pain

a) Incidence: adults, 7%; pediatrics, 17% to 18% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), abdominal pain was reported in 7% of patients who received atomoxetine (n=540) compared to 5% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).
c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), abdominal pain was reported in 18% of atomoxetine-treated patients (n=1597) compared to 10% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).
d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit

hyperactivity disorder (ADHD), abdominal pain was reported in 18% and 17% of patients treated with atomoxetine once (n=882) and twice (n=715) daily, respectively, compared to 7% and 13% of patients treated with placebo once (n=500) and twice (n=434) daily, respectively (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.2 Constipation

a) Incidence: adults, 9%; pediatric, 1% to 2%(Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), constipation was reported in 9% of patients who received atomoxetine (n=540) compared to 3% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), constipation was reported in 1% and 2% of patients treated with atomoxetine once (n=882) and twice (n=715) daily, respectively, compared to 0% and 1% of patients treated with placebo once (n=500) and twice (n=434) daily, respectively. Reports of constipation were significantly higher in patients classified as poor metabolizers of CYP2D6 drugs than those classified as extensive metabolizers (7% and 4%, respectively) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.3 Decrease in appetite

a) Incidence: adult, 11%; pediatrics, 16% (Prod Info STRATTERA(R) oral capsules, 2008),

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), decreased appetite was reported in 11% of patients who received atomoxetine (n=540) compared to 2% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), anorexia was reported in 16% of atomoxetine-treated patients (n=1597) compared to 4% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.4 Indigestion

a) Incidence: adults, 4% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), dyspepsia was reported in 4% of patients who received atomoxetine (n=540) compared to 2% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.5 Loss of appetite

a) Incidence: pediatrics, 3% (Prod Info STRATTERA(R) oral capsules, 2008),

b) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), anorexia was reported in 3% of atomoxetine-treated patients (n=1597) compared to 1% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.6 Nausea

a) Incidence: adults, 21%; pediatrics, 7% to 13% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), nausea was reported in 21% of patients who received atomoxetine (n=540) compared to 5% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), nausea was reported in 10% of atomoxetine-treated patients (n=1597) compared to 5% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), nausea was reported in 13% and 7% of patients treated with atomoxetine once (n=882) and twice (n=715) daily, respectively, compared to 4% and 6% of patients treated with placebo once (n=500) and twice (n=434) daily, respectively (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.7 Sialolithiasis

a) Sialolithiasis developed and then recurred each time atomoxetine was restarted in a 36-year-old male. Initially, he was on dextroamphetamine spansules 20 mg/day for 16 weeks for attention deficit hyperactivity disorder prior to adding atomoxetine 18 mg/day. An extruded, left submandibular sialolith in the salivary gland developed within 10 days of starting atomoxetine, with a second recurrence 10 days later. Subsequently, atomoxetine was discontinued and the stone passed. Within 4 to 5 days of restarting atomoxetine 2 weeks later, the sialolithiasis recurred with 3 subsequent episodes each time atomoxetine was discontinued and restarted. The time to onset was quicker for each recurrence. The stone was passed by massaging the gland. Pain and swelling of the gland was evident and at no time did he experience dry mouth. At a 6-month follow-up after permanently discontinuing atomoxetine, no further stones developed. Significant medical history included 3 events of sialolithiasis, all occurring within a few months of each other and 18 months prior to starting atomoxetine. The first of these 3

episodes was identified by computed tomography scan, and each time the stone was passed by massaging the gland (Jerome et al, 2007).

3.3.4.A.8 Vomiting

a) Incidence: adults, 3%; pediatrics, 11%(Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), vomiting was reported in 3% of patients who received atomoxetine (n=540) compared to 2% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).
c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), vomiting was reported in 11% of atomoxetine-treated patients (n=1597) compared to 6% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).
d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), vomiting was reported in 11% of patients treated with either atomoxetine once (n=882) or twice (n=715) daily compared to 4% and 8% of patients treated with placebo once (n=500) and twice (n=434) daily, respectively (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.4.A.9 Xerostomia

a) Incidence: adults, 21% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), dry mouth was reported in 21% of patients who received atomoxetine (n=540) compared to 7% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.6 Hepatic Effects

3.3.6.A Atomoxetine Hydrochloride

3.3.6.A.1 Injury of liver (Severe)

a) Incidence: rare (Prod Info STRATTERA(R) oral capsules, 2008)
b) During postmarketing surveillance severe liver injury has occurred in rare instances including hepatic enzymes elevated by up to 40 times the upper limit of normal (ULN) and jaundice with a bilirubin up to 12 times ULN recurring upon rechallenge and recovering upon discontinuation of atomoxetine. Severe liver injury may occur several months after therapy initiation and may worsen for several weeks upon discontinuation with the potential to progress to acute liver failure and death or the need for a liver transplant. In patients with laboratory evidence of liver injury or jaundice, atomoxetine should be discontinued and not reinstituted. Additionally, at the first sign or symptom of liver dysfunction (eg, pruritus, dark urine, jaundice, right upper quadrant tenderness, unexplained flu-like symptoms), liver enzyme levels should be obtained (Prod Info STRATTERA(R) oral capsules, 2008).
c) Liver injury has been reported in clinical trials and postmarketing reports in patients with attention-deficit hyperactivity disorder (ADHD) treated with atomoxetine. Of 7961 pediatric or adult patients with ADHD who received treatment with atomoxetine in 45 clinical trials, 41 cases of liver injury were possibly related to atomoxetine therapy and included mild to moderate increases in total bilirubin consistent with Gilbert's syndrome (n=18) and elevated ALT, AST, alkaline phosphatase (ALP) and CPK levels. When laboratory data from 14 pediatric and 2 adult placebo-controlled trials were reviewed, no significant differences in treatment-related elevations in AST, ALT, ALP, CPK, or total bilirubin levels were found between patients who received atomoxetine and placebo. Additionally, out of 351 postmarketing case reports (calculated reported liver injury rate of less than 0.01%), 133 and 3 cases, respectively, were possibly and probably related to atomoxetine therapy. All 3 probable cases were reversible: (Bangs et al, 2008).

1) A male adolescent patient developed lethargy and abdominal pain after receiving atomoxetine 40 mg twice daily for 3 to 4 months. Atomoxetine and sertraline were discontinued and liver enzyme elevations were noted the following day (ALT, 33 x ULN; AST, 15 x ULN; total bilirubin, 1.5 x ULN). Liver enzymes returned to normal within 2 months; however, upon rechallenge with atomoxetine 40 mg/day, liver enzymes and bilirubin were elevated within approximately 5 weeks of therapy and a liver biopsy revealed hepatitis with focal hepatocellular necrosis. A subsequent liver biopsy 2 months later revealed hepatitis with cholestasis, primarily lymphocytic inflammatory infiltrate. Liver enzymes returned to normal within 4.5 months (Bangs et al, 2008).
2) The second patient was a female adolescent who was hospitalized with jaundice, abdominal pain, diarrhea, vomiting, conjunctival icterus, and right upper quadrant tenderness after receiving atomoxetine 40 mg/day for almost one year. On admission, liver enzyme elevations were present (ALT, 65 x ULN; AST, 67 x ULN; total bilirubin, 9.1 x ULN). Liver biopsy showed moderate, mixed portal inflammatory infiltrate (mainly lymphoid with some eosinophils) and normal interlobular ducts and central veins. After discontinuing atomoxetine, liver enzymes returned to normal and symptoms resolved over the next 4 weeks (Bangs et al, 2008).
3) The third patient was a female child who was receiving atomoxetine 25 mg/day (1.03 mg/kg/day) presented with a 2-day history of emesis after 37 days of therapy, and was admitted to the hospital. The patient had elevated liver enzymes (ALT, 80 x ULN; AST, 115 x ULN; total

bilirubin, 10.8 x ULN; alkaline phosphatase, 3.5 x ULN), and symptoms of jaundice and hepatomegaly. A liver biopsy demonstrated mixed portal inflammation with lymphocytes, neutrophils and eosinophils in the lobule with moderate piecemeal necrosis. Improvement of signs and symptoms was observed and the patient was discharged from the hospital after 13 days (Bangs et al, 2008).

3.3.7 Immunologic Effects

3.3.7.A Atomoxetine Hydrochloride

3.3.7.A.1 Immune hypersensitivity reaction

a) Allergic reactions, including angioneurotic edema, urticaria, and rash, have been reported with atomoxetine use (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9 Neurologic Effects

3.3.9.A Atomoxetine Hydrochloride

Akathisia

Cerebrovascular accident

Dizziness

Dyskinesia

Headache

Insomnia

Seizure

Sinus headache

Somnolence

Tic

3.3.9.A.1 Akathisia

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.2 Cerebrovascular accident

a) Stroke has occurred in adult patients receiving atomoxetine at usual doses. Consider not using atomoxetine in adult patients with clinically significant cardiac abnormalities (eg, coronary artery disease, serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, other serious cardiac problems) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.3 Dizziness

a) Incidence: adult, 6%; pediatric, 5% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), dizziness was reported in 6% of patients who received atomoxetine (n=540) compared to 4% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral

capsules, 2008).
c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), dizziness was reported in 5% of atomoxetine-treated patients (n=1597) compared to 2% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.4 Dyskinesia
a) Dyskinesias with other neurological abnormalities developed in 2 pediatric patients with attention deficit hyperactivity disorder after starting atomoxetine. Both patients required hospitalization due to severity of tremors and psychiatric disturbances. The events resolved after discontinuation of atomoxetine in 1 patient and atomoxetine and venlafaxine in the other patient (Bond et al, 2007).
1) A 9-year-old boy on amphetamine/dextroamphetamine extended-release and clonidine for attention deficit hyperactivity disorder developed insomnia and involuntary hand and mouth movements within 14 days of starting atomoxetine 25 mg every day. He initially developed anorexia a few days after starting atomoxetine with subsequent signs of disturbed sleep, compulsive lip licking, seeing things ("bugs") that caused fear. All signs progressively worsened. Vital signs were a temperature of 36.9 degrees Celsius, heart rate of 89 beats per minute, respiration rate of 24 breaths/minute, and blood pressure of 145/93 mmHg, which was slightly above his baseline diastolic blood pressure. He was alert and oriented to person and place. Neurologic examination revealed involuntary, continuous twitching movements of his perioral area and writhing fingers and restless legs, which moved continuously as he lay on the bed. Intravenous diphenhydramine 50 mg failed to provide any improvement in symptoms. He was admitted for observation. Amphetamine/dextroamphetamine and atomoxetine were discontinued. Although he did not sleep that night, the abnormal movements resolved the next day. At a 5-month follow-up visit, there was no evidence of movement disorder while on amphetamine/dextroamphetamine, clonidine, and sertraline (Bond et al, 2007).
2) An 18-year-old female with attention deficit hyperactivity disorder and generalized anxiety disorder with panic attacks on venlafaxine developed severe tremors and abnormal facial movements after starting atomoxetine. Approximately 2 months prior to the event she started paroxetine, which was subsequently replaced with venlafaxine 37.5 mg daily. Atomoxetine 18 mg every day was started about 3 weeks prior to the event. The dose of venlafaxine and atomoxetine were gradually increased. Approximately 5 days after attaining maximum doses of venlafaxine 225 mg every day and atomoxetine 40 mg every day, she developed fine hand tremors present only at rest. The dose of venlafaxine was reduced to 150 mg every day and atomoxetine was discontinued. Within 3 days the following evolved: the tremors worsened in her upper extremities and progressed to her lower extremities (intentional movements did not improve the tremors); she developed abnormal facial movements with muscular twitching and uncontrollable movements of her lips and tongue, which rendered her unable to vocalize; and the tremors progressively worsened rendering her unable to ambulate. Vital signs were a temperature of 36.5 degrees Celsius, heart rate of 110 beats per minute, respiration rate of 18 breaths/minute, and blood pressure of 108/67 mmHg. Neurologic examination revealed intact cranial nerves II-XII, no nystagmus, intact sensations, and slightly increased deep tendon reflexes (DTR) of the lower and normal DTR of the upper extremities. She was admitted and administered diphenhydramine 50 mg intramuscularly and intravenous (IV) normal saline. The tremors improved slightly. An additional diphenhydramine 12.5 mg IV was of no benefit. She was discharged 24 hours later with moderate improvement in tremors. Complete resolution of the event was reported at follow-up day 7, while off venlafaxine and atomoxetine (Bond et al, 2007).

3.3.9.A.5 Headache
a) Incidence: pediatrics, 19% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), headache was reported in 19% of atomoxetine-treated patients (n=1597) compared to 15% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.6 Insomnia
a) Incidence: adults, 16%; pediatrics, at least 2%; (Prod Info STRATTERA(R) oral capsules, 2008)
b) Insomnia has been commonly reported in adult patients with attention-deficit hyperactivity disorder (ADHD) who were receiving atomoxetine in clinical trials. However, anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, especially during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).
c) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit

hyperactivity disorder (ADHD), insomnia was reported in 15% of patients who received atomoxetine (n=540) compared to 7% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).
d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), insomnia was reported in at least 2% of atomoxetine-treated patients (n=1597) compared to 2% or less of placebo-treated patients (n=934). Reports of insomnia were significantly higher in patients classified as poor metabolizers of CYP2D6 drugs than those classified as extensive metabolizers (15% and 10%, respectively) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.7 Seizure
a) Incidence: adults, 0.1%; pediatrics, 0.2% (Prod Info STRATTERA(R) oral capsules, 2008)
b) Clinical studies did not systematically evaluate adult or pediatric patients with seizure disorders. However, in clinical development program, seizures were reported in children (average age 10 years, range 6 to 16 years) with an incidence of 0.2% (12/5073). In clinical trials among poor metabolizers of CYP2D6 the incidence of seizure in pediatrics was 0.3% (1/293) and was 0.2% (11/4741) for extensive metabolizers of CYP2D6 (Prod Info STRATTERA(R) oral capsules, 2008).
c) In adults, the incidence of seizures was 0.1% (1/748) and was 0.1% (1/705) of adult extensive metabolizers of CYP2D6. There have also been postmarketing reports of seizures, which have included patients both with and without a history of seizure disorders or identified risk factors for developing seizures (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.8 Sinus headache
a) Incidence: adults, 3% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), sinus headache was reported in 3% of patients who received atomoxetine (n=540) compared to 1% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.9 Somnolence
a) Incidence: adult, 4%; pediatrics, 11% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), somnolence was reported in 4% of patients who received atomoxetine (n=540) compared to 3% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).
c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), somnolence was reported in 11% of atomoxetine-treated patients (n=1597) compared to 4% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.9.A.10 Tic
a) Tics reoccurred or were exacerbated in 4 pediatric patients within approximately 5 to 30 days of starting atomoxetine for attention deficit hyperactivity disorder (ADHD). Three of the 4 patients had experienced tics on stimulants such as amphetamine/dextroamphetamine and 1 patient had a comorbid condition of Tourette's syndrome. Significant improvement or resolution resulted when atomoxetine was discontinued. Two of the patients subsequently tolerated guanfacine for ADHD (Lee et al, 2004).
1) A 9-year-old boy with combined type attention deficit hyperactivity disorder developed motor tics with the stimulants methylphenidate, amphetamine/dextroamphetamine, and dextroamphetamine. The tics resolved after discontinuation of the stimulants. After a 6-month washout, atomoxetine was started at 10 mg every day for 7 days then 20 mg every day. Within a few days of starting 20 mg, he developed motor tics described as rapid, severe eye blinking. This event was similar to the event with previous stimulants. Vocal tics were absent. Within 1 to 2 days of stopping atomoxetine, the tics resolved. There was no recurrence of tics after 1 year on guanfacine (Lee et al, 2004).
2) A 14-year-old boy with attention deficit hyperactivity disorder developed eye-blinking motor tic on methylphenidate. Methylphenidate was discontinued and atomoxetine 20 mg every day was started. The eye blinking worsened, and he subsequently developed a vocal tic of severe episodes of throat clearing. The vocal tics stopped and the eye-blinking improved following discontinuation of atomoxetine. Mild eye blinking persisted with no other signs of tics while on guanfacine (Lee et al, 2004).
3) A 9-year-old boy with attention deficit hyperactivity disorder and chronic tic disorders experienced tic exacerbations on stimulants. Prior to starting atomoxetine, facial tics were the sole symptoms. He started atomoxetine 18 mg every day and within 30 days developed dramatic vocal tics and increased motor tics. Associated adverse effects were irritability, anxiety, dysphoria, compulsive finger picking, and obsessional ruminations. The event improved after discontinuation of atomoxetine (Lee et al, 2004).
4) A 15-year-old boy with attention deficit hyperactivity disorder and Tourette's syndrome experienced tic exacerbations on stimulants. Significant increase in tics, impulsivity, and fatigue occurred within 5 days of starting atomoxetine 10 mg every day. The event improved after discontinuation of atomoxetine(Lee et al, 2004).

3.3.12 Psychiatric Effects

3.3.12.A Atomoxetine Hydrochloride

Aggressive behavior

Agitation

Anxiety

Hostile behavior

Hypomania

Impulsive character

Irritability

Mania

Panic attack

Psychotic disorder

Suicidal thoughts

3.3.12.A.1 Aggressive behavior

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

b) Although not statistically significant, short-term placebo-controlled clinical trials of children and adolescents with attention-deficit hyperactivity disorder reported observations of aggressive behavior or hostility more frequently in atomoxetine-treated patients (1.6%; n=21 of 1308) than placebo-treated patients (1.1%; n=9 of 806) (overall risk ratio of 1.33; 95% confidence interval, 0.67-2.64; p=nonsignificant). Monitor patients for the appearance or worsening of aggressive behavior or hostility (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.2 Agitation

a) An 11-year-old boy on atomoxetine for attention deficit hyperactivity disorder developed acute agitation and suicidal ideation within 17 days of starting atomoxetine. He also had anxiety, obsessive compulsive disorder and oppositional defiant behaviors. Atomoxetine 25 mg was administered every day for 14 days, with the medication scheduled to increase to 60 mg every day thereafter. He initially showed a marked reduction in anxiety and obsessive symptoms; however, the family noted increased emotional liability, cycling of his mood and agitation, and that his handwriting had changed from neat script to messy and 'tiny.' After the dose increase as planned on day 14, the boy developed increased agitation, greater mood swings with more rapid cycling, increased crying, and he threatened suicide. The family discontinued the medication, and the patient’s agitation calmed after a few days and he was described as back to his normal self (Paxton & Cranswick, 2008).

b) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should

be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.3 Anxiety

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.4 Hostile behavior

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

b) Although not statistically significant, short-term placebo-controlled clinical trials of children and adolescents with attention-deficit hyperactivity disorder reported observations of aggressive behavior or hostility more frequently in atomoxetine-treated patients (1.6%; n=21 of 1308) than placebo-treated patients (1.1%; n=9 of 806) (overall risk ratio of 1.33; 95% confidence interval, 0.67-2.64; p=nonsignificant). Monitor patients for the appearance or worsening of aggressive behavior or hostility (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.5 Hypomania

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.6 Impulsive character

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.7 Irritability

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging

suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.8 Mania

a) In a review of 49 randomized, controlled pediatric ADHD clinical trials involving pscyhostimulant medications (atomoxetine hydrochloride, methylphenidate hydrochloride, modafinil and dextromethylphenidate hydrochloride), the rate of psychosis/mania events in pediatric subjects receiving active drug was 1.48 (95% CI, 0.74 to 2.65) per 100 person-years, with no comparable adverse events recorded in the placebo group. A request from the US Food and Drug Administration to manufacturers of marketed ADHD drugs for submission of postmarketing case reports of psychosis or mania events between 2000 and 2005, yielded a total of 865 reports (pediatrics and adults) in which signs and/or symptoms of psychoses or mania were reported. The majority of reports involved pediatric subjects, with almost half of the reports in children 10 years-old or younger, and approximately 90% of cases involving no prior history of similar psychiatric conditions. Visual and/or tactile sensations of insects, snakes, or worms were commonly reported. Positive rechallenge was reported for each of the psychostimulant medications (methylphenidate hydrochloride, atomoxetine hydrochloride, and mixed salts of a single entity amphetamine product) included in the analysis; and in many cases a strong temporal association was identified. The onset of psychiatric symptoms ranged from days to weeks, but in some cases it was months or years from the start of ADHD treatment and symptom onset (Mosholder et al, 2009).

b) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

c) A pooled analysis of multiple short-term, placebo-controlled studies in children and adolescents without a prior history of psychotic illness or mania demonstrated that about 0.2% of atomoxetine-treated patients (n=4 of 1939) exhibited treatment emergent psychotic or manic symptoms (eg, hallucinations, mania, delusional thinking) compared to 0% of placebo-treated patients (n=0 of 1056). Discontinuation of treatment should be considered if such symptoms develop during atomoxetine therapy (Prod Info STRATTERA(R) oral capsules, 2008).

d) Mania was described in one patient with major depression after more than a year of atomoxetine therapy (up to 80 mg daily). However, a causal relationship to the drug was not established; numerous other factors may have contributed to the manic episode (Steinberg & Chouinard, 1985).

3.3.12.A.9 Panic attack

a) Anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania have been reported with atomoxetine use and may be precursors to emerging suicidality. It is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or precursors to emerging suicidality, particularly if symptoms are severe or present with an abrupt onset and were not part of original presenting symptoms (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.12.A.10 Psychotic disorder

a) In a review of 49 randomized, controlled pediatric ADHD clinical trials involving pscyhostimulant medications (atomoxetine hydrochloride, methylphenidate hydrochloride, modafinil and dextromethylphenidate hydrochloride), the rate of psychosis/mania events in pediatric subjects receiving active drug was 1.48 (95% CI, 0.74 to 2.65) per 100 person-years, with no comparable adverse events recorded in the placebo group. A request from the US Food and Drug Administration to manufacturers of marketed ADHD drugs for submission of postmarketing case reports of psychosis or

mania events between 2000 and 2005, yielded a total of 865 reports (pediatrics and adults) in which signs and/or symptoms of psychoses or mania were reported. The majority of reports involved pediatric subjects, with almost half of the reports in children 10 years-old or younger, and approximately 90% of cases involving no prior history of similar psychiatric conditions. Visual and/or tactile sensations of insects, snakes, or worms were commonly reported. Positive rechallenge was reported for each of the psychostimulant medications (methylphenidate hydrochloride, atomoxetine hydrochloride, and mixed salts of a single entity amphetamine product) included in the analysis; and in many cases a strong temporal association was identified. The onset of psychiatric symptoms ranged from days to weeks, but in some cases it was months or years from the start of ADHD treatment and symptom onset (Mosholder et al, 2009).

3.3.12.A.11 Suicidal thoughts

a) Incidence: pediatrics, 0.4% (Prod Info STRATTERA(R) oral capsules, 2008)

b) An 11-year-old boy on atomoxetine for attention deficit hyperactivity disorder developed acute agitation and suicidal ideation within 17 days of starting atomoxetine. He also had anxiety, obsessive compulsive disorder and oppositional defiant behaviors. Atomoxetine 25 mg was administered every day for 14 days, with the medication scheduled to increase to 60 mg every day thereafter. He initially showed a marked reduction in anxiety and obsessive symptoms; however, the family noted increased emotional liability, cycling of his mood and agitation, and that his handwriting had changed from neat script to messy and 'tiny.' After the dose increase as planned on day 14, the boy developed increased agitation, greater mood swings with more rapid cycling, increased crying, and he threatened suicide. The family discontinued the medication, and the patient's agitation calmed after a few days and he was described as back to his normal self (Paxton & Cranswick, 2008).

c) An association has been reported between the use of atomoxetine and the development of suicidal ideation in children and adolescents. A pooled analysis of 12 short-term (6 to 18 weeks) clinical trials conducted in pediatric patients with attention-deficit hyperactivity disorder (11 trials) or enuresis (1 trial) demonstrated that 0.4% of patients (n=5 of 1357) who received atomoxetine therapy experienced suicidal ideation compared to no patients who received placebo (n=0 of 851). Although no suicides were reported in these trials (one suicide attempt), it is recommended that pediatric patients receiving atomoxetine be monitored for clinical worsening, suicidal ideation, suicidal behavior, irritability, agitation, or unusual changes in behavior, particularly during the first few months of therapy or following a dosage adjustment. Monitoring should be daily by family members or caregivers and by healthcare providers weekly for the first 4 weeks, then every other week for 4 weeks, then every 12 weeks and as clinically indicated thereafter. Consider changing the therapeutic regimen and possibly discontinuing atomoxetine therapy if patients experience suicidality or possible precursors to emerging suicidality (eg, anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, mania) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.13 Renal Effects

3.3.13.A Atomoxetine Hydrochloride

Delay when starting to pass urine

Urinary retention

3.3.13.A.1 Delay when starting to pass urine

a) Incidence: adults, 5.6% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), urinary hesitation has been reported in 5.6% of atomoxetine-treated patients (n=30 of 540) compared to 0.5% of placebo-treated patients (n=4 of 402). Additionally, urinary hesitation and/or urinary retention were reported in 7% of patients who received atomoxetine compared to 1% of patients who received placebo (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.13.A.2 Urinary retention

a) Incidence: adults, 1.7% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), urinary retention has been reported in 1.7% of atomoxetine-treated patients (n=9 of 540) compared to 0% of placebo-treated patients (n=0 of 402). Additionally, urinary hesitation and/or urinary retention were reported in 7% of patients who received atomoxetine compared to 1% of patients who received placebo (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.14 Reproductive Effects

3.3.14.A Atomoxetine Hydrochloride

Disorder of ejaculation

Dysmenorrhea

Erectile dysfunction

Priapism

Sexual dysfunction

3.3.14.A.1 Disorder of ejaculation

a) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), ejaculation delayed and/or ejaculation disorder were reported in 3% of patients who received atomoxetine (n=326) compared to 1% of patients who received placebo (n=260) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.14.A.2 Dysmenorrhea

a) Incidence: adults, 6% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), dysmenorrhea was reported in 6% of patients who received atomoxetine (n=214) compared to 2% of patients who received placebo (n=142) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.14.A.3 Erectile dysfunction

a) Incidence: adults, 9% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), erectile dysfunction was reported in 9% of patients who received atomoxetine (n=326) compared to 1% of patients who received placebo (n=260) (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.14.A.4 Priapism

a) Incidence: rare (Prod Info STRATTERA(R) oral capsules, 2008)

b) There have been rare postmarketing reports of priapism lasting more than 4 hours in pediatric and adult patients receiving atomoxetine. If priapism occurs during atomoxetine therapy, patients should seek prompt medical attention (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.14.A.5 Sexual dysfunction

a) While changes in sexual desire, sexual performance, and sexual satisfaction have not been assessed in clinical trials, atomoxetine appears to impair sexual function in some male and female patients. Patients receiving atomoxetine should be routinely asked about sexual side effects (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.16 Other

3.3.16.A Atomoxetine Hydrochloride

Angioedema

Fatigue

Menopausal flushing

3.3.16.A.1 Angioedema

a) Allergic reactions, including angioneurotic edema, have been reported with atomoxetine use (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.16.A.2 Fatigue

a) Incidence: adults, 9%; pediatrics, 6% to 9% (Prod Info STRATTERA(R) oral capsules, 2008)

b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), fatigue was reported in 9% of patients who received atomoxetine (n=540) compared to 4% of patients who received placebo (n=402) (Prod Info STRATTERA(R) oral capsules, 2008).

c) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), fatigue was reported in 8% of atomoxetine-treated patients (n=1597) compared to 3% of placebo-treated patients (n=934) (Prod Info STRATTERA(R) oral capsules, 2008).
d) In acute (up to 18 weeks), placebo-controlled trials in pediatric patients with attention-deficit hyperactivity disorder (ADHD), fatigue was reported in 9% and 6% of patients treated with atomoxetine once (n=882) and twice (n=715) daily, respectively, compared to 2% and 4% of patients treated with placebo once (n=500) and twice (n=434) daily, respectively (Prod Info STRATTERA(R) oral capsules, 2008).

3.3.16.A.3 Menopausal flushing

a) Incidence: adults, 8% (Prod Info STRATTERA(R) oral capsules, 2008)
b) In acute (up to 25 weeks), placebo-controlled trials in adult patients with attention-deficit hyperactivity disorder (ADHD), hot flushes were reported in 8% of patients who received atomoxetine (n=214) compared to 1% of patients who received placebo (n=142) (Prod Info STRATTERA(R) oral capsules, 2008).

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy
1) U.S. Food and Drug Administration's Pregnancy Category: Category C (Prod Info Strattera(TM), 2002s) (All Trimesters)
a) Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
See Drug Consult reference: PREGNANCY RISK CATEGORIES
2) Crosses Placenta: Unknown
3) Clinical Management
a) There is insufficient clinical experience with the use of atomoxetine in pregnancy to confirm its safety in that patient population. Until additional data are available, caution should be exercised with the use of atomoxetine in pregnant women.
4) Literature Reports
a) Adverse fetal effects and some evidence of teratogenicity was reported with relatively high doses of atomoxetine in animal studies (Prod Info Strattera(TM), 2002s).
B) Breastfeeding
1) Thomson Lactation Rating: Infant risk cannot be ruled out.
a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk when used during breastfeeding. Weigh the potential benefits of drug treatment against potential risks before prescribing this drug during breastfeeding.
2) Clinical Management
a) It is not known whether atomoxetine is excreted into human breast milk and the potential for adverse effects in the nursing infant from exposure to the drug are unknown. It is not known if atomoxetine affects the quantity or composition of breastmilk. According to the manufacturer, atomoxetine and/or its metabolites were excreted into the milk of lactating rats (Prod Info STRATTERA(TM) Oral Capsule, 2002).
3) Literature Reports
a) No reports describing the use of atomoxetine during human lactation or measuring the amount, if any, of the drug excreted into milk have been located.

3.5 Drug Interactions

3.5.1 Drug-Drug Combinations

Albuterol

Amitriptyline

Amoxapine

Brofaromine

Clomipramine

Clorgyline

Desipramine

Dibenzepin

Dothiepin

Doxepin

Fluoxetine

Furazolidone

Imipramine

Iproniazid

Isocarboxazid

Lazabemide

Linezolid

Lofepramine

Moclobemide

Nialamide

Nortriptyline

Opipramol

Pargyline

Paroxetine

Phenelzine

Procarbazine

Protriptyline

Quinidine

Rasagiline

Selegiline

Tianeptine

Toloxatone

Tranylcypromine

Trimipramine

3.5.1.A Albuterol

1) Interaction Effect: an increase in heart rate and blood pressure
2) Summary: Albuterol (600 mcg intravenously over 2 hours) induced increases in heart rate and blood pressure. The effects were potentiated by atomoxetine (60 mg BID for 5 days) and were most marked after the initial coadministration of albuterol and atomoxetine (Prod Info Strattera(TM), 2002h).
3) Severity: major
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Close monitoring of blood pressure and heart rate is indicated during combined therapy with atomoxetine and albuterol or other beta-2 agonists, particularly in patients with cardiovascular disease.
7) Probable Mechanism: unknown

3.5.1.B Amitriptyline
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as amitriptyline. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with amitriptyline, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002n).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with amitriptyline.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by amitriptyline

3.5.1.C Amoxapine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as amoxapine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with amoxapine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002j).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with amoxapine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by amoxapine

3.5.1.D Brofaromine
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.E Clomipramine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are

increased with selective inhibitors of CYP2D6, such as clomipramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with clomipramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002m).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with clomipramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by clomipramine

3.5.1.F Clorgyline
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.G Desipramine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as desipramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with desipramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002r).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with desipramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by desipramine

3.5.1.H Dibenzepin
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as dibenzepin. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with dibenzepin, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002e).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with dibenzepin.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by dibenzepin

3.5.1.I Dothiepin
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-

hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as dothiepin. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with dothiepin, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002d).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with dothiepin.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by dothiepin

3.5.1.J Doxepin
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as doxepin. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with doxepin, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002g).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with doxepin.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by doxepin

3.5.1.K Fluoxetine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as fluoxetine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with fluoxetine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002c).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with fluoxetine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by fluoxetine

3.5.1.L Furazolidone
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.M Imipramine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are

increased with selective inhibitors of CYP2D6, such as imipramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with imipramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002a).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with imipramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by imipramine

3.5.1.N Iproniazid
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.O Isocarboxazid
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.P Lazabemide
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.Q Linezolid

1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.R Lofepramine

1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as lofepramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with lofepramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002o).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with lofepramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by lofepramine

3.5.1.S Moclobemide

1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.T Nialamide

1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical

6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.U Nortriptyline
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as nortriptyline. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with nortriptyline, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002l).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with nortriptyline.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by nortriptyline

3.5.1.V Opipramol
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as opipramol. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with opipramol, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002f).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with opipramol.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by opipramol

3.5.1.W Pargyline
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.X Paroxetine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as paroxetine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with paroxetine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002i).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical

6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with paroxetine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by paroxetine

3.5.1.Y Phenelzine
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.Z Procarbazine
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.AA Protriptyline
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as protriptyline. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with protriptyline, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002q).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with protriptyline.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine

3.5.1.AB Quinidine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as quinidine. The exposure is similar to that observed in poor metabolizers (Prod Info Strattera(TM), 2002p).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with

quinidine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by quinidine

3.5.1.AC Rasagiline
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.AD Selegiline
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.AE Tianeptine
1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as tianeptine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with tianeptine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002k).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with tianeptine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by tianeptine

3.5.1.AF Toloxatone
1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).

3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.AG Tranylcypromine

1) Interaction Effect: an increased risk of serotonin syndrome (hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delerium and coma)
2) Summary: The combination of atomoxetine and a monoamine oxidase inhibitor (MAOI) may increase the risk of serotonin syndrome. There have been reports of serious, sometimes fatal, reactions (including hyperthermia, rigidity, myoclonus, autonomic instability with possible rapid fluctuations of vital signs, and mental status changes that include extreme agitation progressing to delirium and coma) when atomoxetine is coadministered with an MAOI. Some case presented with signs and symptoms similar to neuroleptic malignant syndrome (Prod Info Strattera(TM), 2002).
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Atomoxetine should not be taken with a monoamine oxidase inhibitor (MAOI), or within 2 weeks after discontinuing an MAOI. Treatment with an MAOI should not be initiated within 2 weeks after discontinuing atomoxetine. Observe the patient closely for signs and symptoms of serotonin syndrome or neuroleptic malignant syndrome.
7) Probable Mechanism: additive serotonergic effect

3.5.1.AH Trimipramine

1) Interaction Effect: an increase in atomoxetine steady-state plasma concentrations
2) Summary: Atomoxetine is primarily metabolized by the cytochrome P450 2D6 (CYP 2D6) pathway to 4-hydroxyatomoxetine. In extensive metabolizers, atomoxetine steady-state plasma concentrations are increased with selective inhibitors of CYP2D6, such as trimipramine. The exposure is similar to that observed in poor metabolizers. In extensive metabolizers treated with trimipramine, the area under the concentration-time curve of atomoxetine is approximately 6- to 8-fold greater, and maximum plasma concentration at steady-state is about 3- to 4-fold greater than atomoxetine alone (Prod Info Strattera(TM), 2002b).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dosage adjustment of atomoxetine may be necessary when coadministered with trimipramine.
7) Probable Mechanism: inhibition of cytochrome P450 2D6-mediated metabolism of atomoxetine by trimipramine

4.0 Clinical Applications

Monitoring Parameters

Patient Instructions

Place In Therapy

Mechanism of Action / Pharmacology

Therapeutic Uses

4.1 Monitoring Parameters

A) Atomoxetine Hydrochloride
1) Therapeutic
a) Physical Findings
1) Improvement in mental and behavioral symptoms of ADHD, including inappropriate inattention, impulsivity, hyperactivity, and cognitive performance.
2) Toxic

a) Laboratory Parameters

1) Monitor hepatic function tests if signs of liver dysfunction are present including pruritus, dark urine, jaundice, right upper quadrant tenderness, or unexplained flu-like symptoms (Prod Info STRATTERA(R) oral capsules, 2009).

b) Physical Findings

1) The American Academy of Pediatrics (AAP) does not recommend the routine use of electrocardiograms (ECGS) or routine subspecialty cardiology evaluations (which were previously recommended by the American Heart Association (AHA) scientific statement to detect cardiac conditions that might place the child at risk for sudden cardiac death) before initiating stimulant therapy to treat attention-deficit/hyperactivity disorder ADHD in most children. The APA cited specific reasons for changing the recommendation including: lack of evidence establishing a relationship between stimulant drugs used to treat ADHD and sudden cardiac death (SCD), the frequency of sudden unexpected deaths among patients taking stimulant drugs is not higher than that in the general population of children, and lack of cost-effective analysis to support ECG screening or special evaluation by pediatric cardiologist (Perrin et al, 2008).

2) Based on the American Academy of Pediatrics (AAP) and the American Heart Association (AHA) consensus statements, the following cardiac monitoring recommendations have been established to assist clinicians in the evaluation of children treated with stimulant drugs, including atomoxetine, for ADHD (Perrin et al, 2008; Vetter et al, 2008):

- Conduct a thorough examination prior to initiating atomoxetine therapy for a diagnosis of ADHD. Special attention should be given to symptoms indicative of a cardiac condition, including palpitations, near syncope, or syncope. Palpitations have been reported with atomoxetine use in adults.
- Obtain a complete family and patient history for conditions associated with SCD, and determine current use of any other prescription or over-the-counter medications.
- Conduct a complete physical evaluation of the patient for hypertension, cardiac murmurs, physical findings associated with Marfan syndrome, and signs of irregular cardiac rhythms.
- Perform further evaluation if family history, patient history or physical exam is suggestive of cardiac disease during initial visit or at follow up visits, and if indicated, consult pediatric cardiologist .
- Continue to assess the patient for cardiac symptoms and any changes in family history at follow up visits.
- Blood pressure and heart rate should be evaluated at baseline, during routine follow-up within 1 to 3 months, and at follow up visits every 6 to 12 months. Increases in blood pressure and heart rate have been reported with the use of certain ADHD drugs.

3) Monitor children and adolescents receiving atomoxetine for signs of clinical worsening, suicidal thinking or behaviors, and unusual changes in behavior at the start of therapy and during the first few months of therapy or when the dose is increased or decreased. Symptoms of clinical worsening may include anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania (Prod Info STRATTERA(R) oral capsules, 2009; US Food and Drug Administration, 2005).

4) Monitor for signs of liver dysfunction including pruritus, dark urine, jaundice, right upper quadrant tenderness, or unexplained flu-like symptoms (Prod Info STRATTERA(R) oral capsules, 2009).

5) Monitor growth in pediatric patients (Prod Info STRATTERA(R) oral capsules, 2006).

6) Monitor for signs of hypersensitivity including angioneurotic edema, urticaria, and rash.

4.2 Patient Instructions

A) Atomoxetine (By mouth)

Atomoxetine

Treats attention-deficit/hyperactivity disorder (ADHD).

When This Medicine Should Not Be Used:
You should not use this medicine if you or your child have had an allergic reaction to atomoxetine, if you or your child have narrow angle glaucoma, or have used an MAO inhibitor such as Eldepryl®, Marplan®, Nardil®, or Parnate® in the past 14 days. After you or your child stop using atomoxetine, do not use an MAO inhibitor for at least 14 days.

How to Use This Medicine:
Capsule

Your doctor will tell you how much of this medicine to use and how often. Do not use more medicine or use it more often than your doctor tells you to.
This medicine should come with a Medication Guide. Read and follow these instructions carefully. Ask your doctor or pharmacist if you have any questions. Ask your pharmacist for the Medication Guide if you do not have one. Your doctor might ask you to sign some forms to show that you understand this information.
For children or teenagers, the dose may need to be changed several times in order to find out what works best for them. Pay close attention to any changes in behavior that might happen.
Swallow the capsule whole. Do not crush, break, chew, or open it.

You may take this medicine with or without food.

If a Dose is Missed:
If you miss a dose or forget to use your medicine, use it as soon as you can. If it is almost time for your next dose, wait until then to use the medicine and skip the missed dose. Do not use extra medicine to make up for a missed dose.

How to Store and Dispose of This Medicine:
Store the medicine in a closed container at room temperature, away from heat, moisture, and direct light.
Ask your pharmacist, doctor, or health caregiver about the best way to dispose of any leftover medicine after you have finished your treatment. You will also need to throw away old medicine after the expiration date has passed.
Keep all medicine away from children and never share your medicine with anyone.

Drugs and Foods to Avoid:
Ask your doctor or pharmacist before using any other medicine, including over-the-counter medicines, vitamins, and herbal products.
Make sure your doctor knows if you are using dopamine (Intropin®), dobutamine (Dobutrex®), an asthma medicine (such as albuterol), or a heart rhythm medicine (such as disopyramide, procainamide, quinidine, Norpace®, or Procanbid®). Tell your doctor if you are also using a medicine for depression, such as fluoxetine, paroxetine, Luvox®, Paxil®, Prozac®, or Sarafem®.

Warnings While Using This Medicine:
Make sure your doctor knows if you or your child are pregnant or breastfeeding, or if you or your child have high or low blood pressure, liver disease, heart disease, heart rhythm problems, blood vessel disease, or problems with urination.
This medicine may make you or your child dizzy or drowsy. Avoid driving, using machines, or doing anything else that could be dangerous if you are not alert.
This medicine may cause slow growth. If your child is using this medicine, the doctor will need to keep track of your child's height and weight to make sure that your child is growing properly.
For some children and teenagers, this medicine can increase thoughts of suicide. All of the warnings in this leaflet are true for a child or teenager who is using this medicine.Tell your doctor right away if you start to feel more depressed. Also tell your doctor right away if you have thoughts about hurting yourself. Report any unusual thoughts or behaviors that trouble you, especially if they are new or get worse quickly.Make sure your caregiver knows if you have trouble sleeping, get upset easily, have a big increase in energy, or start to act reckless. Also tell your doctor if you have sudden or strong feelings, such as feeling nervous, angry, restless, violent, or scared.Let your doctor know if you or anyone in your family has bipolar disorder (manic-depressive) or has tried to commit suicide.
Your doctor will need to check your progress at regular visits while you are using this medicine. Be sure to keep all appointments.

Possible Side Effects While Using This Medicine:
Call your doctor right away if you notice any of these side effects:
Allergic reaction: Itching or hives, swelling in your face or hands, swelling or tingling in your mouth or throat, chest tightness, trouble breathing.
Change in how much or how often you urinate.
Chest pain or shortness of breath.
Dark-colored urine or pale stools.
Fast, pounding, or irregular heartbeat.
Flu-like symptoms.
Headache, lightheadedness, dizziness, or fainting.
Mood changes, aggressiveness, irritability, or depression.
Nausea, vomiting, loss of appetite, constipation, upset stomach, or pain in your upper stomach.
Painful, prolonged erection of the penis.
Seeing, hearing, or feeling things that are not there.
Seizures or tremors.
Yellowing of your skin or the whites of your eyes.

If you notice these less serious side effects, talk with your doctor:
Changes in your menstrual cycle (periods), or menstrual cramps.
Dry mouth.
Loss of interest in sex, or trouble having sex.
Tiredness.
Trouble sleeping.
Warmth or redness in your face, neck, arms, or upper chest.

If you notice other side effects that you think are caused by this medicine, tell your doctor.

4.3 Place In Therapy

A) ADHD

1) Atomoxetine is promoted as an equally efficacious form of ADHD therapy as conventional agents (eg, methylphenidate, dextroamphetamine, pemoline, bupropion, tricyclic antidepressants). Controlled studies, essential for evaluation of this agent, have shown evidence of efficacy; direct comparisons are lacking. Unpublished data suggest that the frequency and severity of some adverse effects are similar to those of methylphenidate (eg, cardiovascular effects, weight loss).

2) At the very least, prospective comparisons with short- and long-acting forms of methylphenidate (usual agent of choice) are indicated before the place in therapy of atomoxetine can be addressed.

3) Until additional data for atomoxetine are made available, it should not be considered over conventional therapy.

B) DEPRESSION

1) Clinical data for atomoxetine in major depression are limited to small, uncontrolled studies. Placebo-controlled studies are required to confirm efficacy; comparisons with selective serotonin reuptake inhibitors (SSRIs)/other antidepressants are needed to assess its role in therapy.

4.4 Mechanism of Action / Pharmacology

A) MECHANISM OF ACTION

1) Atomoxetine is a methylphenoxy-benzene propanamine derivative with antidepressant activity (Zerbe et al, 1985; Chouinard et al, 1985); its structure is unlike that of other antidepressants. The drug is under investigation as a "nonstimulant" treatment of attention-deficit/hyperactivity disorder (ADHD) in both adults and children, and for treatment of adult depression.

2) Atomoxetine purportedly enhances noradrenergic function via selective inhibition of the presynaptic norepinephrine transporter (Ki of 4.5 nanomols (nM)) (Michelson et al, 2001; Kratochvil et al, 2001). It has minimal-to-no affinity for other neuronal transporters or neurotransmitter receptor sites (eg, muscarinic, histaminic, dopaminergic, serotonergic, alpha-adrenergic) (Zerbe et al, 1985; Cusack et al, 1994; Spencer et al, 1998a; Chouinard et al, 1985; Spencer et al, 1998).

3) Animal and human studies suggest a low propensity for anticholinergic and adverse cardiovascular effects with atomoxetine (Zerbe et al, 1985; Kratochvil et al, 2001; Spencer et al, 2001). No significant hypertensive effects were seen in healthy subjects given single doses of 20 or 40 mg twice daily for one week in one study (Zerbe et al, 1985).

B) REVIEW ARTICLES

1) Drug treatment of attention-deficit/hyperactivity disorder (ADHD) (Popper, 2000).

2) Diagnostic dilemmas in ADHD and treatment modalities (Spencer et al, 1998a).

3) Use of nonstimulant agents in ADHD (Biederman & Spencer, 2000).

4.5 Therapeutic Uses

4.5.A Atomoxetine Hydrochloride

Attention deficit hyperactivity disorder

Attention deficit hyperactivity disorder - Social phobia

Nocturnal enuresis

4.5.A.1 Attention deficit hyperactivity disorder

FDA Labeled Indication

a) Overview

FDA Approval: Adult, yes; Pediatric, yes (6 years and older)
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Atomoxetine hydrochloride (HCl) is indicated for the acute treatment of attention-deficit hyperactivity disorder (ADHD) in pediatric (ages 6 years and older) and adult patients and as maintenance/extended therapy in pediatric patients (aged 6 to 15 years) (Prod Info STRATTERA (R) oral capsules, 2008).

Atomoxetine is used as an integral part of a total treatment program for (ADHD) that may include other psychological, educational, and/or social measures (Prod Info STRATTERA(R) oral capsules, 2008).

In two 10-week, randomized, placebo-controlled studies (n=536), atomoxetine hydrochloride produced significant improvement in symptoms in adult patients with attention-deficit/hyperactivity disorder (Prod Info STRATTERA(R) oral capsules, 2008).

Oral atomoxetine has shown short-term efficacy for treating attention-deficit hyperactivity disorder (ADHD) in over 600 children/adolescents (6 to 18 years of age) in open and placebo-controlled trials (Spencer et al, 2002; Kratochvil et al, 2001a; Michelson et al, 2001b; Spencer et al, 2001a). Pediatric patients (ages 6 to 15 years) with attention-deficit hyperactivity disorder who received maintenance treatment with atomoxetine hydrochloride had significantly longer times to relapse compared to patients who received placebo (Prod Info STRATTERA(R) oral capsules, 2008).

c) Adult:

1) In two 10-week, randomized, placebo-controlled studies in adult patients with attention-deficit hyperactivity disorder (n=536), atomoxetine hydrochloride (HCl) produced significant improvement in symptoms as assessed on the ADHD symptom score from the Conners Adult ADHD Rating Scale Screening Version (CAARS). Atomoxetine HCl was titrated to 60 to 120 mg/day given in 2 daily divided doses (mean daily dose, 95 mg). Efficacy was similar regardless of gender and age (older or younger than 42 years) (Prod Info STRATTERA(R) oral capsules, 2008).

2) Oral atomoxetine 40 to 80 milligrams (mg) daily for three weeks was effective in adult attention-deficit/hyperactivity disorder (ADHD). In a small placebo-controlled crossover study (n=21), improvements in the ADHD Rating Scale significantly favored atomoxetine after the second week of treatment; the average dose at week three was 76 mg daily. A 30% or greater decrease in ADHD symptoms was observed in 52% of patients during treatment (10% response with placebo) (Spencer et al, 1998b). However, several aspects of the study design were not included, and this response rate is less than that observed with methylphenidate or desipramine in some other studies.

d) Pediatric:

1) Acute Treatment

a) Oral atomoxetine has shown short-term efficacy for treating Attention- Deficit/Hyperactivity Disorder (ADHD) in over 600 children/adolescents (6 to 18 years of age) in open and placebo-controlled trials. The primary efficacy measure was ADHD Rating Scale-IV-Parent Version (ADHD RS), which has demonstrated validity in prior studies. Compared to placebo, oral atomoxetine in doses ranging from 1.2 to 1.8 milligrams/kilogram/day resulted in a significantly greater mean reduction in ADHD RS total score (p less than 0.05 for all studies); smaller doses failed to show consistent efficacy. Therapeutic doses of atomoxetine also generally but less consistently produced significant improvements on select subscales of the ADHD RS, namely scores of inattentiveness and hyperactivity/impulsivity. Other secondary measures showing improvements with atomoxetine included the Clinical Global Impressions-ADHD- Severity (CGI-ADHD-S) score (p less than 0.05 for all studies) and the Conners' Parent Rating Scale-Revised: Short Form (CPRS-R:S) (p less than or equal to 0.05 for all studies). Similar efficacy was reported in a subset analysis in school- age girls. Furthermore, no differences were reported between patients with and without previous psychostimulant treatment or among age groups (Biderman et al, 2002)(Spencer et al, 2002; Kratochvil et al, 2001a; Michelson et al, 2001b; Spencer et al, 2001a).

2) Maintenance Treatment

a) Pediatric patients with attention-deficit hyperactivity disorder (ADHD) who received maintenance treatment with atomoxetine hydrochloride (HCl) had significantly longer times to relapse compared to patients who received placebo. Patients (aged 6 to 15 years) who had a continuous response (defined as a Clinical Global Impressions of Severity of ADHD (CGI-ADHD-S) score of 2 or less and 25% or greater decrease from baseline in the ADHD rating scale-IV Parent Version with the hyperactivity/impulsive and inattentive subscales (ADHDRS-IV-Parent:Inv) total score) for approximately 4 weeks during an initial 10-week, open-label treatment phase were randomized to either their current atomoxetine HCl dose (n=292) of 1.2 to 1.8 milligrams/kilogram/day or placebo (n=124). Patients who experienced a continuous response for approximately 8 months with atomoxetine HCl therapy were randomized again to either their current atomoxetine HCl dose (n=81) or placebo (n=82). In both randomized, double-blind maintenance treatment phases, time to relapse (defined as the time to a CGI-ADHD-S score increase of 2 or more and a ADHDRS-IV-Parent:Inv total score of 90% or greater from baseline for 2 consecutive visits) was significantly longer in patients who received atomoxetine HCl compared to placebo (Prod Info STRATTERA(R) oral capsules, 2008).

b) Maintenance treatment with low-dose atomoxetine did not lead to a statistically significant difference in relapse rates compared to the higher, acute treatment dose in a randomized, double-blind, dose-response study in patients with Attention-Deficit/Hyperactivity Disorder (ADHD). Patients aged 6 to 16 years (n=229), who had a robust response to initial 7- to 9-week treatment with oral atomoxetine for ADHD, were randomized to either continue atomoxetine at the same dose (mean dose, 1.43 +/- 0.28 milligrams/kilogram (mg/kg) per day; n=116) or at a low dose of 0.5 mg/kg per day (n=113) for up to 8 months. Symptom severity was low and similar in both groups at randomization. The primary efficacy measure was relapse, which was determined using the investigator-administered and investigator-scored version of the ADHD Rating Scale (ADHD-RS) and was defined as a total ADHD-RS score of 90% of more of the original baseline value (prior to acute treatment) for 2 consecutive visits. At study conclusion, relapse rates did not differ significantly between the 2 groups (p=0.924), and were 2.6% (3/116) and 2.7% (3/113) for the continued same-dose and the low-dose groups, respectively. The mean change in the ADHD-RS total scores was similar for both groups (p=0.237), with a mean change of 1.1 +/- 10.8 (p=0.751) for the continued same-dose group and 3.1 +/- 10.4 (p=0.017) for the low-dose group. Among

secondary measures, there were no statistically significant differences between the 2 groups in mean changes in the Clinical Global Impressions-ADHD-Severity scores (p=0.078) and in the Child Health Questionnaire psychosocial summary scores (p=0.205). However, scores on the role emotion/behavior subscale were significantly lower (worsening) for patients in the low-dose group (-1.13 +/- 33.9) compared to patients in the continued same-dose group (5.75 +/- 29.9) (p=0.017). Among treatment-emergent adverse events, reports of affective lability were higher in the low-dose group (5/112 versus 0/116; p=0.027) while increases in heart rate (HR) were higher in the continued same-dose group (mean change in HR, 9 +/- 12.5 versus 5.2 +/- 13.9; p=0.013) (Newcorn et al, 2006).

4.5.A.2 Attention deficit hyperactivity disorder - Social phobia

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy; Pediatric, Evidence favors efficacy
Recommendation: Adult, Class IIb; Pediatric, Class IIb
Strength of Evidence: Adult, Category B; Pediatric, Category B
See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Atomoxetine was superior to placebo for the treatment of attention deficit hyperactivity disorder (ADHD) in adults with comorbid social anxiety disorder in a randomized, double-blind, placebo-controlled trial demonstrated (n=442) (Adler et al, 2009).
Atomoxetine was superior to placebo for the treatment of attention deficit hyperactivity disorder (ADHD) in pediatric and adolescent patients with comorbid generalized anxiety disorder (GAD) in a randomized, double-blind, placebo-controlled trial (n=176) (Geller et al, 2007).

c) Adult:

1) A multicenter, randomized, double-blind, placebo-controlled, parallel-group study demonstrated that atomoxetine was superior to placebo for the treatment of attention deficit hyperactivity disorder (ADHD) in adults with comorbid social anxiety disorder (SAD) (n=442). Adult patients, aged 18 to 65 years, with Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) diagnosis for ADHD and SAD were enrolled. Patients were randomized to receive either placebo (n=218) or atomoxetine (n=224) 40 milligrams (mg) daily in 2 divided doses for a minimum of 7 days, then 80 mg total daily dose (target dose) for a minimum of 7 days. After randomization, all patients entered a 2-week placebo lead-in period. At week 10, atomoxetine may be increased to 100 mg/day if significant residual symptoms remained. The study duration was 16 weeks. The primary outcome was the mean change from baseline to endpoint in the Conners' Adult ADHD Rating Scale: Investigator-Rates: Screening Version (CAARS:Inv:SV) Total ADHD symptoms score. The statistical analysis for the primary outcome was performed on the per protocol population of qualified patients (n=342). Qualified patients included those who had 25% or less improvement in social anxiety symptoms during the placebo lead-in phase. At baseline, the mean CAARS:Inv:SV total ADHD score was 29.6 +/- 10.4 and 31.2 +/- 9.4 in the atomoxetine and placebo group, respectively. The per protocol analysis revealed that atomoxetine was significantly superior to placebo in the mean CAARS:Inv:SV total ADHD score improvement from baseline (-8.7 +/- 10 vs -5.6 +/- 10.2; p less than 0.001). Similarly, the mean change in Liebowitz Social Anxiety Scale total score (LSAS) from baseline to endpoint was -22.9 +/- 25.3 and -14.4 +/-20.3 (p less than 0.001) in the atomoxetine and placebo groups, respectively. Common adverse effects included insomnia (17% vs 9%), nausea (16% vs 7.6%), dry mouth (15.6% vs 4.3%) and dizziness (7.5% vs 2.4%) in the atomoxetine vs placebo groups, respectively (Adler et al, 2009).

d) Pediatric:

1) Atomoxetine was superior to placebo for the treatment of attention deficit hyperactivity disorder (ADHD) in pediatric and adolescent patients with comorbid generalized anxiety disorder (GAD) in a multicenter, randomized, double-blind, parallel-design, placebo-controlled trial, with an optional, open-label extension period (n=176). Patients aged 8 to 17 years (yr), who met the DSM-IV criteria for ADHD and at least 1 of the following anxiety disorders (separation anxiety, generalized anxiety or social phobia) were enrolled. Study period I included a medication washout period for approximately 2 weeks. Study period II included a 2-week, placebo lead-in period to identify high placebo responders. After the placebo lead-in period, patients were randomized to receive atomoxetine (n=87; mean age 12.2 +/- 2.8 yr; 62.1% male) or placebo (n=89; age 11.8 +/- 2.5 yr; 67.4% male) twice daily for 12 weeks. The atomoxetine group received an initial dose of 0.8 milligrams/kilogram (mg/kg) daily, in 2 divided doses for 3 days, then a target dose of 1.2 mg/kg/day. At visit 6, atomoxetine could be increased to a maximum dose of 1.8 mg/kg/day for significant residual ADHD symptoms. The primary outcome was reduction of ADHD and GAD symptoms assessed by the mean change from baseline to endpoint in the Attention-Deficit/Hyperactivity Disorder Rating Scale-IV-Parent Version: Investigator Administered and Scored (ADHDRS-IV-PI) and the Pediatric Anxiety Rating Scale (PARS) total scores. Statistical analysis for the primary outcome was performed on the per protocol population of eligible patients (n=133) who had a baseline and at least 1 post baseline measurement and 25% or less reduction on the PARS total score during the blinded placebo lead-in period. The per protocol analysis revealed that atomoxetine was significantly superior to placebo for improvement of both the ADHDRS-IV-PI and PARS total scores. The mean change from baseline in the ADHDRS-IV-PI scale improvement was -10.5 vs -1.4 (95% CI for difference, -12.56 to -5.58; p less than 0.001) in the atomoxetine group compared with the

placebo group. The corresponding mean change in the PARS score was -5.5 and -3.2, respectively (95% CI for difference, -4.01 to -0.52; p less than 0.012). Subjects in the atomoxetine group had a higher response rate compared with cohorts in the placebo group (61.8% vs 12.1%; p less than 0.001). Atomoxetine was associated with higher incidence of decreased appetite (14.3% vs 3.8%), headache (14.3% vs 8.8%), upper abdominal pain (11.7% vs 5%) and vomiting (10.4% vs 5%) relative to placebo (Geller et al, 2007).

4.5.A.3 Nocturnal enuresis

a) Overview

FDA Approval: Adult, no; Pediatric, no
Efficacy: Adult, Evidence favors efficacy
Recommendation: Adult, Class IIb
Strength of Evidence: Adult, Category B

See Drug Consult reference: RECOMMENDATION AND EVIDENCE RATINGS

b) Summary:

Efficacy is limited to case report; a controlled trial is needed

c) Pediatric:

1) Atomoxetine shows efficacy in treatment of nocturnal enuresis. In a multicenter, randomized, double-blind, placebo-controlled, intent-to-treat (ITT) trial in which 87 patients (aged 6 to 18 years) received atomoxetine (n=44) or placebo (n=43) for 12 weeks. Atomoxetine was dosed at 0.5 milligrams/kilogram (mg/kg) daily for 3 days, followed by 1 mg/kg/day for the next 3 days and then increased to 1.5 mg/kg/day for the rest of the study. Doses were given twice daily, in the morning and late afternoon. The primary outcome measure was change from baseline in the number of dry nights as recorded on the Day Night Log-Parent Report. At baseline, the mean number of dry nights was 1.51 for the atomoxetine group and 1.01 for the placebo group (statistical difference not provided). Results were reported for 42 atomoxetine-treated and 41 placebo- treated patients. Patients treated with atomoxetine had an average increase of 1.47 dry nights per week compared with 0.60 for the placebo-treated patients (p=0.02). Headache was the most common adverse event occurring in 9 atomoxetine-treated patients and 4 placebo-treated patients (Sumner et al, 2003; Sumner et al, 2003a); (Anon, 2003; Anon, 2003a).

DRUGDEX® Evaluations

CARBAMAZEPINE

0.0 Overview

1) Class

a) This drug is a member of the following class(es):

Anticonvulsant
Antimanic
Dibenzazepine Carboxamide
Neuropathic Pain Agent

2) Dosing Information

a) Adult

1) Bipolar I disorder, acute manic and mixed episodes

a) ORAL; (extended-release capsules) initial, 400 mg/day ORALLY in 2 divided doses, may increase dosage 200 mg/day up to a max of 1600 mg/day as needed (Prod Info EQUETRO(TM) oral extended release capsul

2) Epilepsy, Partial, generalized, and mixed types

a) ORAL; (suspension) initial, 1 teaspoon (100 mg) ORALLY 4 times a day for the first week, may increase d mg/day at weekly intervals (usual max dosage 1000 mg/day in children 12-15 years of age, 1200 mg/day in p years of age, and up to 1600 mg/day in adults) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, TEGRETOL(R) XR extended-release oral tablets, 2003)

b) ORAL; (regular-release tablet) initial, 200 mg orally twice daily for the first week, may increase dose by 20 weekly intervals (usual max dosage 1000 mg/day in children 12-15 years of age, 1200 mg/day in patients ab age, and up to 1600 mg/day in adults) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, oral susp TEGRETOL(R) XR extended-release oral tablets, 2003)

c) ORAL; (extended-release tablet) initial, 200 mg ORALLY twice daily for the first week, may increase dosa at weekly intervals until optimal response is obtained (usual max dosage 1000 mg/day in children 12-15 year mg/day in patients above 15 years of age, and up to 1600 mg/day in adults) (Prod Info TEGRETOL(R) chewa oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

d) ORAL; maintenance, adjust dosage to the minimum effective level, usually 800-1200 mg/day ORALLY (P TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release ora

3) Glossopharyngeal neuralgia

a) ORAL; (suspension) initial, 50 mg ORALLY 4 times a day on the first day, may increase dosage by 200 m doses/day) as needed for pain control, do not exceed 1200 mg/day (Prod Info TEGRETOL(R) chewable oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

b) ORAL; (regular-release tablets) initial, 100 mg ORALLY every 12 hr, may increase by 200 mg/day (divide needed for pain control (max dose 1200 mg/day) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablet TEGRETOL(R) XR extended-release oral tablets, 2003)

c) ORAL; (extended-release tablets) initial, 100 mg ORALLY every 12 hr, may increase by 200 mg/day (divi as needed for pain control (max dose 1200 mg/day) (Prod Info TEGRETOL(R) chewable oral tablets, oral tab suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

d) maintenance, 400-800 mg/day ORALLY (range 200-1200 mg/day); at least once every 3 months throughc period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release ora

4) Psychotic disorder

a) 200 to 400 mg/day ORALLY in 3 to 4 divided doses, may increase dosage gradually at weekly intervals u mg/day as needed

5) Trigeminal neuralgia

a) ORAL; (suspension) initial, 50 mg ORALLY 4 times a day on the first day, may increase dosage by 200 m doses/day) as needed for pain control, do not exceed 1200 mg/day (Prod Info TEGRETOL(R) chewable oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

b) ORAL; (regular-release tablets) initial, 100 mg ORALLY every 12 hr, may increase by 200 mg/day (divide needed for pain control (max dose 1200 mg/day) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablet TEGRETOL(R) XR extended-release oral tablets, 2003)

c) ORAL; (extended-release tablets) initial, 100 mg ORALLY every 12 hr, may increase by 200 mg/day (divi as needed for pain control (max dose 1200 mg/day) (Prod Info TEGRETOL(R) chewable oral tablets, oral tab suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

d) maintenance, 400-800 mg/day ORALLY (range 200-1200 mg/day); at least once every 3 months throughc period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release ora

b) Pediatric

1) Epilepsy, Partial, generalized, and mixed types

a) ORAL; children up to 6 years of age (suspension), initial, 10-20 mg/kg/day ORALLY in 4 divided doses, m dosage by 100 mg/day at weekly intervals as needed, do not exceed 35 mg/kg/day (Prod Info TEGRETOL(R tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)

b) ORAL; children up to 6 years of age (regular-release tablet), initial, 10-20 mg/kg/day ORALLY in 2 or 3 div increase dosage by 100 mg/day at weekly intervals as needed, do not exceed 35 mg/kg/day (Prod Info TEGR chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 2003)
c) ORAL; children up to 6 years of age, maintenance, adjust to the minimum effective dosage, usually 250-3 max 400 mg/day or 35 mg/kg/day) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, oral suspens (R) XR extended-release oral tablets, 2003)
d) ORAL; children 6-12 years of age (suspension), initial, 0.5 teaspoon (50 mg) ORALLY 4 times daily (total mg), may increase dosage by 100 mg/day at weekly intervals as needed, do not exceed 1000 mg/day (Prod (R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release oral tablets, 20
e) ORAL; children 6-12 years of age (regular-release tablet), initial, 100 mg twice daily, may increase dosage weekly intervals as needed, doses greater than 200 mg/day should be given in 3 to 4 divided doses, do not e mg/day (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR ex oral tablets, 2003)
f) ORAL; children 6-12 years of age (extended-release tablet), initial, 100 mg twice daily, may increase dosa at weekly intervals as needed, doses greater than 200 mg/day may continue to be given twice daily, do not e mg/day (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR ex oral tablets, 2003)
g) ORAL; children 6-12 years of age, maintenance, adjust to the minimum effective dosage, usually 400-800 TEGRETOL(R) chewable oral tablets, oral tablets, oral suspension, TEGRETOL(R) XR extended-release ora

3) Contraindications
a) bone marrow depression, history of previous (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, TEGRETOL(R)-XR extended-release oral tablets, 2007)
b) concomitant use of an MAOI, or use within 14 days of discontinuing an MAOI (Prod Info TEGRETOL(R) oral chewa tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)
c) concomitant use of nefazodone; decreased nefazodone plasma levels may reduce drug effectiveness (Prod Info TE chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)
d) hypersensitivity to carbamazepine or tricyclic compounds (Prod Info TEGRETOL(R) oral chewable tablets, tablets, Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

4) Serious Adverse Effects
a) Acute intermittent porphyria
b) Acute renal failure
c) Agranulocytosis
d) Angioedema
e) Aplastic anemia
f) Atrioventricular block
g) Bone marrow depression
h) Cardiac dysrhythmia
i) Congestive heart failure
j) Drug-induced eosinophilia
k) Hepatitis
l) Hypocalcemia
m) Hyponatremia
n) Leukocytosis
o) Leukopenia
p) Nephrotoxicity
q) Pancytopenia
r) Stevens-Johnson syndrome
s) Syncope
t) Thrombocytopenia
u) Toxic epidermal necrolysis

5) Clinical Applications
a) FDA Approved Indications
1) Bipolar I disorder, acute manic and mixed episodes
2) Epilepsy, Partial, generalized, and mixed types
3) Glossopharyngeal neuralgia
4) Trigeminal neuralgia
b) Non-FDA Approved Indications
1) Psychotic disorder

Carbamazepine

C) Physicochemical Properties

1) Molecular Weight

a) 236.27 (Fleegler & Carolyn A., 1986)

2) pKa

a) 7 (Anon, 1980) (Goodman and Gilman, 1980)

1.2 Storage and Stability

A) Suspension

1) Do not store in temperatures above 86 degrees F (30 degrees C) and dispense in a tight, light-resistant contai Tegretol(R), 2002b). Shake well before using. CARBAMAZEPINE suspension (commercially available) repackage mL aliquots in amber glass vials, polypropylene vials, amber polypropylene syringes and in 2-mL aliquots in ambe syringes were found to be stable for 8 weeks at room temperature under constant fluorescent lighting. These repa suspensions retained at least 86% of the initial carbamazepine concentration (Lowe et al, 1989).

2) Tegretol suspension(R) (carbamazepine) should not be administered simultaneously with other liquid medicati (Prod Info Tegretol(R), 2002b). In a case report, a man passed an orange rubbery mass after ingesting Tegretol S immediately followed by Thorazine(R) solution (chlorpromazine). The manufacturer reports that mixing Tegretol s chlorpromazine solution (generic and brand name) results in the precipitation of a rubbery orange mass.

B) Tablet

1) Do not store tablets above 86 degrees F (30 degrees C). Protect from moisture and dispense in tight containe Tegretol(R), 2002b).

2) The Food and Drug Administration (FDA) found that carbamazepine, in both its generic and brand-name forms third or more of its potency if stored in humid conditions. Tablets exposed continuously to 97% humidity at room t weeks hardened and dissolved poorly. Patients should be instructed to keep their carbamazepine supply in a tigh prescription container and in a dry location, away from showers, bathrooms, and humidifiers (Anon, 1990).

C) Tablet, Chewable

1) Do not store above 86 degrees F (30 degrees C). Protect from light and moisture; do not keep medicine in the chewable tablets should be dispensed in a tight, light-resistant container (Prod Info Tegretol(R), 2002b).

D) Tablet, Extended Release

1) EXTENDED RELEASE TABLETS

a) Tegretol(R) extended-release tablets should be stored at controlled room temperature between 15 and 30 (59 to 86 degrees Fahrenheit) and protected from moisture. Dispense in a tight container (Prod Info Tegretol(

b) Carbatrol(R) extended-release capsules should be stored at controlled room temperature between 15 and Celsius (59 to 77 degrees Fahrenheit) and protected from moisture. Dispense in a tight, light-resistant contai Carbatrol(R), 2002).

c) Equetro(TM) extended-release capsules should be stored at controlled room temperature between 15 and Celsius (59 to 86 degrees Fahrenheit) and protected from light. (Prod Info Equetro(TM) extended release cap

E) Extemporaneous Formulation - Oral route

1) Carbamazepine oral suspension 200 mg/5 mL was stable for 90 days when prepared with the following vehicle degrees C in amber bottles:

Sucrose	95 g
Sorbitol 70%	49 mL
Glycerin	8.5 mL
Saccharin sodium	170 mg
Methylparaben	340 mg
Methylcellulose 400	4.7 g
Methylcellulose 4000	2.1 g
FD&C Yellow	510 mg
Lemon Lime Flavor	1 mL
Purified Water	QS 500 mL

2) This formulation is easier to pour and produces less foam than simple syrup formulations (Burkart et al, 1981).

3) A carbamazepine 40 mg/mL suspension, 120 mL, may be prepared using 24 carbamazepine 200 mg tablets (and a sufficient quantity of simple syrup to bring the volume to 120 mL. This suspension should be labeled "shake "refrigerate" and is stable for 90 days (Burkart et al, 1981).

4) A carbamazepine 50 mg/mL suspension, 120 mL, may be prepared using 30 carbamazepine 200 mg tablets (Basel), distilled water to levigate, Cologel(R) (methylcellulose; Lilly) 40 mL, and a sufficient quantity of a 2:1 simpl syrup mixture to bring the volume to 120 mL. This suspension should be labeled "shake well" and "refrigerate" an days (Anon, 1987).

5) The palatability of an extemporaneously prepared oral suspension of carbamazepine was reported (Bloomer e suspension was prepared by combining fifty 200 mg carbamazepine tablets (Tegretol(R)) with HSC suspending v syrup 300 mL/L, methylcellulose 1% gel 700 mL/L, and sodium benzoate 0.14%) to yield a volume of 500 mL of s was flavored with banana, tutti-frutti, or grape. A cherry-mint suspension was prepared by using Tegretol(R) in ch The final suspension consisted of 20 mg/mL of carbamazepine. The cherry-mint formulation was judged least pal volunteers, with no trend in preference between the unflavored suspension and other flavors (banana, tutti-frutti, g

F) Extemporaneous Formulation - Rectal route

1) Carbamazepine has also been formulated into a gel for rectal administration without the addition of sorbitol to the associated premature defecation. The preparation consisted of:

2) 200 milligrams (mg) of carbamazepine powder dissolved in 5 milliliters of 20% alcohol and then incorporated w methylhydroxyethylcellulose 250 mg

3) This mixture may be dispensed in syringes as 200 mg doses for rectal administration. The syringes should be degrees Centigrade prior to administration to maintain adequate gelation and discourage microbial growth (Broua

4) The total absorption of a carbamazepine suspension following rectal and oral administration was similar in a a volunteers (Neuvonen PJ & Tokola O, 1987); however, slower absorption was associated with the rectal route. Th mixture consisted of:

5) Carbamazepine 20 milligrams/mL, Sorbitol 300 milligrams/mL, and Water.

1.3 Adult Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage in Geriatric Patients

Dosage Adjustment During Dialysis

Dosage in Other Disease States

1.3.1 Normal Dosage

Oral route

Restless legs syndrome

Tinnitus

1.3.1.A Oral route

Bipolar I disorder, acute manic and mixed episodes

Epilepsy, Partial, generalized, and mixed types

Trigeminal neuralgia

1.3.1.A.1 Bipolar I disorder, acute manic and mixed episodes

a) The recommended initial dose for the treatment of acute manic and mixed episodes associated with b 200 milligrams (mg) twice daily (400 mg/day), and may be taken with or without food. The dose should b increments of 200 mg/day to achieve the optimum clinical response; doses above 1600 mg/day have no Equetro(TM) capsules may be opened and the beads sprinkled over applesauce or other similar food pr Do not crush or chew capsules (Prod Info Equetro(TM) extended release capsules, 2004).

b) The longer-term or prophylactic use of Equetro(TM) capsules for the treatment of bipolar mania has r Physicians who choose to prescribe this medication for extended periods of time should re-evaluate the benefits of the drug for the individual patient at regular intervals (Prod Info Equetro(TM) extended releas

c) Most patients with bipolar disorder have responded to carbamazepine 600 to 1600 milligrams (mg)/da

divided doses, although some patients have required doses as high as 2000 to 3000 mg/day (Ballenger, cycling patients usually require higher doses of 1000 to 2000 mg daily (Perry et al, 1991).

1.3.1.A.2 Epilepsy, Partial, generalized, and mixed types

a) The initial recommended dosage is 200 milligrams (mg) twice a day (tablets or sustained-release tabl four times a day (suspension). The dosage is then increased by adding 200 mg per day in weekly interva daily regimen for sustained-release tablets or a 3 or 4 times a day regimen for conventional tablets or su desired clinical response is obtained (Prod Info Tegretol(R), 2002c). Usual average dose ranges are 17 t mg/kilogram/day (Anon, 1975a). Usual effective maintenance doses reported by the manufacturer are 8((Prod Info Carbatrol(R), 20029)(Prod Info Tegretol(R), 2002c). This medication should be taken with fooc

b) Dosage should generally not exceed 1200 milligrams (mg)/day in adults, although doses of up to 160 been used in rare instances (Prod Info Tegretol(R), 2002c). Serum drug levels should guide dosage requ

1.3.1.A.3 Trigeminal neuralgia

a) The recommended initial dose is 100 milligrams (mg) twice a day of carbamazepine tablets or extend (Prod Info Tegretol(R), 2002c) or one carbamazepine 200 mg extended-release capsule per day (Prod In 2002) or 1/2 teaspoonful 4 times daily of carbamazepine suspension (Prod Info Tegretol(R), 2002c). This increased by up to 200 mg a day using increments of 100 mg every 12 hours for tablets or sustained-rele Info Tegretol(R), 2002c) or by a single 200 mg extended-release capsule (Prod Info Carbatrol(R), 2002) teaspoonsful of carbamazepine suspension administered in divided doses 4 times a day (Prod Info Tegr Effective maintenance doses for most patients have been 400 to 800 mg/day. Do not exceed 1200 mg/d Carbatrol(R), 2002; Prod Info Tegretol(R), 2002c).

b) At 3-month intervals attempts should be made to reduce the dose of the drug to the minimum effectiv discontinue the drug (Prod Info Tegretol(R), 2002c).

1.3.1.B Restless legs syndrome

See Drug Consult reference: RESTLESS LEG SYNDROME - DRUGS OF CHOICE

1.3.1.C Tinnitus

See Drug Consult reference: DRUG THERAPY OF TINNITUS

1.3.1.D IMPORTANT NOTE

1) The dosage of carbamazepine should be adjusted to meet the needs of the individual patient based upon and monitoring of blood levels (Prod Info Tegretol(R), 2002c).

2) To convert patients from regular carbamazepine to the sustained-release formulation (Tegretol(R)-XR or C same total daily milligram dose should be given (Mirza et al, 1998; Prod Info Carbatrol(R), 2002; Prod Info Te When using other formulations besides the Tegretol(R)-XR or Carbatrol(R), please consult the manufacturer's recommendations. The carbamazepine extended release tablets should never be crushed or chewed and sh whole. Damaged tablets or tablets without a release portal should not be consumed (Prod Info Tegretol(R), 2

3) Tegretol suspension(R) (carbamazepine) should not be administered simultaneously with other liquid mec diluents (Prod Info Tegretol(R), 2002c).

4) The suspension will produce higher peak levels than the same dose given as a tablet; therefore, patients the same number of milligrams/day in smaller, more frequent doses (Prod Info Tegretol(R), 2002c).

1.3.1.E SINGLE DAILY DOSE

1) Single daily carbamazepine doses (mean, 13.7 milligrams/kilogram/day) for 4 weeks maintained carbama epoxide metabolite levels in the therapeutic range, but higher fluctuations of serum carbamazepine levels occ compared to divided dose regimens twice a day, three times daily). Adverse effects or loss of efficacy were n once daily dosing; however, the authors suggest further long-term studies (Ghose et al, 1983; Ghose et al, 19

1.3.1.F Oral loading doses of carbamazepine 8 milligrams (mg)/kilogram given as the suspension or as tablets h (Cohen et al, 1998). Therapeutic concentrations (range=7.1 to 9.9 mg/liter) were reached within 2 hours with the s within 5 hours with the tablets. The 6 patients in this study tolerated it well.

1) WITHDRAWAL OF THERAPY

a) SUMMARY

1) The length of time for and method of anticonvulsant withdrawal is not considered to be a prime fa determining the prognosis of the patient. However, sudden withdrawal of medication may precipitate therefore medication should be withdrawn gradually over a period of at least 3 months. Excellent res achieved by withdrawing each anticonvulsant over a period of 9 months, with downward increments month intervals.

b) The risk factors associated with withdrawal of anticonvulsants in 92 patients who had been free of se with single agent therapy were evaluated (Callaghan et al, 1988). The dose of each anticonvulsant was r at intervals of 2 weeks (1 unit equivalent to 200 milligrams of carbamazepine or valproic acid, or 100 mill phenytoin), with a mean follow-up period of 26 months (range, 6 to 62 months). Relapse occurred in 31 p patients remaining free of seizures (relapse rate 33.7%).

1.3.2 Dosage in Renal Failure

A) No dosage reduction is required in patients with renal failure (Bennett et al, 1994).

1.3.3 Dosage in Hepatic Insufficiency

A) Carbamazepine should not be used in cases of aggravated liver dysfunction or active liver disease (Prod Info

2002c).

1.3.4 Dosage in Geriatric Patients

A) The pharmacokinetics of a single 400-milligram carbamazepine dose in 6 young and 5 elderly patients were c (Hockings et al, 1986). No age-related changes in pharmacokinetics or psychomotor function were noted. Dosage not recommended.

1.3.5 Dosage Adjustment During Dialysis

A) No dosage supplementation is required in patients following hemodialysis (Bennett et al, 1994).

B) The half life and apparent clearance of carbamazepine were not changed during hemodialysis in one woman carbamazepine 200 milligrams twice daily. No dosage adjustments are required (Kandrotas et al, 1989).

1.3.6 Dosage in Other Disease States

A) MYOCARDIAL INFARCTION

1) A case of carbamazepine toxicity (carbamazepine levels 18.2 to 21.5 micrograms/milliliter) was reported i two days after cardiothoracic surgery and intraoperative myocardial infarction; levels normalized 10 days afte dosage adjustment (Wright et al, 1990). The authors postulate that the change in levels may relate to change binding and decreased hepatic clearance resulting from both cardiopulmonary bypass surgery and myocardia specific dosage adjustment was recommended.

1.4 Pediatric Dosage

Normal Dosage

Dosage in Renal Failure

Dosage in Hepatic Insufficiency

Dosage Adjustment During Dialysis

1.4.1 Normal Dosage

Oral route

Migraine; Prophylaxis

1.4.1.A Oral route

1.4.1.A.1 Epilepsy, Partial, generalized, and mixed types

a) For children under the age of 6 years, the initial recommended dosage is 10 to 20 milligrams/kilogram administered in divided doses 2 or 3 times a day (chewable or conventional tablets) or 4 times a day (su dose may then be increased in weekly intervals to obtain the desired clinical response; maintenance dos either 3 or 4 times a day for both tablets and suspension. The maximum recommended dose is 35 mg/kg Tegretol(R), 2002c).

b) For children ages 6 to 12 years, the initial recommended dosage is 100 milligrams (mg) twice a day (sustained-release tablets) or 50 mg (one-half teaspoonful) 4 times a day (suspension). The dosage is the adding 100 mg per day in weekly intervals using a twice daily regimen for sustained-release tablets or a regimen for conventional tablets or suspension until the desired clinical response is obtained. The usual dosage is 400 to 800 mg a day; the maximum daily dosage is generally 1000 mg/day or less (Prod Info T 2002c).

c) For children over 12 years of age, the initial recommended dosage is 200 milligrams (mg) twice a day sustained-release tablets) or 100 mg (one teaspoonful) four times a day (suspension). The dosage is the adding 200 mg per day in weekly intervals using a twice daily regimen for sustained-release tablets or a regimen for conventional tablets or suspension until the desired clinical response is obtained (Prod Info T 2002c). Usual effective maintenance doses reported by the manufacturer are 800 to 1000 mg/day in chil years and up to 1200 mg in patients over 15 years old (Prod Info Tegretol(R), 2002c). This medication sh food.

d) In a review of dose-plasma concentration relationships in 196 children, usual pediatric dosage recom to 30 milligrams/kilogram/day were insufficient to achieve therapeutic serum concentrations in many pati on monotherapy. Use of higher dosages requires careful evaluation of efficacy and potential toxicity (Suz

e) Carbamazepine oral suspension was adequately absorbed from the GI tract of newborn infants with a disorders (MacKintosh et al, 1987). All infants were receiving other anticonvulsant agents in addition to c

Maintenance therapy with carbamazepine doses of 5 to 8 milligrams/kilogram orally twice a day resulted carbamazepine serum concentrations in the therapeutic range (10 to 40 micromoles/liter). An elimination from 7.2 to 15.2 hours was observed; carbamazepine oral suspension may be useful for the treatment of SEIZURES, and further study is required to evaluate its efficacy in this age group.

1.4.1.B Migraine; Prophylaxis

1) Carbamazepine 10 to 20 milligrams/kilogram/day divided into 2 daily doses has been used for migraine he prophylaxis (Hamalainen, 1998). Doses should be increased slowly.

1.4.1.C IMPORTANT NOTE

1) The dosage of carbamazepine should be adjusted to meet the needs of the individual patient based upon and monitoring of blood levels (Prod Info Tegretol(R), 2002c).

2) Loss of efficacy has been reported when carbamazepine tablets were exposed to humid conditions (Anon

3) Tegretol suspension(R) (carbamazepine) should not be administered simultaneously with other liquid mec diluents (Prod Info Tegretol(R), 2002c). The suspension will produce higher peak levels than the same dose therefore, patients should be started on lower doses of the suspension and increased slowly (Prod Info Tegre

1.4.1.D MAXIMUM DOSE

1) Dosage of tablets should not exceed 1000 milligrams daily in children 6 to 15 years and 1200 milligrams c or older (Prod Info Tegretol(R), 2002c).

2) The recommended maximum dose of carbamazepine suspension is 1000 milligrams/day in children 6 to 1 1200 milligrams/day in children over 15 years (Prod Info Tegretol(R), 2002c).

1.4.1.E WITHDRAWAL OF THERAPY

1) Withdrawal of anticonvulsant medication in children free of seizures for 2 to 4 years appears to be safe, w children remaining free of seizures after medication withdrawal (Shinnar et al, 1985). In a prospective study, a medications were discontinued in 88 epileptic children who had not had a seizure for 2 to 4 years. Anticonvul withdrawn gradually over 2 to 3 months. The mean age at the time of the first seizure was 5 years (0 to 16 ye mean age at the time of the last seizure being 8.7 years (0 to 22 years). The mean duration of seizures was 3 to 17.4 years). Sixty-six (75%) patients remained free of seizures after withdrawal of anticonvulsants, and the of remaining seizure-free was 79% at 12 months, 77% at 24 months, and 74% at 30 months. The risk of recu was highest within the first few months of initiation of withdrawal. Of 22 patients with recurrence of seizures, 9 the first 3 months, 13 in the first 6 months and 18 (82%) within the first year of withdrawal. The type of seizure and EEG characteristics were considered important in predicting the outcome of anticonvulsant withdrawal. It that anticonvulsants be discontinued in children with good prognostic factors after a 2- year period without se

1.4.2 Dosage in Renal Failure

A) No dosage reduction is required in patients with renal impairment (Bennett et al, 1994).

1.4.3 Dosage in Hepatic Insufficiency

A) DOSAGE IN HEPATIC INSUFFICIENCY

1) Carbamazepine should not be used in cases of aggravated liver dysfunction or active liver disease (Prod 2002c).

1.4.4 Dosage Adjustment During Dialysis

A) No dose supplementation is required in patients following hemodialysis (Bennett et al, 1994).

B) The half life and apparent clearance of carbamazepine were not changed during hemodialysis in one woman carbamazepine 200 milligrams twice daily. No dosage adjustments are required (Kandrotas et al, 1989).

2.0 Pharmacokinetics

Drug Concentration Levels

ADME

2.2 Drug Concentration Levels

A) Therapeutic Drug Concentration

1) Seizure disorder, 4 to 12 mcg/mL (16 to 50 mmol/L) (Prod Info Tegretol(R), 2002a; Rapeport, 1985).

a) Monitoring of free CARBAMAZEPINE concentrations is indicated in conditions associated with altered bin (Perucca, 1984).

b) Saliva and plasma carbamazepine, total and free levels, have a strong and highly significant correlation (r respectively) (Gorodischer et al, 1997).

c) According to plasma levels, no dosage adjustments are needed during the gestational period (Tomson et al, 1985).

d) Urine levels correlate closely with free plasma levels (Elmquist et al, 1991).

e) Extended-release capsules taken every 12 hours provide steady state plasma levels comparable to imme tablets taken every 6 hours at the same milligram dose (Prod Info Carbatrol(R), 2002a).

f) Some researchers advocate the need for monitoring the carbamazepine-10, 11-epoxide metabolite (Potter

1998).
2) Antidepressant/Antimania, no correlation (Post et al, 1983).
B) Time to Peak Concentration
1) Oral, immediate release: 4 to 5 hours (Prod Info Tegretol(R), 2002a; Sillanpaa, 1981).
2) Oral, chew tablets: 6 hours (Prod Info Tegretol(R), 1990).
3) Oral, extended release: 3 to 12 hours (Prod Info Tegretol(R), 2002a; Prod Info Carbatrol(R), 2002a).
4) Oral, suspension: 1.5 hours (Prod Info Tegretol(R), 2002a).

2.3 ADME

Absorption

Distribution

Metabolism

Excretion

Elimination Half-life

Extracorporeal Elimination

2.3.1 Absorption
A) Bioavailability
1) Oral, tablet: 70% to 79% (Hvidberg & Dam, 1976; Levy et al, 1975).
2) Oral, solution: 95.9% (Levy et al, 1975).
3) Oral, extemporaneously formulated suspension: 94.5% (Bloomer et al, 1987).
a) An extemporaneously prepared oral suspension of carbamazepine had a mean bioavailability of 94.5 tablet formulation. However, peak serum concentrations occurred earlier and were higher as compared t formulation; peak serum concentrations occurred in 3.8 hours and 11.8 hours following administration of tablet, respectively. These data suggest that more frequent administration of lower doses of the suspens indicated to avoid toxicity, as compared to the tablet formulation (Bloomer et al, 1987).
B) Effects of Food
1) increases bioavailability (Levy et al, 1975).

2.3.2 Distribution
A) Distribution Sites
1) Protein Binding
a) 76% (Prod Info Carbatrol(R), 2002a; Prod Info Tegretol(R), 2002a).
1) Unbound drug decreases with increasing total concentrations (Hooper et al, 1975).
2) Tissues and Fluids
a) Cerebrospinal fluid (CSF), the CSF/serum ratio 0.22 (Prod Info Tegretol(R), 2002a).
B) Distribution Kinetics
1) Volume of Distribution
a) 0.8 to 2 L/kg (Graves et al, 1985; Hvidberg & Dam, 1976; Rawlins et al, 1975).

2.3.3 Metabolism
A) Metabolism Sites and Kinetics
1) Liver, 98% (Levy et al, 1975)
a) Carbamazepine induces its own metabolism during prolonged treatment, and is complete in 3 to 5 we dosing regimen (Prod Info Tegretol(R), 2002a).
b) With increasing carbamazepine doses in children, a dose-dependent autoinduction process was seer al, 1997).
c) Metabolism occurs via cytochrome P450 3A4 (Prod Info Tegretol(R), 2002a).
B) Metabolites
1) Carbamazepine-10,11-epoxide, active (Bertilsson, 1978; Tomson et al, 1983)
a) Carbamazepine-10,11-epoxide/CARBAMAZEPINE ratios are higher in infants and preschool children 1985a).
b) Epoxide metabolite exists in a 0.1 to 0.2 ratio to CARBAMAZEPINE 120 hours after administration (E 1975). In 1 study, the carbamazepine epoxide to carbamazepine ratio in serum was 0.12 during monothe et al, 1998). This ratio rose to 0.14 when phenobarbital was added, to 0.18 when phenytoin was added, both phenobarbital and and phenytoin were added. These increased ratios were seen as carbamazepine declined.
c) The epoxide metabolite is partly responsible for CARBAMAZEPINE intoxication (Hvidberg & Dam, 19

d) Higher epoxide levels are seen in patients receiving concomitant valproate or lamotrigine therapy (Pc 1998).

2) 9 hydroxymethyl-10-carbamoyl acridan, active (Wad et al, 1997).

2.3.4 Excretion

A) Kidney

1) Renal Excretion (%)

a) 72% (Prod Info Tegretol(R), 2002a)

B) Total Body Clearance

1) 3.85 L/hr (Graves et al, 1985).

a) Clearance in children was reported to be 2.37 liters/hour (Iribarnegaray et al, 1997). Clearance increa increasing doses. Clearance decreases with increasing age (Gray et al, 1998).

b) Patients 70 years and older had a decreased clearance by approximately 70% (Graves et al, 1985).

C) Other

1) Feces, 28% (Prod Info Tegretol(R), 2002a; Hvidberg & Dam, 1976).

2.3.5 Elimination Half-life

A) Parent Compound

1) ELIMINATION HALF-LIFE

a) 12 to 17 hours (Prod Info Carbatrol(R), 2002a; Prod Info Tegretol(R), 2002a; Hvidberg & Dam, 1976)

1) The half-life is 25 to 65 hours with single doses (Prod Info Tegretol(R), 2002a; Hvidberg & Dam,

2) Newborn infants, receiving the drug transplacentally, have half-life values within the same range multiple doses (Rane et al, 1975).

B) Metabolites

1) 10,11-epoxide metabolite, 6.1 hours (Tomson et al, 1983; Bertilsson & Tomson, 1986).

2.3.6 Extracorporeal Elimination

A) Hemodialysis

1) Dialyzable: Yes, 53.6 mL/min (Lee et al, 1980)

a) Clearance ranges from 40 to 64 mL/min (mean 53.6 mL/min). Calculated total drug removed over a 4 period ranges from 40.5 to 53.1 mg (Lee et al, 1980).

B) Peritoneal

1) Dialyzable: No (Bradley et al, 1984)

a) Carbamazepine is minimally dialyzable during peritoneal dialysis (Bradley et al, 1984).

3.0 Cautions

Contraindications

Precautions

Adverse Reactions

Teratogenicity/Effects in Pregnancy/Breastfeeding

Drug Interactions

3.0.A Black Box WARNING

1) Oral (Tablet; Tablet, Chewable; Suspension; Tablet, Extended Release; Capsule, Extended Release)

Serious Dermatologic Reactions and HLA-B*1502 Allele

Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrolysis (TEN) and Stevens syndrome (SJS), have been reported during treatment with carbamazepine. These reactions are estimated to per 10,000 new users in countries with mainly Caucasian populations, but the risk in some Asian countries is about 10 times higher. Studies in patients of Chinese ancestry have found a strong association between the r SJS/TEN and the presence of HLA-B*1502, an inherited allelic variant of the HLA-B gene. HLA-B*1502 is fou exclusively in patients with ancestry across broad areas of Asia. Patients with ancestry in genetically at-risk p be screened for the presence of HLA-B*1502 prior to initiating treatment with carbamazepine. Patients testing allele should not be treated with carbamazepine unless the benefit clearly outweighs the risk.

Aplastic Anemia and Agranulocytosis

Aplastic anemia and agranulocytosis have been reported in association with the use of carbamazepine. Data based case control study demonstrate that the risk of developing these reactions is 5-8 times greater than in population. However, the overall risk of these reactions in the untreated general population is low, approxima per one million population per year for agranulocytosis and two patients per one million population per year fo Although reports of transient or persistent decreased platelet or white blood cell counts are not uncommon in the use of carbamazepine, data are not available to estimate accurately their incidence or outcome. However

of the cases of leukopenia have not progressed to the more serious conditions of aplastic anemia or agranulc
Because of the very low incidence of agranulocytosis and aplastic anemia, the vast majority of minor hemato
observed in monitoring of patients on carbamazepine are unlikely to signal the occurrence of either abnormal
complete pretreatment hematological testing should be obtained as a baseline. If a patient in the course of tre
low or decreased white blood cell or platelet counts, the patient should be monitored closely. Discontinuation
be considered if any evidence of significant bone marrow depression develops (Prod Info TEGRETOL(R) ora
tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007).

3.1 Contraindications

A) bone marrow depression, history of previous (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, TEGRETOL(R)-XR extended-release oral tablets, 2007)

B) concomitant use of an MAOI, or use within 14 days of discontinuing an MAOI (Prod Info TEGRETOL(R) oral chew tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

C) concomitant use of nefazodone; decreased nefazodone plasma levels may reduce drug effectiveness (Prod Info T chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

D) hypersensitivity to carbamazepine or tricyclic compounds (Prod Info TEGRETOL(R) oral chewable tablets, tablets, Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

3.2 Precautions

A) dermatologic reactions, serious and sometimes fatal (eg, Stevens-Johnson syndrome, toxic epidermal necrolysis) reported; discontinue drug if signs or symptoms develop (Prod Info TEGRETOL(R) oral chewable tablets, tablets, susp Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

B) HLA-B*1502-positive (most common in Asians including South Asian Indians); increased risk of Stevens-Johnson toxic epidermal necrolysis; test for HLA-B*1502 and if positive do not initiate carbamazepine (Prod Info TEGRETOL(R tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

C) adverse hematologic drug reaction, history of; increased risk of bone marrow suppression (Prod Info TEGRETOL(tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

D) (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR exte tablets, 2007a)

E) atypical absence seizures or other mixed seizure disorders, history of; may increase generalized convulsion freque TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral

F) cardiac conduction disturbance, history; increased risk of atrioventricular heart block (Prod Info TEGRETOL(R) ora tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

G) cardiac damage (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL release oral tablets, 2007)

H) elderly patients; may cause confusion or agitation (Prod Info TEGRETOL(R) oral chewable tablets, tablets, susper Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

I) electrocardiogram abnormalities; increased risk of atrioventricular heart block (Prod Info TEGRETOL(R) oral chewa suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

J) hypersensitivity drug reactions, history of; risk of cross-sensitivity (Prod Info TEGRETOL(R) oral chewable tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

K) hepatic damage (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL release oral tablets, 2007)

L) hepatic porphyria; acute attacks have been reported and use should be avoided (Prod Info TEGRETOL(R) oral che tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

M) interrupted courses of carbamazepine therapy, history of (Prod Info TEGRETOL(R) oral chewable tablets, tablets, Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

N) increased intraocular pressure; exacerbation of condition due to cholinergic antagonism (Prod Info TEGRETOL(R) tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

O) mental illness, history; risk of latent psychosis activation (Prod Info TEGRETOL(R) oral chewable tablets, tablets, Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007)

P) renal damage (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R release oral tablets, 2007)

Q) suicidality, increased risk of; based on data analysis of 199 placebo-controlled studies of 11 antiepileptic drugs, sm occurred as early as 1 week after starting therapy and continued to at least 24 weeks (US Food and Drug Administrati

R) women of childbearing potential; teratogenic effects have been reported and efficacy of oral contraceptives may be Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release

3.3.1 Cardiovascular Effects

Cardiac dysrhythmia

Cardiovascular finding

Congestive heart failure

Heart disease

Vasculitis

3.3.1.A Cardiac dysrhythmia

1) Summary

a) Carbamazepine may suppress both atrioventricular conduction and ventricular automaticity shortly af
administration. bradyarrhythmia and av block occur at therapeutic or mildly elevated carbamazepine bloc
most frequently reported in elderly women. sinus tachycardia has also been reported in overdose situatic
Tegretol(R), 2002b; Kasarskis et al, 1992).

2) Literature Reports

a) Three cases of stokes-adams attacks caused by intermittent AV block, SA block with junctional escap
intermittent asystole secondary to carbamazepine were described (Boesen et al, 1983). Conduction distu
after withdrawal of therapy and recurrence of symptoms was noted after resumption of treatment in 2 pa
pacemaker insertion. Since epileptic seizures and Stokes-Adams attacks are at times difficult to different
suggested that if syncope or changes in seizure patterns occur in patients treated

b) Cardiac conduction abnormalities were reported in an isolated case involving a 13-month-old child, d
serum levels of both carbamazepine and 10,11-epoxide metabolite (Weig & Pollack, 1993). The patient h
tuberous sclerosis and cardiac rhabdomyoma. After two weeks of therapy with carbamazepine, the child
irregular heart rate; EKG and Holter monitor showed intermittent periods of Mobitz type II second-degree
block and occasional premature ventricular beats. Carbamazepine was discontinued with resolution of ca
irregularities.

3.3.1.B Cardiovascular finding

1) Cardiovascular effects reported in patients receiving carbamazepine include AV block, arrhythmias, conge aggravation of hypertension, hypotension, syncope and collapse, edema, vasculitis, aggravation of coronary primary thrombophlebitis, and recurrence of thrombophlebitis. Some of these cardiovascular effects have res

3.3.1.C Congestive heart failure

1) Summary

a) One case of congestive heart failure associated with carbamazepine therapy was reported (Prod Info 2002b; Terrence & Fromm, 1980).

2) Literature Reports

a) A 33-year-old black man with a 12-year history of complex partial and left-sided sensory seizures hac 200 mg added to his anticonvulsant regimen. The dose was subsequently increased to 400 and 600 milli hospital days 4 and 6, respectively. On day 13 the patient complained of pedal edema, shortness of brea Over the next 48 hours the patient received 100 mg furosemide orally and carbamazepine was discontin of diuresis, the patient was asymptomatic and follow-up for 15 months was uneventful with no recurrence symptoms of congestive heart failure (Terrence & Fromm, 1980).

3.3.1.D Heart disease

1) Summary

a) Cardiovascular effects reported in patients receiving carbamazepine include aggravation of hypertens syncope and collapse, edema, aggravation of coronary artery disease, primary thrombophlebitis, and rec thrombophlebitis. Some of these cardiovascular effects have resulted in death (Prod Info Tegretol(R), 20

3.3.1.E Vasculitis

1) Summary

a) A case of leukocytoclastic vasculitis was reported in a 66-year-old male using carbamazepine therap Shant, 1987).

2) Literature Reports

a) Nonthrombocytopenic purpura with histological features of leukocytoclastic vasculitis was described i male with trigeminal neuralgia following carbamazepine 200 milligrams by mouth, three times daily (PO approximately 3 weeks. Withdrawal of carbamazepine and therapy with hydrocortisone IV resulted in gra purpura resolved within 3 months. Rechallenge was not undertaken in this patient (Harats & Shant, 1987

3.3.2 Dermatologic Effects

Acne

Alopecia

Dermatitis

Diaphoresis

Disorder of skin pigmentation

Drug-induced toxic pustuloderma

Eosinophilic pustular folliculitis

Erythema

Erythema multiforme

Fixed drug eruption

Hirsutism

Lichenoid dermatitis

Onychomadesis

Photosensitivity

Pruritic rash

Rash

Stevens-Johnson syndrome

Summary

Toxic epidermal necrolysis

Urticaria

3.3.2.A Acne

1) Summary

a) The prevalence of acne in patients on anticonvulsant medication compared to those in a control popu different (Greenwood et al, 1983; Harman, 1967; Simpson, 1966).

2) Literature Reports

a) One long-term study has evaluated the incidence of acne in 243 patients with epilepsy receiving varic on a long- term basis. Results were compared with matched controls from a normal population of 2,176 i prevalence of acne or sebum excretion rate was not different in anticonvulsant treated patients as compa group, or in patients taking phenytoin as compared to those who were not taking phenytoin. However, pr regarding length of anticonvulsant treatment, types of drugs administered and doses were not presented 1983; Harman, 1967; Simpson, 1966).

3.3.2.B Alopecia

1) Summary

a) Alopecia has been reported with carbamazepine therapy (Prod Info TEGRETOL(R) oral chewable tab suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007; Ikeda et al, 1997).

2) Literature Reports

a) Two young women developed alopecia after being treated with carbamazepine for partial seizures. O also experienced alopecia with valproic acid. Alopecia began after 2 to 3 months of therapy. The hair los was described as becoming sparse mostly in the front of her head. Hair loss stopped after one woman's decreased and the other woman was switched to phenobarbital (Ikeda et al, 1997).

3.3.2.C Dermatitis

1) Summary

a) Exfoliative dermatitis induced by carbamazepine has been reported in the literature (Prod Info TEGRI chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, Bieder, 1968; Reed et al, 1982). These reactions usually resolve upon withdrawal of carbamazepine.

3.3.2.D Diaphoresis

1) Diaphoresis has been reported with carbamazepine therapy. Discontinuation of therapy may be necessar (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR ext tablets, 2007).

3.3.2.E Disorder of skin pigmentation

1) Alterations in skin pigmentation have been reported with carbamazepine therapy. Discontinuation of thera necessary in some cases (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Ir (R)-XR extended-release oral tablets, 2007).

3.3.2.F Drug-induced toxic pustuloderma

1) Toxic pustuloderma was described in a 24-year-old woman, in association with erythema multiforme, follo carbamazepine therapy 200 milligrams daily for approximately 2 weeks. The patient improved following 4 da wet packs and hydrocortisone topical cream; however, there was a residual post inflammatory hyperpigmenta Fischer, 1988). These data suggest that carbamazepine is capable of producing pustular drug reactions.

3.3.2.G Eosinophilic pustular folliculitis

1) Summary

a) A 58-year-old male developed eosinophilic pustular folliculitis (Ofuji's disease) after taking acetamino carbamazepine for headache and fever (Mizoguchi et al, 1998).

2) Literature Reports

a) A 58-year-old male developed eosinophilic pustular folliculitis (Ofuji's disease) after taking acetamino

carbamazepine for headache and fever (Mizoguchi et al, 1998). Patch testing revealed carbamazepine a drug. Initially, he experienced stomatitis and edematous erythema with papules and pustules. Two montl edema of the upper eyelids, erythema with follicular papules and pustules on the face, neck, chest and u Eosinophil-rich folliculitis with mononuclear cells and neutrophil infiltration was seen on biopsy. He also h and elevated IgE. The eruptions subsided over 2 months with prednisolone 30 milligrams/day.

3.3.2.H Erythema

1) Although prudence suggests the withdrawal of carbamazepine following the occurrence of dermatologic re reactions necessitate permanent carbamazepine (CBZ) withdrawal. Three patients developed an erythemato their face and neck, accompanied by slight fever. Symptoms resolved within 5 to 6 days following CBZ withdr rechallenge with the drug several months later was uneventful (Livingston et al, 1974).

3.3.2.I Erythema multiforme

1) Summary

a) Several cases of erythema multiforme have been noted with carbamazepine therapy. Erythema nodo reported (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRET extended-release oral tablets, 2007; Ward, 1987; Green, 1986; Meisel & North, 1984; Reed et al, 1982; I 1968).

2) Literature Reports

a) Product selection may have a bearing on the occurrence of dermatological reactions secondary to ca 38-year-old woman who had been treated with carbamazepine for several years without incident, develo multiforme a week after receiving a generic version of the drug. Symptoms resolved spontaneously one discontinuation of the drug. Because of her continuing pain from trigeminal neuralgia, carbamazepine (T restarted and there was no recurrence of symptoms (Busch, 1989).

b) A 36-year-old woman receiving chronic carbamazepine therapy experienced facial erythema and ede photocopier for 2 hours. Superficial corneal burns were present one month later (Ward, 1987).

c) Erythema multiforme was described twice in the same patient (43-year-old woman): first in associatio and then with carbamazepine (Green, 1986). The patient developed a seizure disorder secondary to an i malignant neoplasm considered inoperable, and was given phenytoin 300 milligrams by mouth at bedtim betamethasone. A maculopapular rash developed 3 weeks later, which extended to much of the skin sur multiforme was diagnosed and phenytoin was discontinued resulting in improvement despite replacemer carbamazepine 100 milligrams by mouth 3 times a day (PO TID). Approximately one year later, the patie with a severe dull red maculopapular rash covering most of the body surface. Withdrawal of carbamazep subsidence of symptoms, and the patient was treated with valproic acid (and betamethasone) without fu sequelae. It is suggested that concurrent betamethasone therapy in this patient may have prevented a m reaction from occurring. However, based upon data provided in this report, it is unclear if either phenytoi carbamazepine were the sole cause of the erythema multiforme episodes in this patient.

d) Severe erythema multiforme with extreme eosinophilia was described in a 57-year-old Navajo Indian carbamazepine therapy 200 milligrams by mouth 3 times a day (PO TID) for 2 months for partial seizure reaction occurred upon inadvertent reinstitution of drug therapy by the patient (Meisel & North, 1984).

3.3.2.J Fixed drug eruption

1) A case of a fixed drug eruption due to carbamazepine has also been reported (Shuttleworth & Graham-Br

3.3.2.K Hirsutism

1) Isolated cases of hirsutism have been reported although a causal relationship has not been established (F TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended-rele 2007)

3.3.2.L Lichenoid dermatitis

1) A 75-year-old male developed a lichenoid reaction (biopsy specimens confirming lichen planus) within 2 w of carbamazepine therapy. The rash resolved 7 days after discontinuation of the drug. On rechallenge with ca lichenoid rash reappeared (Thompson & Skaehill, 1994).

3.3.2.M Mycosis fungoides

1) Summary

a) Mycosis fungoides-like lesions have been reported in association with carbamazepine therapy. Cases several months of therapy and skin lesions were present without evidence of systemic symptoms. Skin b revealed lymphoid infiltrates. Patients responded promptly to discontinuation of the drug and treatment w (Welykyj et al, 1990; Rijlaarsdam et al, 1991).

b) Several different types of skin reactions have been associated with carbamazepine (CBZ), including r pruritic rash, erythema multiforme, light sensitive dermatitis, lichenoid eruptions and mycosis fungoides (Rijlaarsdam et al, 1991).

3.3.2.N Onychomadesis

1) Summary

a) A possible case of onychomadesis induced by carbamazepine in a 31-year-old man with complex-pa reported (Mishra et al, 1989).

2) Literature Reports

a) A possible case of onychomadesis induced by carbamazepine in a 31-year-old man with complex-pa reported (Mishra et al, 1989). Nail detachment and pale color were first reported following 4 months of th discontinuation of carbamazepine, fingernails eventually grew back but had a mild bluish hue.

3.3.2.O Photosensitivity

1) Photosensitivity reactions have been reported with carbamazepine therapy. Discontinuation of therapy ma some cases (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETC extended-release oral tablets, 2007).

3.3.2.P Pruritic rash

1) Purpura has been reported with carbamazepine therapy. Discontinuation of therapy may be necessary in Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended tablets, 2007).

3.3.2.Q Rash

1) Summary

a) Reactions including erythematous and pruritic rashes have occurred. Concomitant rashes and blood also been reported associated with carbamazepine therapy (Prod Info TEGRETOL(R) oral chewable tab suspension, 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007; Cates & Powers, 1

2) Literature Reports

a) Thirty-three out of 335 (9.9%) children with epilepsy, who were treated with carbamazepine develope Rash was more frequent in children over 6 years old, and appeared on the average, within 2 weeks of in (Konishi et al, 1993).

b) A case of a generalized, pruritic, erythematous rash, which developed after 3 months of carbamazepi been reported. Over the course of a month, this rash developed into florid lichenoid lesions. Biopsy revea hyperkeratosis, localized acanthosis and the presence of eosinophilic infiltrates. Gradual resolution of th following discontinuation of the drug and treatment with betamethasone cream (Atkin et al, 1990).

c) Prednisone 40 milligrams daily was effective in treating carbamazepine-induced skin rash in 3 patient unresponsive to other anticonvulsants. Gradual tapering of prednisone followed by discontinuation succe carbamazepine to be continued in 2 patients. The third patient again experienced a rash after prednison had a permanent response to another course of prednisone therapy after 6 weeks of tapering (Vick, 198

d) Rashes were described in 3 patients who received treatment with carbamazepine. A 75-year-old mar receiving carbamazepine 800 milligrams (mg) daily for 2 weeks for treatment of trigeminal neuralgia dev rash, which rapidly became widespread and involved the limbs. Lichenoid papules were present on his w dorsal surfaces of his feet. Carbamazepine therapy was discontinued with notable improvement in the ra within 7 days. The patient was rechallenged with 800 mg/day of carbamazepine and within 24 hours pru days later, a red, scaly, itchy rash appeared, which was most prominent in light-exposed areas. Two oth developed an exfoliative eczema, which subsequently disappeared when carbamazepine therapy was di (Roberts & Marx, 1981).

e) A skin reaction occurred in a 63-year-old male with a previous history of dermatological disease. Duri therapy, an eruption developed which was identical to his previous eczema. In 3 months, a non-irritant ra different nature developed in his right scapular region and was associated with pain and malaise. The pa developed an eruption of heliotrope color affecting the eyelids, eyebrows, elbows, and wrists. The clinica suggestive of either lupus erythematosus or dermatomyositis. Upon discontinuation of the drug the patie spontaneously. There was prompt recurrence of the skin reaction when therapy was restarted (Simpson,

3.3.2.R Stevens-Johnson syndrome

1) Summary

a) Carbamazepine therapy has been associated with serious and sometimes fatal dermatologic reactior Stevens-Johnson Syndrome (SJS). Over 90% of the patients experience these reactions within the first f carbamazepine therapy. These reactions occurred at an estimated rate of 1 to 6 per 10,000 new users w Caucasian populations, but the risk in some Asian countries is estimated to be about 10 times higher. Th correlation between the risk of developing these reactions and the presence of human leukocyte antigen B*1502) allele, an inherited allelic variant of the HLA-B gene, among patients of Asian ancestry, particula ancestry. Based on a case control study, there is an absolute risk of 5% for TEN/Stevens Johnson Syndr B*1502 positive patients on carbamazepine. Individuals not of Asian origin (eg, Caucasians, African-Ame and Native Americans) generally are not HLA-B*1502 positive, yet, are still at risk for fatal dermatologic r Genetically at-risk patients should be screened prior to receiving carbamazepine. Careful assessment of should be conducted among patients tested positive for the allele prior to initiation of carbamazepine. Pa been taking carbamazepine for more than a few months (including HLA-B*1502 positive Asians) are at lo (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR oral tablets, 2007; US Food and Drug Administration, 2007).

2) Human Leukocyte Antigen-B*1502 (HLA-B*1502) Positive

a) Human leukocyte antigen-B*1502 (HLA-B*1502) allele is common in Asians including South Asian In prevalence of HLA-B*1502 is not known for all regions of Asia. The following are known HLA-B*1502 pos rates in some regions of Asia: greater than 15% in Hong Kong, Thailand, Malaysia, and parts of the Phili in Taiwan; 4% in North China; 2% to 4% in South Asians, including Indians but may be higher in some gr

than 1% in Japan and Korea. Individuals not of Asian origin (eg, Caucasians, African-Americans, Hispan Americans) generally are not HLA-B*1502 positive (Prod Info TEGRETOL(R) oral chewable tablets, tabl 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007).

3) Literature Reports

a) Short-term therapy with carbamazepine has been associated with Stevens Johnson Syndrome (SJS) epidermal necrolysis (TEN) in a case-control study and appears to be a risk factor. Twenty- one cases w either SJS or TEN following a range of therapy of 2 to 4 weeks. The risk is largely confined to the start of therapy (Rzany et al, 1999).

b) Stevens-Johnson syndrome (erythema multiforme major) was described in a 22-year-old male followi 4 weeks of carbamazepine therapy (200 milligrams by mouth 3 times a day). At that time, the patient pre rash, fever, chills, and sore throat of three days duration; carbamazepine as well as previous (lithium and discontinued; however, the rash progressed to multiple confluent bullous lesions about the face, shoulde mucosa. A maculopapular rash extended over the rest of the thorax, anteriorly and posteriorly, and to the Stevens-Johnson syndrome was diagnosed and the patient was eventually treated intensively with IV flu The patient recovered following several months of hospitalization. However, based upon data presented ascertain if carbamazepine was the cause of this patient's skin reaction (Fawcett, 1987).

c) Cases of exfoliative dermatitis, including Steven's-Johnson syndrome, have been reported in patients carbamazepine (CBZ). Generally these patients have been successfully treated with steroids and discon with recovery occurring within 3 weeks (Hoang-Xuan et al, 1990); (Vaillant et al, 1989)(Pagliaro & Paglia

3.3.2.S Summary

1) Various dermatologic reactions have been associated with carbamazepine use in an estimated 4% of trea onset generally occurs at approximately 1 month (range 2 weeks to 5 months) after starting therapy. Reactio erythematous and pruritic rashes, urticaria, toxic epidermal necrolysis, Stevens-Johnson syndrome, photoser alterations in skin pigmentation, exfoliative dermatitis, erythema multiforme and nodosum, purpura, alopecia, Hirsutism has been reported in isolated cases. In addition, toxic pustuloderma and onychomadesis were eac case. Cases of exfoliative dermatitis induced by carbamazepine have been reported in the literature. These r resolve upon withdrawal of carbamazepine. Other reactions such as mild erythema may resolve even with co

3.3.2.T Toxic epidermal necrolysis

1) Summary

a) Carbamazepine therapy has been associated with serious and sometimes fatal dermatologic reactior epidermal necrolysis (TEN). Over 90% of the patients experience these reactions within the first few mor carbamazepine therapy. These reactions occurred at an estimated rate of 1 to 6 per 10,000 new users w Caucasian populations, but the risk in some Asian countries is estimated to be about 10 times higher. Th correlation between the risk of developing these reactions and the presence of human leukocyte antigen B*1502) allele, an inherited allelic variant of the HLA-B gene, among patients of Asian ancestry, particula ancestry. Based on a case control study, there is an absolute risk of 5% for TEN/Stevens Johnson Syndr B*1502 positive patients on carbamazepine. Individuals not of Asian origin (eg, Caucasians, African-Ame and Native Americans) generally are not HLA-B*1502 positive, yet, are still at risk for fatal dermatologic r Genetically at-risk patients should be screened prior to receiving carbamazepine. Careful assessment of should be conducted among patients tested positive for the allele prior to initiation of carbamazepine. Pa been taking carbamazepine for more than a few months (including HLA-B*1502 positive Asians) are at lo (Prod Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR oral tablets, 2007; US Food and Drug Administration, 2007).

2) Literature Reports

a) Toxic epidermal necrolysis was reported in a 5 year-old male following treatment with carbamazepine a history of epileptic seizures treated with carbamazepine 100 mg/day. Titration of carbamazepine was b 100 mg weekly. Three weeks later, (1 day after the last increment) the patient was admitted to the hospit of malaise, fever, and erythematous rash on his face and neck. Carbamazepine was immediately discon antihistamine with methylprednisolone 2 mg/kg/day was initiated. His rash and bullae continued to sprea his body within 24 hours and the patient was transferred to the pediatric ICU. Both the antihistamine and methylprednisolone were discontinued. IV immunoglobulin 1 g/kg/day was given for 2 days along with ag replacement, enteral and parenteral nutrition , and appropriate infection and wound management. On da cultures were positive for Escherichia coli, which was treated with cefotaxime and amikacin. A 3-day cou colony-stimulating factor was initiated. From day 10, no new lesions occurred. On day 37 of hospitalizatio epithelialized and the patient was discharged (Sevketoglu et al, 2009).

b) A suspected case of Lyell's syndrome was reported in a 52-year-old male treated with carbamazepin neuralgia. The patient received 200 milligrams (mg) 3 times daily for 15 days and developed a pruritic ra dryness of the oral mucosa. After a 2 day interval, a single 200 mg dose was administered resulting in ge headache and fever with a general exudative erythema. The patient then developed icterus, hepatomega hemorrhage. Tachycardia, hypotension, and respiratory difficulty ensued. Complete epidermal necrolysis followed. Laboratory findings were consistent with those of Lyell's syndrome. The patient also developed septicemia. He was treated with corticosteroids, antihistamines and antibiotics with complete recovery (M Khramtsova, 1976).

3) Human Leukocyte Antigen-B*1502 (HLA-B*1502) Positive

a) Human leukocyte antigen-B*1502 (HLA-B*1502) allele is common in Asians including South Asian In prevalence of HLA-B*1502 is not known for all regions of Asia. The following are known HLA-B*1502 pos

rates in some regions of Asia: greater than 15% in Hong Kong, Thailand, Malaysia, and parts of the Phili in Taiwan; 4% in North China; 2% to 4% in South Asians, including Indians but may be higher in some g than 1% in Japan and Korea. Individuals not of Asian origin (eg, Caucasians, African-Americans, Hispan Americans) generally are not HLA-B*1502 positive (Prod Info TEGRETOL(R) oral chewable tablets, tabl 2007; Prod Info TEGRETOL(R)-XR extended-release oral tablets, 2007).

3.3.2.U Urticaria

1) Urticaria has been reported with carbamazepine therapy. Discontinuation of therapy may be necessary in Info TEGRETOL(R) oral chewable tablets, tablets, suspension, 2007; Prod Info TEGRETOL(R)-XR extended tablets, 2007).

3.3.3 Endocrine/Metabolic Effects

Acute intermittent porphyria

Body temperature above normal

Hyperhomocysteinemia

Hypocalcemia

Hyponatremia

Hypophosphatemia

Hypothyroidism due to drugs

Lipids abnormal

Male sex hormones - serum level - finding

Porphyria

Summary

Syndrome of inappropriate antidiuretic hormone secretion

Vitamin D deficiency

Weight gain

3.3.3.A Acute intermittent porphyria

See Drug Consult reference: DRUGS CONSIDERED UNSAFE- ACUTE PORPHYRIAS

3.3.3.B Body temperature above normal

1) A case of recurrent fever was reported in a 62-year-old woman who was receiving carbamazepine 800 mi control of epilepsy. The patient's fever began 2 days after the first dose of carbamazepine and spiked to 40 d daily. Carbamazepine therapy was discontinued and the fever ceased. Carbamazepine was reintroduced at a fever recurred; however, they were not as high as before. The patient's dose was again raised to 800 milligra fever returned to 40 degrees C twice daily. When the medication was discontinued the second time the fever (Stewart et al, 1980).

3.3.3.C Hyperhomocysteinemia

1) In a study of 60 adolescent epileptic patients (aged 14 to 18 years), a one-year course of carbamazepine therapy was found to produce significantly higher plasma concentrations of homocysteine. this was compare levels prior to therapy and compared with levels in a healthy age- and sex-matched control group (n=63; p les comparisons). the finding of hyperhomocysteinemia held true with both fasting and post- methionine homocys measurements. For the patients taking carbamazepine or valproate, serum concentrations of folate and plasr phosphate (PLP) were significantly decreased with respect to pre- treatment values and to values in the cont than 0.01, folate; p less than 0.001, PLP). Levels of vitamin B12 and erythrocyte folate remained in the norma

al, 2000a).

3.3.3.D Hypocalcemia

1) In a study of 21 epileptic patients, hypocalcemia, hypophosphatemia, and elevated serum alkaline phosph noted (Hoikka et al, 1984).

3.3.3.E Hyponatremia

1) Summary

a) The significant antidiuretic actions of carbamazepine have resulted in water intoxication and hyponatr children. Hyponatremia was demonstrated in 4% to 21.7% of patients receiving carbamazepine. Hypona likely to occur in older patients (Dong et al, 2005; Prod Info Tegretol(R), 2002b; Kamiyama et al, 1993; L O'Griofa & Voris, 1991; Rajantie et al, 1984; Hoikka et al, 1984; Kalff et al, 1984; Yeung Laiwah et al, 19 Valikangas, 1983; Uhde & Post, 1983; Byrne et al, 1979; Ashton et al, 1977; Stephens et al, 1977; Henry incidence of hyponatremia appears to be lower with carbamazepine use as compared with the use oxca al, 2005). In a case report, a woman experienced tonic-clonic seizures secondary to carbamazepine-indu (Kuz & Manssourian, 2005).

2) Incidence: 4% to 21.7% (Dong et al, 2005; Lahr, 1985; Kalff et al, 1984)

3) The results of one study indicate that oxcarbazepine use is associated with a greater incidence of hypona compared with the use of carbamazepine. In a cross-sectional study, the sodium levels of patients receiving t either oxcarbazepine (n=97; mean age, 36.3 years) or carbamazepine (n=451; mean age, 38.2 years) were e presence of hyponatremia. Hyponatremia was defined as a sodium level less than or equal to 134 milliequiva severe hyponatremia was defined as a sodium level less than or equal to 128 mEq/L. Hyponatremia was obs significantly greater number of oxcarbazepine-treated patients, as compared with those receiving carbamaze (29.9% (29/97) vs 13.5% (61/451), respectively; p less than 0.0001). The incidence of severe hyponatremia v the oxcarbazepine group as compared with the carbamazepine group (12.4% (12/97) vs 2.8%(13/451), respe hyponatremia accounted for 41% (12/29) of all hyponatremia cases in oxcarbazepine-treated patients, while 21.3% (13/61) of all hyponatremia cases reported in patients receiving carbamazepine therapy (p less than 0 investigators also found that, for both groups, hyponatremia was more likely to occur in older patients. Hypon observed in 62.2% and 20.6% of oxcarbazepine- and carbamazepine-treated patients 40 years of age or olde with 10% and 7.9% of oxcarbazepine- and carbamazepine-treated patients less than 40 years of age, respec 0.0001, both values) (Dong et al, 2005).

4) In a case report, a 44-year-old woman experienced new-onset, tonic-clonic seizures secondary to hypona a larger than her usual dose of carbamazepine. Concomitant medications include paroxetine, risperidone, bu and hydroxyzine. The night before the seizures she took double the bedtime dose of carbamazepine (1200 m instead of 600 mg). The next day, symptoms experienced were faintness, dizziness, light-headedness, and th blood rushing to her head and immediately prior to seizures were vision "began narrowing" and loss of consc emergency room, serum sodium concentration was 122 milliequivalent/liter and serum carbamazepine was 1 microgram/milliliter. Past medical history includes a similar event after she took a large dose of carbamazepir Manssourian, 2005).

5) Sixty patients receiving carbamazepine and 61 age-matched controls were studied to determine the preva hyponatremia. There was a significant difference between the mean serum sodium levels of the subjects (138 milliequivalents/liter) and the controls (141.7+/-0.4 milliequivalents/liter). Thirteen (21.7%) of the subjects, but controls, had sodium levels less than 135 milliequivalents/liter. The risk of hyponatremia increased with age a serum level (Lahr, 1985).

6) In 1 study, hyponatremia was demonstrated in 28 of 674 (4%) of patients receiving carbamazepine for sei patients, 113 were on carbamazepine monotherapy and 460 were receiving carbamazepine in combination w anticonvulsant medications. Of the 23 patients available for long-term follow- up, 10 were consistently hypona remainder were intermittently hyponatremic. All patients who developed hyponatremia were receiving carbam these were on monotherapy. In all patients, the hyponatremia was slight and did not cause clinical symptoms

3.3.3.F Hypophosphatemia

1) In a study of 21 epileptic patients, hypocalcemia, hypophosphatemia, and elevated serum alkaline phosph noted (Hoikka et al, 1984)

3.3.3.G Hypothyroidism due to drugs

1) One study found that carbamazepine and oxcarbazepine both decrease serum thyroxine (T4) and free thy girls with epilepsy. These effects were reversible upon discontinuation of therapy. Patients, between the ages years, were compared to 54 age-matched controls. Mean T4 and FT4 levels in patients receiving carbamaze 11.5 nM and 70.2 nM compared to 14.4 nM and 96.6 nM in the control group (p less than 0.01 and 0.001, res T4 and FT4 in patients receiving oxcarbazepine (n=18) were 11.3 nM and 74.9 nM (p less than 0.001 for both compared control). Thyrotropin and free triiodothyronine levels were not significantly different. A second evalu mean of 5.8 years later, was performed. Thyroid hormone levels in patients who had discontinued therapy (1 patients and 10 oxcarbazepine patients) did not significantly differ from the controls. Patients had been off the 5 and 4.8 years, respectively (Vainionpaa et al, 2004).

2) Carbamazepine may increase the hepatic clearance of thyroid hormones as well as having an inhibitory e hypothalamic level. The effect of carbamazepine on thyroid function was examined in 40 epileptic patients. A levels of thyroxine, free thyroxine and thyroxine binding globulin were decreased at both 2 and 12 months foll therapy; low serum thyroxine and free thyroxine concentrations were also found after long-term therapy. No p

demonstrated clinical signs of hypothyroidism. Thyrotropin levels were not changed although the response to releasing hormone increased slightly. The decreased thyroid function tests did not correlate with serum carba (Prod Info Tegretol(R), 2002b; Isojarvi et al, 1989).

3.3.3.H Lipids abnormal

1) Significant increases in atherogenic lipids (total cholesterol, very-low-density lipoprotein (VLDL), LDL, and noted after 3 months of carbamazepine therapy in a prospective study of children with partial epilepsy. Over a 29 children (mean age 7.3 years (yr); range 3 to 12 yr; 16 male) were enrolled within 48 hours of presentation seizures, placed on carbamazepine monotherapy, and followed up monthly for 3 months to study the effect o therapy on serum lipids. Family histories, weight, height, and body mass index were recorded. Participants w carbamazepine at a dose of 10 mg/kg per day, with doses increased by 5 mg/kg per day if required, up to a m 30 mg/kg/day. Participants were advised against dietary changes. After 12 hours of fasting, venous blood sam lipid levels were taken. Participants were monitored monthly and compliance was noted. Blood samples were months for lipid profiles and carbamazepine levels. Correlation of lipid levels with carbamazepine was determ of correlation. A p-value of less than 0.05 was taken as significant. Results for the study participants were an liver function tests and lipid levels. Baseline lipid and liver function levels were compared with 3-month finding increased 10% during the study period with mean total cholesterol at baseline 130.6 +/- 27.4 mg/dL and 144. 3 months (p=0.018). Significant increases were also noted in LDL, VLDL, total cholesterol/HDL ratio, and LDL There was no significant change in HDL levels, alkaline phosphate or serum glutamine transaminase. At 3 m the mean dose of carbamazepine was 10.3 +/- 1.1 mg/kg per day, and the mean carbamazepine levels were mcg/dL. There was no correlation of carbamazepine level with lipid levels at 3 months, and no correlation wa the change in lipids and carbamazepine levels. Lipid monitoring should be advised for high-risk patients on ca therapy. Long-term implications of increased risk of atherosclerosis needs further study (Aggarwal et al, 2009

2) In a study evaluating lipids in children and adolescents receiving carbamazepine (n=14), valproic acid (n= phenobarbital (n=20), serum lipid and lipoprotein levels returned completely to normal at 1 to 1.5 years after t discontinued (Verrotti et al, 1998). During therapy patients receiving carbamazepine demonstrated increased cholesterol, triglycerides, low-density lipoprotein cholesterol, and high-density lipoprotein as compared to a co (n=110) (all p less than 0.01). Children receiving valproic acid had low triglycerides (p less than 0.05) and low lipoproteins (p less than 0.05) and high levels of high-density lipoproteins (p less than 0.01) as compared to t Children receiving phenobarbital had high concentrations of total cholesterol and low-density lipoprotein chole concentrations of triglycerides as compared to the control group (all p less than 0.01).

3) Carbamazepine was shown to adversely affect serum lipids in a study comparing 57 healthy children to 2 treated children (Sozuer et al, 1997). The carbamazepine-treated children had significantly higher levels of m cholesterol (p less than 0.01), mean low-density lipoprotein (p less than 0.005), and mean total cholesterol/hi lipoprotein (p less than 0.05).

4) High-density lipoprotein cholesterol levels were significantly elevated in epileptic children receiving carban as phenobarbital and valproic acid (Heldenberg et al, 1983); however, this effect may be protective against th heart disease.

5) The effects of valproic acid, carbamazepine or phenobarbital on serum lipids, lipoproteins and apolipoprot examined in 101 epileptic patients and 75 age-matched controls (Calandre et al, 1991). Patients treated with demonstrated significantly higher high-density lipoprotein and apolipoprotein A concentrations. The total chol cholesterol ratio was also significantly lower in patients receiving carbamazepine. The change in serum lipid p correlate with drug concentrations or with duration of therapy.

3.3.3.I Male sex hormones - serum level - finding

1) Antiepileptic agents have been associated with changes in serum concentrations of male reproductive hor compared to healthy controls (n=41), carbamazepine treated men with partial epilepsy (n=15) had lower seru dehydroepiandrosterone sulfate concentrations (3068 ng/mL for controls versus 1952 ng/mL for carbamazep 0.001). No statistically significant differences in dehydroepiandrosterone levels were detected between contro oxcarbazepine treated (n=18) or valproic acid treated (n=27) men with generalized epilepsy. It was also found valproic acid group had higher androstenedione levels (5.9 ng/mL) when compared to the control group (2.2 0.001) whereas the other arms did not. Serum testosterone, sex hormone binding globulin, free androgen inc hormone, follicle stimulating hormone, prolactin and inhibin B measurements were not statistically significantl all 4 groups. Whether the differences in reproductive hormones are epilepsy-induced changes or antiepileptic changes remains to be determined (Isojarvi et al, 2004).

2) Reproductive hormone levels in men with epilepsy may be affected by use of valproic acid or carbamazep effect shown by oxcarbazepine at high doses. In valproate-treated men (n=21), androstenedione levels were increased compared with controls (n=25) (p less than 0.001), and more than half of the cohort taking valproat serum concentrations of testosterone, androstenedione, or dehydroepiandrosterone (DHEA) above the refere than 0.001). Follicle stimulating hormone levels were abnormally low in valproate- treated men (p less than 0. carbamazepine-treated men (n=40), serum concentrations of DHEA were low (p less than 0.001) and sex hor globulin (SHBG) levels were high (p less than 0.05). In men taking high doses of oxcarbazepine (900 mg/day concentrations of testosterone, luteinizing hormone, and SHBG were high (p=0.008, p=0.02, p=0.005, respec authors noted that serum insulin levels were high across all groups (Rattya et al, 2001).

3) Carbamazepine and (to a lesser extent) valproic acid were found to alter serum concentrations of sex hor male epileptic patients (aged 15 to 18 years; n=48) treated at least 2 years with these drugs; however, serum permanently changed and soon after the drugs were withdrawn, hormone levels normalized (Verrotti et al, 20 with concentrations in normal healthy male controls, subjects treated with carbamazepine monotherapy (n=2

levels of free testosterone (FT) (p less than 0.05) and dehydro- epiandrosterone sulphate (DHEAS) (p less th concentrations of sex hormone-binding globulin were significantly increased (p less than 0.01). Subjects treat acid monotherapy (n=18) had insignificantly decreased levels of FT and DHEAS. Subjects on combination ca valproic acid (n=10) had the same significant alterations as those on carbamazepine monotherapy. At least fo withdrawal of these drugs, all values had returned to normal. Levels of testosterone, luteinizing hormone, folli hormone, and prolactin were normal throughout the study.

3.3.3.J Porphyria

1) Carbamazepine has been associated with the development of nonhereditary acute porphyria, similar to ac porphyria, in a 38-year-old male during treatment of epilepsy. Carbamazepine reportedly produces direct sup on the enzyme uroporphyrinogen I synthase. Decreases in this enzyme are also present in hereditary acute i porphyria (Yeung Laiwah et al, 1983).

3.3.3.K Summary

1) The significant antidiuretic actions of carbamazepine have resulted in water intoxication and hyponatremia children. Hyponatremia was demonstrated in 4% to 21.7% of patients receiving carbamazepine. Hyponatrem to occur in older patients (Dong et al, 2005; Prod Info Tegretol(R), 2002b; Kamiyama et al, 1993; Lampl et al, Voris, 1991; Rajantie et al, 1984; Hoikka et al, 1984; Kalff et al, 1984; Yeung Laiwah et al, 1983; Koivikko & V Uhde & Post, 1983; Byrne et al, 1979; Ashton et al, 1977; Stephens et al, 1977; Henry et al, 1977). In a study epileptic patients, hyperhomocystinemia was reported (Verrotti et al, 2000a). Reproductive hormone levels in may be affected by carbamazepine use (Rattya et al, 2001). Soon after the drug is withdrawn, the hormone le normal (Verrotti et al, 2000). Serum calcium concentrations and 25-hydroxyvitamin D levels were found to be in mentally retarded patients and patients on chronic carbamazepine monotherapy (Rajantie et al, 1984). In a epileptic patients, hypocalcemia, hypophosphatemia, and elevated serum alkaline phosphatase levels were r 1984). Carbamazepine may increase the hepatic clearance of thyroid hormones as well as having an inhibito hypothalamic level(Prod Info Tegretol(R), 2002b; Isojarvi et al, 1989). Carbamazepine has been shown to ad serum lipids and lipoprotein levels in children (Prod Info Tegretol(R), 2002b; Verrotti et al, 1998) (Souzuer et et al, 2009). Syndrome of inappropriate antidiuretic hormone secretion has been reported (Prod Info Tegretol
2) There have been case reports of recurrent fever (Stewart et al, 1980), nonhereditary acute porphyria, simi intermittent porphyria (Yeung Laiwah et al, 1983), and weight gain (Lampl et al, 1991).

3.3.3.L Syndrome of inappropriate antidiuretic hormone secretion

1) Syndrome of inappropriate antidiuretic hormone secretion has been reported (Prod Info Tegretol(R), 2002

3.3.3.M Vitamin D deficiency

1) A 2-year cross-sectional and retrospective study reported lower 25-hydroxy vitamin D serum levels in prep treated with carbamazepine when compared to children treated with valproic acid and controls. Sixty-six childc antiepileptics (carbamazepine: 20 boys, 13 girls; mean age 9.7 +/-1.6 years; valproic acid: 17 boys, 16 girls; r years) were compared to age- and sex-matched controls (13 boys, 9 girls; mean age 8.9 +/- 2.3 years). Mear treatment was 35.52 +/- 12.84 months for carbamazepine and 33.72 +/- 15 months for valproic acid. Serum 2 D levels in patients treated with carbamazepine were significantly lower than those of patients treated with va controls (9.8 +/- 3.6 micrograms per liter (mcg/L), 15.1 +/- 3.5 mcg/L, and 16.6 +/- 4.7 mcg/L, respectively; p< carbamazepine) (Kumandas et al, 2006).
2) Serum calcium concentrations and 25-hydroxyvitamin D levels were reported to decrease in mentally reta receiving carbamazepine, as compared to a control group. Alkaline phosphatase levels were higher in patien carbamazepine and administration of vitamin D in the diet abolished the syndrome. It is suggested that hypov occur during long-term carbamazepine treatment especially if other risks for vitamin D deficiency exist (Rajan
3) Bone mineral metabolism was studied in 21 epileptic patients on chronic carbamazepine monotherapy at of 505 milligrams. In 3 cases, hypocalcemia was identified; hypophosphatemia was noted in 1 patient and 4 p demonstrated elevated serum alkaline phosphatase levels. Serum 25-hydroxyvitamin D levels were significar controls. No significant difference was noted in bone mineral density or in the amount of trabecular bone betv controls. Two patients were found to have histological evidence of osteomalacia (Hoikka et al, 1984).

3.3.3.N Weight gain

1) Weight gain induced by carbamazepine has been reported in 4 adolescent patients taking the drug at usu doses for control of seizures. Over a 2-month period, all patients developed an increase in appetite with conc increased food intake; body weight increased by 7 to 15 kilograms. Dietary restriction was ineffective in achie while the patients remained on the drug; a return to original body weight was achieved 2 to 3 months followin of the drug (Lampl et al, 1991).

3.3.4 Gastrointestinal Effects

Diarrhea

Disease of mouth

Disorder of gastrointestinal tract

Gastrointestinal tract finding

Nausea and vomiting

Pancreatitis

3.3.4.A Diarrhea

1) Summary

a) Several cases of intractable diarrhea have been reported with therapeutic carbamazepine therapy (P
(R), 2002b; Mahajan et al, 1997; Iyer et al, 1992).

2) Literature Reports

a) An 8-year-old boy with Lennox-Gastaut syndrome developed protracted watery diarrhea while receivi
(Mahajan et al, 1997). The diarrhea started approximately 3 weeks after beginning carbamazepine. A ra
biopsy was consistent with the diagnosis of LYMPHOCYTIC COLITIS. No improvement was noted after
of sulfasalazine. The diarrhea gradually resolved over a 2-month period while the carbamazepine was ta

b) Three cases of intractable diarrhea were reported following initiation of carbamazepine therapy (Iyer
three cases, the patients experienced frequent loose stools approximately one week after starting carba
abdominal pain or discomfort were noted, and antidiarrheal medications were ineffective. The diarrhea c
carbamazepine was discontinued.

3.3.4.B Disease of mouth

1) Summary

a) Dryness of the mouth and pharynx, glossitis, stomatitis, and loss of taste have been reported in patie
carbamazepine therapy (Prod Info Tegretol(R), 2002b).

3.3.4.C Disorder of gastrointestinal tract

1) Summary

a) Constipation, abdominal cramps, and anorexia have been reported in patients receiving carbamazepi
Info Tegretol(R), 2002b).

3.3.4.D Gastrointestinal tract finding

1) Nausea and vomiting are two of the most frequent adverse effects associated with carbamazepine therap
usually occur during the initiation of therapy. Diarrhea, constipation, abdominal cramps, anorexia, and drynes
pharynx, glossitis, stomatitis, pancreatitis, and loss of taste have been reported in patients receiving carbama

3.3.4.E Nausea and vomiting

1) Summary

a) Nausea and vomiting are two of the most frequent adverse effects associated with carbamazepine th
effects usually occur during the initiation of therapy (Prod Info Tegretol(R), 2002b).

3.3.4.F Pancreatitis

1) Summary

a) Pancreatitis has been reported in one case during carbamazepine therapy (Soman & Swenson, 1985

2) Literature Reports

a) A 73-year-old female receiving carbamazepine 200 mg twice a day for partial seizures developed nau
anorexia, malaise, headache, and increased thirst 4 weeks after starting therapy. Her symptoms continu
the addition of lower abdominal pain. Her serum amylase rose to 429 units/dL (normal 60 to 160). The ca
discontinued with an immediate decrease in symptoms. Ten days after stopping the carbamazepine, the
was 172 units/dL and the patient was free of symptoms (Soman & Swenson, 1985).

3.3.5 Hematologic Effects

Agranulocytosis

Aplastic anemia

Disorder of hematopoietic structure

Drug-induced eosinophilia

Hematology finding

Hemolytic anemia

Leukemoid reaction

Leukopenia

Malignant lymphoma

Pancytopenia

Pure red cell aplasia

Thrombocytopenia

3.3.5.A Agranulocytosis

1) Summary

a) Agranulocytosis is one of the most severe hematologic effects. It is reported to occur 5 to 8 times mo patients treated with carbamazepine than in the general population. While agranulocytosis is a low risk e untreated general population (6 patients/1 million population/year), a fatal case has been associated with therapy (Prod Info Tegretol(R), 2002b; Luchins, 1984; Owens et al, 1980; Hawson et al, 1980; Murphy e Agranulocytosis can occur after different periods of exposure and is not clearly related to the total dose c cases over 12 years have been reported during chronic therapy. It appears to be an idiosyncratic respon 1995; Pellock, 1998a; Owens et al, 1980).

2) Literature Reports

a) A 49-year-old asthmatic epileptic woman began receiving carbamazepine 200 milligrams three times epilepsy, and within a week she developed an erythematous non-itchy rash which resolved spontaneous recurred and was itchy 3-1/2 weeks later. Twenty days after commencing therapy, routine blood count sh 1.8 x 10(9)/liter with neutrophil count of 0.4 x 10(9)/liter. Three days later the patient became febrile and (9)/liter with 1% myelocytes but no neutrophils was seen. Carbamazepine was discontinued and a bone examination two days later showed normal cellularity with 3% promyelocytes, 25% myelocytes and 34% and band cells and virtually no mature neutrophils. The patient made an uneventful recovery (Hawson et

b) A case of fatal agranulocytosis was reported in a 48-year-old chronic schizophrenic patient after carb milligrams twice daily for 1 month for aggression (Luchins, 1984). Routine hematological monitoring was prior to or during carbamazepine therapy.

3.3.5.B Aplastic anemia

1) Summary

a) Aplastic anemia is one of the most severe hematological effects and it occurs rarely during carbamaz (Gerson et al, 1983; Donaldson & Graham, 1965). Aplastic anemia is reported to occur 5 to 8 times more patients treated with carbamazepine than in the general population. It has also been reported during chr cases over 12 years) (Prod Info Tegretol(R), 2002b; Tohen et al, 1995; Pellock, 1998a).

2) Literature Reports

a) Aplastic anemia is one of the most severe hematologic effects. Aplastic anemia is reported to occur 5 frequently in patients treated with carbamazepine than in the general population. The risk of aplastic ane low with approximately 2 persons per 1,000,000 population per year likely to develop the disorder (Prod 2002b).

b) Clinically significant hematological toxicity with carbamazepine is uncommon in adults (Hart & Easton review indicated the occurrence of aplastic anemia in 20 patients since 1964, with leukopenia and throm occurring in about 2% of patients treated.

1) Monitoring - The authors suggested a conservative approach to hematological monitoring during complete blood and platelet count performed prior to therapy; 2) CBC performed every 2 weeks for t (if no abnormalities are present, CBC should be obtained quarterly or with the appearance of signs c bone marrow depression); 3) if leukopenia develops, white blood cell count should be monitored at 2 seeking the expected return to baseline (withdrawal is indicated in the presence of WBC less than 3 millimeters) (Hart & Easton, 1982).

c) A low incidence of hematologic toxicity with carbamazepine in children has been reported (Silverstein

1) Monitoring - The authors recommend the following monitoring guidelines: 1) hemoglobin, hemato platelet count prior to therapy, monthly for 6 months, then every 3 months; 2) obtain neutrophil, plate reticulocyte count if WBC falls less than 4000; 3) if neutrophil count decreases to 1000 to 1500/cubi in 2 weeks, and consider withdrawal of therapy if remains in this range (neutrophil counts below 100 decreased dosage or drug withdrawal); 4) request hematologic consultation if depression in platelet count occurs in addition to neutropenia (Silverstein et al, 1983).

3.3.5.C Disorder of hematopoietic structure

1) Summary

a) Rates of blood dyscrasias per 100,000 anticonvulsant prescriptions have been reported as 2.8 for ne thrombocytopenia, and 0.5 for hemolytic anemia. These were determined using the United Kingdom Dep Health's General Practice Research Database with 5-year records of 16,686 carbamazepine recipients. differ between phenytoin, phenobarbital, carbamazepine, or valproate throughout all age groups (Blackb

3.3.5.D Drug-induced eosinophilia

1) Summary

a) A slight increase of eosinophilia was reported in patients taking carbamazepine (De Marco & Melchio

2) Literature Reports

a) A 5% increase of eosinophilia with normal leukocyte counts was reported in 653 patients taking carba 48 months. Blood levels ranged from 3 to 12 milligrams/milliliter (Prod Info Tegretol(R), 2002b; Perry et a & Melchiori, 1986; Killian & Fromm, 1968).

b) A 13-year-old boy developed fever, rash, and eosinophilia (white blood cell count of 20,400 cells/cubi eosinophils) weeks after starting carbamazepine therapy. He developed chest pain and died from uncon dysrhythmias. Autopsy revealed severe eosinophilic myocarditis Salzman & Valderrama, 1997).

3.3.5.E Hematology finding

1) Hematopoietic toxicity (neutropenia, thrombocytopenia, and aplastic anemia) has been reported following but not acute overdose. Pancytopenia, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, agranulocy dyscrasia, hemolytic anemia, and pure red cell aplasia have also been reported in patients receiving carbama

3.3.5.F Hemolytic anemia

1) Summary

a) CASE REPORT - Hemolytic anemia was reported in a 63-year-old male following carbamazepine ad milligrams daily for approximately 20 days). Withdrawal of the drug resulted in

3.3.5.G Leukemoid reaction

1) Summary

a) CASE REPORT - A case of leukocytosis induced by carbamazepine has been reported. A 26-year-ol receiving carbamazepine for the treatment of epilepsy had a white blood cell count of 21.2 x 10(3)/cubic patient's medication was changed from carbamazepine 600 milligrams/day to phenytoin 400 milligrams/c phenobarbital 120 milligrams/day and her white count decreased to a normal range. The patient experie ataxia and the phenytoin and phenobarbital were replaced with carbamazepine 600 milligrams/day. Whit performed 11 and 13 days later were significantly elevated (Murphy et al, 1980).

3.3.5.H Leukopenia

1) Summary

a) Carbamazepine may produce leukopenia in 10% of patients for whom it is prescribed. Usually the rea transient although a few cases of persistent neutropenia have been described. In some patients, the rea dose-related (Prod Info Tegretol(R), 2002b; Perry et al, 1991); (de Marco & Melchiori, 1986)(Killian & Fro

b) Transient leukopenia is not an absolute indication to stop the drug although it is an indication to moni Upon continuation of therapy, the WBC has returned to normal in some patients, while in others it has flu normal and low values. Where the drug is discontinued, the WBC returns to normal within a period of 1 v Cook, 1977).

c) In an evaluation of chronic leukopenia resulting from antiepileptic drug use, it was demonstrated that antiepileptic drug regimen was safe to continue despite asymptomatic leukopenia when the percentage polymorphonuclear leukocytes (PMN) remained normal. If the absolute PMN count dropped to less than cells/microliter, a bone marrow aspirate should be obtained and the ratio of myeloid to erythroid precurso ratio is reduced, or the absolute PMN count remains less than 500, the antiepileptic agent should be disc (O'Connor et al, 1994). Several authors have suggested that carbamazepine be discontinued when the t count is less than 3000/cubic millimeter or neutrophils are less than 1500/cubic millimeter (Hart & Easter al, 1985).

2) Literature Reports

a) A 66-year-old woman with bipolar disorder developed an initial drop in white blood cell count to a leve millimeter. The drug was discontinued for a 2-week period and then gradually titrated from a dose of 100 carbamazepine daily to 800 mg daily. Although leukopenia occurred, the dosage of carbamazepine was time the white blood cell count reached 3000/cubic millimeter. Her hematologic indices remained normal to the therapeutic dosage (Regan, 1987).

b) Leukopenia and neutropenia occurred in a 27-year-old female who received carbamazepine for at lea time of presentation, the carbamazepine dosage was 1200 milligrams (mg)/day. A reduction in dose to 1 an increase in white cell count. The patient's dose was further reduced to 900 mg/day 21 days later, but carbamazepine serum level rose and white cell count fell again. Approximately 3 months later, the patier carbamazepine and her white cell count rose when the serum concentration of carbamazepine fell to 11 patient's white cell counts showed a relationship to serum concentrations of the drug. The authors sugge important to determine if the hematologic side effects of carbamazepine are dose-related or idiosyncratic particular patient. If it is dose-related, carbamazepine can be continued provided the patient is closely m Beran, 1984).

3.3.5.I Malignant lymphoma

1) Summary

a) An 81-year-old man experienced lymphoma after 50 days of carbamazepine therapy (Lombardi et al, pseudolymphoma induced by carbamazepine in a 78-year-old woman was reported (Sinnige et al, 1990)

2) Literature Reports

a) CD30+ primary cutaneous anaplastic large-cell lymphoma was associated with carbamazepine thera girl. the patient started on carbamazepine, titrated to a dose of 600 mg/day, for lipothymic episodes durir Eight months later she was admitted for an erythematous macular eruption diagnosed as pityriasis rosea regressing, until 1 month later, the patient suddenly developed multiple painless reddish skin nodules on and arms. The nodules were 0.5 to 6 cm, and quickly grew and ulcerated. Histologic examination reveale pseudoepitheliomatous hyperplasia overlying a diffuse lymphoid infiltrate of large anaplastic cells, scatte cohesive clusters. Most of the anaplastic cells expressed the CD30/Ki-1 antigen, the TIA-1 antigen, and antigens. Carbamazepine was tapered and withdrawn. Lesions regressed with radiotherapy; some untre regressed after 4 months, though prominent scarring remained. After 3 years, the patient was healthy, w in remission (Di Lernia et al, 2001).

b) An 81-year-old man experienced lymphoma after 50 days of carbamazepine therapy (Lombardi et al, presented with fever, morbilliform pruritic rash, and jaundice with dark urine and acholic feces. He also h liver and mildly enlarged spleen. Carbamazepine was discontinued. The maculopapular rash progressec erythroderma. The patient also developed oliguria. Leukocyte count fell to 2400/cubic millimeter and hen grams/decaliter. The bone marrow aspirate showed anemia associated with bone marrow hypercellularit dyserythropoietic changes. Lab values improved but a repeat bone marrow aspirate confirmed a low-gra (non-Hodgkin's) and the absence of myelodysplastic changes.

c) A 44-year-old woman, who was allergic to phenytoin, developed anticonvulsant hypersensitivity syndi pseudolymphoma after 1 month of carbamazepine therapy (Nathan & Belsito, 1998). Her symptoms inclu lymphadenopathy, pneumonitis, hepatitis, and a morbilliform eruption. The skin biopsy showed atypical l dermis that were CD-3(+), CD-30(+), and L26(-). Her symptoms resolved 3 weeks after carbamazepine

d) A case of pseudolymphoma induced by carbamazepine in a 78-year-old woman was reported (Sinnig condition was characterized by generalized lymphadenopathy, hepatosplenomegaly, an abnormal differe cell count, hypergammaglobulinemia and anemia with evidence of severe immune dysregulation. Withdr carbamazepine resulted in resolution of all symptoms within a few days.

3.3.5.J Pancytopenia

1) Summary

a) Neutropenia (75 to 100 cases over 12 years) and pancytopenia (8 cases over 12 years), have been r chronic carbamazepine therapy (Tohen et al, 1995; Pellock, 1998a; Prod Info Tegretol(R), 2002b; Perry Marco & Melchiori, 1986)(Killian & Fromm, 1968). (Cates & Powers, 1998) reported concomitant rashes, thrombocytopenia associated with carbamazepine therapy, in 2 geriatric patients.

3.3.5.K Pure red cell aplasia

1) Summary

a) Two cases of pure red cell aplasia were reported in young girls taking carbamazepine for seizures (T Buitendag, 1990).

2) Literature Reports

a) A case of pure red cell aplasia was reported in a 3-year-old girl taking carbamazepine 150 milligrams control. Recovery followed drug discontinuation (Buitendag, 1990). A 7-year-old girl developed pure red months of carbamazepine monotherapy (Tagawa et al, 1997). She began to recover within 1 week of ca discontinuation.

3.3.5.L Thrombocytopenia

1) Summary

a) Thrombocytopenia is an infrequent but potentially serious side effect of carbamazepine and its occur discontinuation of the drug. The mechanism of this effect is unknown, but has been postulated to be imm due to the identification of carbamazepine-dependent antiplatelet antibodies (Tohen et al, 1991). Thromb often develops 2 weeks after initiating carbamazepine treatment, but there have also been cases reporte therapy (Tohen et al, 1995; Pellock, 1998a; Ishikita et al, 1999; Prod Info Tegretol(R), 2002b); (Tohen et al, 1991); (de Marco & Melchiori, 1986)(Killian & Fromm, 1968). Some cases are asymptomatic while oth fever, skin rash, arthralgia or swollen joints. Recovery usually occurs within 1 week of carbamazepine dis (Ishikita et al, 1999). There have been 31 cases reported to the manufacturer over a 12-year span (Pello incidence rate for thrombocytopenia of 0.5 per 100,000 prescriptions was reported by the United Kingdo Health's General Practice Research Database (Blackburn et al, 1998).

2) Literature Reports

a) ADULT

1) A 67-year-old woman, with Lennox-Gasteau syndrome, developed severe, isolated thrombocyto placed on a combination of carbamazepine and valproate for the treatment of generalized tonic-clon patient received carbamazepine 150 milligrams (mg) per day for 7 days, 600 mg/day on day eight, a mg/day by day nine. On day 10, valproate 300 mg/day was added because of nonconvulsive status valproate was discontinued 5 days later because the patient developed urticaria and a maculopapul

The thrombocyte count was 262 GIGA/L (normal: 150-360 GIGA/L) on day 5 and had dropped to 5 G at which time carbamazepine was also discontinued. The patient received two thrombocyte transfus thrombocyte count was within normal limits 3 days after the carbamazepine was discontinued. It cou determine whether it was carbamazepine alone or the combination of carbamazepine and valproate responsible for the severe thrombocytopenia (Finsterer et al, 2001).

2) Four cases of thrombocytopenia were reported in patients taking carbamazepine for bipolar diso the drop in platelet count occurred 14 to 16 days following the initiation of therapy and resolved with discontinuation. Carbamazepine doses in all patients were 400 to 600 milligrams daily. These cases somewhat by the presence of concomitant drug therapy including antipsychotics, lithium and benzoc et al, 1991).

3) A 31-year-old epileptic, female developed thrombocytopenia after receiving carbamazepine thera The patient was admitted with diffuse purpura and ecchymoses and her platelet count was 5000/ cu (3)). A migration inhibition factor test for carbamazepine was positive. Following withdrawal of the dr with phenytoin, her platelet count rose to 210,000/mm(3) (Schoenfeld et al, 1982).

4) In one study, 1 patient out of a total of 79 (1.5%) was reported with a platelet count of less than 8 millimeter and no evidence of bruising. The average doses given in the study were 600 to 800 millig although the specific dose and duration of treatment was not mentioned for this patient. After discon drug, a normal platelet count was measured within 1 week (Davis, 1969).

5) Thrombocytopenia was reported a patient receiving carbamazepine 800 milligrams daily for trige over a 10 month period. The platelet count was 50,000/cubic millimeter and a sternal biopsy reveale megakaryocytes with decreased platelet production. The patient's platelet count returned to normal carbamazepine discontinuation (Pearce & Ron, 1968).

b) PEDIATRIC

1) A 12-year-old boy developed thrombocytopenia 10,000/cubic millimeter with petechial rash after carbamazepine therapy. His platelet count recovered 7 days after withdrawal of carbamazepine and prednisone therapy. The boy was subsequently rechallenged with a single oral dose of carbamazep milligrams/kilogram. After 4 hours he developed fever, flushing, and conjunctival hyperemia. Leukoc increased with a left shift in the neutrophilic series. On the second day, platelet counts decreased ar increased. Levels of platelet glycoprotein IIb/IIIa or Ib were detected in plasma (Ishikita et al, 1999).

2) A 12-year-old girl developed thrombocytopenia and petechiae 2 weeks after starting carbamazep milligrams/kilogram/day. Her platelet count was noted to have decreased from 300,000/cubic millime 100,000/mm(3). Carbamazepine was discontinued with resolution of petechiae and an increase in p days (Ueda et al, 1998).

3) A case of carbamazepine-induced thrombocytopenia was reported in a young child. The child wa hospital with a diagnosis of scattered petechiae, 2 weeks after starting carbamazepine 100 milligram All of the patient's laboratory values were within normal limits except for a platelet count of 14,000/ c (mm(3)). Carbamazepine was withdrawn and the patient's platelet count rose to 239,000/mm(3) by c was not rechallenged (Bradley et al, 1985).

3.3.6 Hepatic Effects

Cholangitis

Hepatotoxicity

Injury of bile duct

Liver finding

3.3.6.A Cholangitis

1) Summary

a) Cholangitis has been reported in patients receiving carbamazepine (La Spina et al, 1994)(Larrey et a

2) Literature Reports

a) Cholangitis was described in a 79-year-old woman following carbamazepine 200 mg daily for approxi the treatment of facial neuralgia. A marked hypereosinophilia (54%) was associated with the hepatic lesi cholestasis was observed in the centrilobular areas on liver biopsy. However, granuloma or hepatocellul observed. Withdrawal of carbamazepine resulted in resolution of symptoms over a period of 2 weeks wit tests and eosinophils returning to normal over 3 months (Larrey et al, 1987). This patient had also been vincamine and clonazepam at the time of acute cholangitis, and these drugs were also discontinued with however, readministration of these 2 latter agents did not result in recurrence of symptoms. A second ca has been reported (La Spina et al, 1994).

3.3.6.B Hepatotoxicity

1) Summary

a) Hepatitis, cholestatic and hepatocellular jaundice, abnormal liver function tests and hepatic failure (ve have been reported in patients receiving carbamazepine. Several cases of hepatotoxicity were reported carbamazepine therapy. Symptoms were alleviated with the discontinuation of the drug (Prod Info Tegre Morales-Diaz et al, 1999; Horowitz et al, 1988; Larrey et al, 1987; Luke et al, 1986).

2) Literature Reports

a) A 9-year-old girl developed hepatotoxicity after 5 months of carbamazepine 500 milligrams per day (M 1999). She presented with persistent vomiting, fever, headache, jaundice and dark urine. Her aspartate a was level 550 International units/liter, alanine aminotransferase 570 International units/liter, alkaline phos International units/liter, and ammonia 148 micrograms/decaliter. She also had hypoprothrombinemia not intravenous vitamin K. Her carbamazepine was discontinued and she received prednisone 50 mg/day wi over the next 8 days.

b) Dose-related carbamazepine hepatotoxicity was reported in a 2-year-old child treated with carbamaz disorder (Luke et al, 1986). In one instance, she received an excessive dose of medication with a resulti blood level of 28 micrograms/milliliter; the concentration of the 10,11-epoxide metabolite was also signifi the second situation, the patient had been maintained on carbamazepine 150 milligrams twice daily for a months. In each situation, the patient developed severe neurological symptoms, significant elevations in (100 to 200 times baseline values) and elevated serum ammonia levels. All evidence of hepatotoxicity di discontinuation of the drug.

c) A 6-year-old, 13-kilogram boy with cerebral palsy suffered hepatorenal failure secondary to carbamaz milligrams/kilogram/day. He presented with fever, flaccidness, lethargy, and seizures. His blood urea nitr milligrams/decaliter, serum creatinine 3 milligrams/decaliter, aspartate aminotransferase 5168 Internatio alanine aminotransferase 6166 International units/liter, and lactate dehydrogenase 7378 International un carbamazepine level was elevated at 17.7 micrograms/milliliter after missing 2 doses. Carbamazepine w and fluid challenges were initiated. Serum creatinine peaked at 5.3 milligrams/decaliter on day 6, and dia on days 3 through 5. He slowly recovered during the next 13 days (Haase, 1999).

3.3.6.C Injury of bile duct

1) Summary

a) Severe bile duct injury and vanishing bile-duct syndrome have been reported with carbamazepine us Johnston, 1999)(de Galoscy et al, 1994; Forbes et al, 1992).

2) Literature Reports

a) A 52-year-old woman developed severe bile duct injury 4 weeks after starting carbamazepine 600 mg Johnston, 1999). She presented with fever and jaundice. Her aspartate aminotransferase level was 166 aminotransferase 122 units/L, alkaline phosphatase 2906 units/L, gamma-glutamyl transferase 4026 uni total/direct serum bilirubin 4.2/4. Histology from a percutaneous liver biopsy showed intact lobular archite few severely damaged bile ductules. Carbamazepine was discontinued and liver enzymes gradually dec next month.

b) Two cases of vanishing bile duct-syndrome occurred following carbamazepine administration (de Gal Forbes et al, 1992). Both patients presented with fever, skin rash, eosinophilia, and disappearance of int on liver biopsy.

3.3.6.D Liver finding

1) Hepatitis, cholangitis, cholestatic and hepatocellular jaundice, hepatorenal failure, abnormal liver function failure (very rare cases) have been reported in patients receiving carbamazepine. The hepatotoxic reaction to generally appears within the first month of therapy and usually improves upon withdrawal of the drug; the me presumed to be an idiosyncratic hypersensitivity reaction. Symptoms occur with usual therapeutic doses and the therapeutic range.

3.3.7 Immunologic Effects

Cross sensitivity reaction

Drug hypersensitivity syndrome

Hypogammaglobulinemia

Immune hypersensitivity reaction

Lymphadenopathy

Summary

Systemic lupus erythematosus

3.3.7.A Cross sensitivity reaction

1) Cross-sensitivity is reported in an 18-year-old male treated with carbamazepine for generalized tonic-clon
treatment with phenytoin resulted in an anticonvulsant hypersensitivity syndrome consisting of fever, rash, my
neck glands. Treatment with switched to carbamazepine 200 milligrams (mg) twice daily (BID), but the patien
following day with worsening symptoms. Physical examination revealed a maculopapular rash and painful lyn
Laboratory tests demonstrated an elevated white blood cell count (17,000 per cubic millimeter) with 9% eosir
elevated hepatic enzymes. Valproic acid 500 mg BID was started, as was intravenous methylprednisolone. T
patient's symptoms resolved and hepatic enzymes began to normalize. The patient was discharged; follow-up
recurrence of symptoms on valproic acid therapy. Cross-sensitivity with phenytoin, carbamazepine, and pher
explained by metabolism of the aromatic ring compounds to a toxic arene oxide intermediate, which stimulate
response. Valproic acid and benzodiazepines, structurally and metabolically different, are suitable alternative
seizures who experience the anticonvulsant hypersensitivity syndrome. Treatment involves discontinuation of
anticonvulsant, supportive care, and corticosteroids (Moss, et al, 1999). Cross sensitivity has been reported b
carbamazepine and phenytoin. Although the drugs are chemically dissimilar, they share the formation of arer
intermediate metabolites which may be responsible for toxicity, including hypersensitivity (Nathan & Balsito, 1
et al, 1991; Reents et al, 1989).

3.3.7.B Drug hypersensitivity syndrome

1) Carbamazepine treatment is suspected to be the cause of Drug Reaction with Eosinophilia and Systemic
(DRESS) syndrome in this 35-year-old male patient who presented with a 1-week history of jaundice, dark-co
lethargy, rash, vomiting, and high-fever. He had been taking phenytoin 200 mg twice daily for 14 months to tr
carbamazepine had been added 8 weeks prior to admission for uncontrolled seizures. The patient had no oth
relevance. Examination revealed a temperature of 104 degrees, jaundice, some facial edema, and a diffuse r
rash on his trunk, limbs, and face. Over the next few days, the rash became exfoliative, and the patients conc
He was screened for infection and started on benzylpenicillin and doxycycline for suspected leptospiral and ri
infections. Blood cultures, serology, cytomegalovirus, and herpes virus 6 screenings were negative. Total wh
was 4.2 X10(9)/L with a normal differential, and eosinophil count was normal. Echocardiogram and CT scan c
were normal. Despite adequate carbamazepine and phenytoin levels, the patient had a grand mal seizure du
A carbamazepine-induced reaction was suspected, therefore carbamazepine was stopped and a high-dose c
was started. Fever lowered, liver function tests that had been 10 times the upper limit of normal improved, an
discharged on a tapering dose of steroids. Follow-up indicated that the jaundice had gradually resolved and h
continued to demonstrate a downward trend. Study authors suspect that phenytoin may have sensitized the p
carbamazepine, and that carbamazepine was likely the causative agent of the clinical manifestation of DRES
2008).

3.3.7.C Hypogammaglobulinemia

1) A 49-year-old woman developed bronchiolitis obliterans organizing pneumonia (BOOP) secondary to carb
induced hypogammaglobulinemia after two years of carbamazepine therapy for epilepsy. The woman presen
progressive exertional dyspnea and prolonged productive cough. BOOP was diagnosed via computerize tom
and transbronchial biopsy. Laboratory analysis revealed severe hypogammaglobulinemia including immunog
milligrams/deciliter (mg/dL), Ig A 20 mg/dL, and Ig M 51 mg/dL. After carbamazepine withdrawal, gammaglob
and roentgenogram findings improved (Tamada et al, 2007).

3.3.7.D Immune hypersensitivity reaction

1) A 62-year-old woman developed a hypersensitivity syndrome associated with carbamazepine therapy. Sh
her first epileptic seizure in a neurological emergency unit. No intracranial pathology was found after an EEG
Cerebral spinal fluid and serum tested negative for parasitic, fungal, viral, or bacterial pathogens, and blood a
fluids were unremarkable. Epilepsy was suspected to cause the seizure; therefore, the patient was started or
carbamazepine 200 mg twice daily. Ten days after starting carbamazepine, she developed a fever, watery di
reddish, pruritic, maculopapulous rash on her entire body except her face and legs. Diarrhea improved, temp
normalized, and skin lesions disappeared after decreasing carbamazepine to 200 mg once daily and institutir
and antipyretic drugs; however, her condition dramatically worsened 20 days later. The patient experienced g
exanthema, watery diarrhea, and an increased temperature. Carbamazepine was discontinued and valproic a
admission, lab tests indicated a normal white blood cell count with relative eosinophilia and elevated transam
reactive protein level of 2.2 mg/dL, elevated serum creatinine of 1.3 mg/dl, and elevated serum potassium wa
ECG indicated terminal negative T waves in I, II, aVL, V(5), and V(6) with normalizing tendency after strain. M
scintigraphy, negative angina history, and normal troponine T and creatinine kinase ruled out an ischemic cai
condition improved, fever and diarrhea stopped, and the ECG normalized after treatment with IV methylpredr
for 1 week and antihistamines. Antiepileptic drug-induced hypersensitivity syndrome (AEDHS) was the plausi
the patient had no previous history of drug related side effects, cardiac, gastrointestinal, or dermatologic diso
apparent acute infection (Aigner et al, 2008).

2) A 5-year-old boy developed a hypersensitivity to carbamazepine after 3 weeks of therapy (Brown et al, 19
with fever, lethargy, diarrhea, abdominal pain, and macular rash. Lab tests showed hyponatremia and elevate
Carbamazepine was discontinued. Over the next few days, he developed edema and right-sided pleural effus
intubation. He improved over a 2-week period during which he required 12 days of ventilation. He also had 5
parenteral nutrition. The patient's peripheral blood monocyte proliferation response in vitro to carbamazepine
diagnosis of carbamazepine hypersensitivity.

3) A patient who had developed fever, headache, and a maculopapular rash while receiving carbamazepine from therapy and her symptoms resolved. Two years later, carbamazepine was reinstituted along with predni milligrams/day. After 10 days of carbamazepine therapy, the patient experienced fever, headache, photophol elevations of transamidase levels, and EEG findings consistent with toxic or metabolic encephalopathy. Altho occurred, no rash developed. All symptoms resolved within 72 hours of discontinuing the carbamazepine. Alt suppressed the rash associated with carbamazepine, the other manifestations of carbamazepine hypersensit prevented (Hampton et al, 1985).
4) A hypersensitivity reaction to carbamazepine, characterized by generalized erythroderma, a severe leuke hyponatremia, marked eosinophilia, and renal failure, was described in a 35-year-old woman with late-onset receiving carbamazepine therapy for approximately 3 weeks (Ray-Chaudhuri et al, 1989). The patient improv of carbamazepine and steroid therapy; however, introduction of sodium valproate resulted in development of leukocytosis, and eosinophilia; valproate was discontinued. The patient was not treated further with anticonvu seizures did not recur. A multisystemic hypersensitivity reaction after 50 days of chronic carbamazepine thera a 81-year-old man. His reaction was characterized by generalized erythroderma and renal, hepatic and bone (dyserythropoietic anemia)(Lombardi et al, 1999). A positive proactive test implicated carbamazepine as the

3.3.7.E Lymphadenopathy

1) A 17-year-old male with seizures secondary to a right parietal abscess developed cervical lymphadenopat of carbamazepine therapy titrated up to 600 milligrams per day (Ganga et al, 1998). He developed fever, mac and painful lymph nodes that were 1 to 2 centimeters, solid and round. Biopsies revealed kikuchi disease witl immunohistochemistry positive for CD68 and CD43. Liver transaminases were elevated with normal leukocyt lymphopenia, monocytosis and eosinophilia. Antibiotics were unsuccessful. Symptoms resolved 1 week after withdrawal.

3.3.7.F Summary

1) Multisystemic hypersensitivity and cross sensitivity has transpired in a variety of carbamazepine treated p al, 1999; Lombardi et al, 1999; Ray-Chaudhuri et al, 1989; Hampton et al, 1985; Moss et al, 1999); (Nathan & (Pirmohamed et al, 1991; Reents et al, 1989). Carbamazepine is suspected to be the most likely cause of a D Eosinophilia and Systemic Symptoms (DRESS) syndrome in a 35-year-old male patient (Fsadni et al, 2008). erythematosus (SLE) has been reported in several cases with varying length of carbamazepine therapy (Toe (Reiffers-Mettelock et al, 1997; Jain, 1991; Drory et al, 1989; Bateman, 1985)

3.3.7.G Systemic lupus erythematosus

1) Systemic lupus erythematosus (SLE) occurred in a 34-year-old male after 8 years of carbamazepine thera occurs after only months of therapy, however, this patient exhibited all of the clinical symptoms (rash, enlarge joint involvement, myalgia, fever, leukopenia, and positive antinuclear antibody titer) associated with SLE (To
2) A syndrome resembling systemic Lupus erythematosus (SLE) was induced by carbamazepine in a 40-yea a paralyzed left arm following an aneurysm. After one year of carbamazepine therapy, she developed red fac Raynaud's phenomenon of the extremities, the left-paralyzed arm being more affected. Her ANA was positive Later she developed a lichen-planus- like eruption with an increased ANA titer of 1/1280. Valproate was subs carbamazepine and after 6 months, the ANA titer was unchanged but anti-DNA antibodies and antihistone ar negative. The cutaneous lichenoid lesions improved (Reiffers-Mettelock et al, 1997).
3) Lupus erythematosus was described in a 30-year-old woman with complex partial seizures following carba daily (plus phenobarbital 120 milligrams daily) for approximately 1 year. At that time, the patient developed st the joints, a blotchy rash on her hands and feet, and eye symptoms (soreness and pruritus). Pleuritic chest pa leukopenia, as well as a positive ANA titer, were observed and the drug was withdrawn with continuance of p therapy and the addition of prednisolone 30 mg daily. Improvement occurred rapidly; however, the ANA titer r at 1:160 (Bateman, 1985).
4) Systemic lupus erythematosus (SLE) was described in an 18- year-old male after receiving carbamazepin each day for approximately 5 months in the treatment of complex partial seizures and secondary generalizati developed severe migrating arthralgia 5 months after initiation of therapy; low-grade fever and profuse sweat weeks later. Antinuclear factor was positive at that time, and anti-DNA was 74% (normal, 14%); a few LE cell Withdrawal of carbamazepine and institution of prednisone therapy (60 milligrams daily) resulted in abatemer However, seizure activity recurred and phenytoin was initiated, resulting in a severe relapse of SLE symptom despite continued steroid therapy. Substitution of phenytoin with sodium valproate, with continued steroid the recovery within 3 weeks. The patient was treated subsequently with sodium valproate and primidone without systemic manifestations. This case report suggests that carbamazepine may be associated with SLE, and tha phenytoin therapy can induce relapse in these patients. Based upon this case report, Ciba-Geigy has include potential adverse effect of carbamazepine in the product data (Drory et al, 1989). However, in the absence of impossible to establish a definite cause-effect relationship between carbamazepine and SLE in this patient. A cases of systemic lupus erythematosus induced by carbamazepine was provided (Jain, 1991).
5) (Verma et al, 2000) report a carbamazepine-induced systemic lupus erythematosus syndrome presenting tamponade after 8 months of therapy in a 45-year-old male. Blood serologic studies revealed a positive ANA Pericardicenteses was performed with immediate relief and carbamazepine was discontinued. The patient ful

3.3.8 Musculoskeletal Effects

Disorder of connective tissue

Musculoskeletal finding

Myasthenia gravis

Osteomalacia

3.3.8.A Disorder of connective tissue

1) Summary

a) The occurrence of connective tissue disorders is 6% of patients who were treated with a single barbit monotherapy (Mattson et al, 1989). It is suggested that switching to an alternative antiepileptic should be patients presenting with symptoms of musculoskeletal problems who are receiving barbiturates.

2) Literature Reports

a) The occurrence of connective tissue disorders in 10 of 178 patients (6%) who were treated with a sin (phenobarbital or primidone) as monotherapy for 6 months or longer were reported in a prospective stud 1989). The disorders occurred in 7 of the 10 patients during the first year of treatment. The connective tis associated with primidone in these patients were frozen shoulder, arthralgias, Dupuytren's contractures; shoulder pain, Dupuytren's contractures, Peyronie's disease were observed. In this study, no associatior between new-onset connective tissue disorders and carbamazepine or phenytoin therapy (for 6 months data support the association between barbiturate use and the development of connective tissue disorder that switching to an alternative antiepileptic (carbamazepine, phenytoin, valproic acid) should be conside presenting with symptoms of musculoskeletal problems who are receiving barbiturates.

3.3.8.B Musculoskeletal finding

1) Summary

a) Aching joints, sore muscles and leg cramps have been reported in patients receiving carbamazepine (R), 2002b).

2) Aching joints and muscles, leg cramps and general connective tissue disorders have been reported in pat carbamazepine. The data is conflicting with regard the propensity of carbamazepine to induce osteomalacia . systemic lupus erythematosus have also been reported.

3.3.8.C Myasthenia gravis

See Drug Consult reference: DRUG-INDUCED MYASTHENIA GRAVIS

3.3.8.D Osteomalacia

1) Summary

a) There are conflicting data regarding the effects of carbamazepine on bone mineral density in children identified reduced bone mineral density in children treated with carbamazepine for an average of approx (Kumandas et al, 2006). Another showed an association between carbamazepine use and increased bor collagen metabolism in young male patients (Verotti et al, 2000). However, earlier studies differed by cor mineral density in the lumbar region of children receiving carbamazepine was not significantly different fr group (Akin et al, 1998; Hoikka et al, 1984; Tjellesen et al, 1983; Zerwekh et al, 1982).

2) A 2-year cross sectional and retrospective study concluded that lumbar spine bone mineral density values reduced in prepubertal children treated with carbamazepine and valproic acid compared to controls. Sixty-six with antiepileptics (carbamazepine: 20 boys, 13 girls; mean age 9.7 +/-1.6 years; valproic acid: 17 boys, 16 g +/- 2 years) were compared to age- and sex-matched controls (13 boys, 9 girls; mean age 8.9 +/- 2.3 years). ambulatory with normal activity and had adequate nutritional intake, which excluded factors that could reduce biochemical markers of bone turnover. Mean length of treatment was 35.52 +/- 12.84 months for carbamazep 15 months for valproic acid. Mean BMD z-scores at lumbar spine were -1.69 +/- 0.85 for carbamazepine, -1.2 valproic acid, and -0.23 +/- 0.87 for the control group. Differences in serum insulin-like growth factor (IGF)-I a protein (IGFBP)-3 levels, which affect bone metabolism and BMD, between children receiving antiepileptics c controls were not significant. It is thought that the mechanism of carbamazepine-associated reduction in BMD altered hepatic conversion of vitamin D or excessive enzymatic degradation of vitamin D (Kumandas et al, 20

3) Carbamazepine has been associated with increased bone turnover and collagen metabolism in young ma et al, 2000). Bone mineral density in the lumbar region in children receiving carbamazepine was not significar the control group (Akin et al, 1998; Hoikka et al, 1984; Tjellesen et al, 1983; Zerwekh et al, 1982).

4) A prospective evaluation demonstrated that carbamazepine therapy was associated with increased bone collagen metabolism in young male patients receiving the drug for idiopathic partial epilepsy. Markers of bone (alkaline phosphatase, Osteocalcin, and propeptides of type I and III procollagen) were significantly higher at carbamazepine-treated patients as compared to those in 15 healthy, age-matched volunteers. Similarly, mark resorption (serum telopeptide of type I collagen and urinary N- telopeptides of type I collagen) were significar patients. Serum levels of calcium, phosphate, magnesium, parathyroid hormone, and vitamin D metabolites v normal range before and after carbamazepine treatment. Carbamazepine-treated patients received usual dos milligrams per kilogram per day and had therapeutic serum concentrations (Verotti et al, 2000).

5) Bone mineral density at L2-L4 levels of lumbar vertebrae in children receiving carbamazepine (n=28, aver micrograms/milliliter (mcg/mL)) for an average of 2.6 years were not significantly different from a control grou than 0.05). Bone mineral density measured by dual-energy x-ray absorptiometry was 0.611 grams per centim the carbamazepine group and 0.568 grams per centimeter squared in the control group (Akin et al, 1998).
6) Bone mineral metabolism was studied in 21 epileptic patients on chronic carbamazepine monotherapy at of 505 milligrams. In 3 cases, hypocalcemia was identified; hypophosphatemia was noted in 1 patient and 4 p demonstrated elevated serum alkaline phosphatase levels. Serum 25-hydroxy vitamin D levels were significa controls in all patients. No significant difference was noted in bone mineral density or in the amount of trabec patients and controls. Two patients were found to have histological evidence of osteomalacia (Hoikka et al, 1
7) Data are conflicting with regard to the propensity of carbamazepine to induce osteomalacia to a similar de Reductions in 24,25-dihydroxycholecalciferol concentrations during carbamazepine, phenytoin and phenobar been reported (Zerwekh et al, 1982). This deficiency may play an important role in the pathogenesis of anticc osteomalacia induced by carbamazepine. Reduction in 25-hydroxycholecalciferol occurred only in patients tre phenobarbital. Calcium metabolism was evaluated in 30 adult epileptic patients receiving carbamazepine as therapy for 1 to 10 years (serum levels, 3 to 11 micrograms/milliliter) (Tjellesen et al, 1983). Their examinatio normal bone mass in these patients as well as normal serum concentrations of 25-hydroxycholecalciferol. Se were decreased and alkaline phosphatase levels were increased. The authors suggest that single agent ther carbamazepine is not associated with adverse effects on bone metabolism (anticonvulsant osteomalacia). In 25- hydroxycholecalciferol levels were decreased significantly only in patients treated with phenobarbital, anc receiving carbamazepine, suggesting that this deficiency is not the abnormality in anticonvulsant osteomalaci reductions in 24,25- dihydroxycholecalciferol may be implicated (Zerwekh et al, 1982). Serum levels of 24,25,dihydroxycholecalciferol were not performed in the other study (Tjellesen et al, 1983).

3.3.9 Neurologic Effects

Aseptic meningitis

Finding related to coordination / incoordination

Impaired cognition

Motor dysfunction

Movement disorder

Myoclonus

Neuroleptic malignant syndrome

Neurological finding

Nystagmus

Seizure

Somnolence

3.3.9.A Aseptic meningitis

1) Summary
a) Aseptic meningitis has been associated with the use of carbamazepine in 2 cases (Simon et al, 1990 1989).
2) Literature Reports
a) Aseptic meningitis, confirmed on rechallenge, has been described in a 45-year-old female during carb therapy (Hilton & Stroh, 1989). Three days after beginning therapy with carbamazepine 100 milligrams tv patient developed a fever, sore throat, and rhinorrhea. Carbamazepine was discontinued and therapy wi milligrams 3 times a day was initiated. The patient's symptoms resolved over 5 days and carbamazepine restarted. Within 1 day, the patient developed perioral numbness, which progressed over 2 days to perip paresthesias. Fever developed and a malar rash was noted. The patient was diagnosed wish aseptic me basis of physical examination and laboratory findings. Symptoms again resolved over 7 to 10 days follow discontinuation of carbamazepine. A similar case without rechallenge has been reported (Simon et al, 19

3.3.9.B Finding related to coordination / incoordination

1) Summary

a) Vertigo, unsteadiness and dizziness are relatively common side effects of carbamazepine therapy, ge with the initiation of therapy (Prod Info Tegretol(R), 2002b).

3.3.9.C Impaired cognition

1) Summary

a) Carbamazepine did not impair the elderly patient's reflexes while driving (Etminan et al, 2004). Cogni memory tests performed in 7 children during carbamazepine therapy demonstrated that therapeutic dose associated with adverse neurologic effects (Riva & Devoti, 1999).

2) Literature Reports

a) Elderly users of lithium (but not carbamazepine) are at increased risk of having an injurious car accid than age-matched controls. A case-control study nested within a cohort was conducted. The cohort cons drivers between the age of 67 and 84 years living in Quebec providence for at least two years. Cohort su followed until they reached 85 years of age, left the providence, or the end of study date, May 31, 1993. vehicle crash was defined as one person in the car sustaining a physical injury. Drug exposure was defir prescription dispensed within the 60 days before the date of car accident. Of the 5579 subjects that had during the study period, 20 were prescribed lithium and 18 carbamazepine. A random sample of 6% (13, subjects within the cohort showed 27 and 48 were prescribed lithium and carbamazepine, respectively. I accidents were more likely to occur with elderly drivers who were prescribed lithium (rate ratio 2.08 (95% interval (CI), 1.11 to 3.9)). The rate of injurious car accidents with drivers prescribed carbamazepine, wa different from controls (rate ratio 0.83 (95% CI, 0.48 to 1.44)) (Etminan et al, 2004).

b) Cognitive function and memory tests performed in 7 children during carbamazepine therapy demonst therapeutic doses were not associated with adverse neurologic effects. Patients with symptomatic partia carbamazepine for 4 to 15 years, with measured serum concentrations consistently within the therapeuti Withdrawal of treatment was allowed if patients were seizure- free for 2 years and demonstrated no electroencephalographic abnormalities for 1 year. At a mean of 17 months following carbamazepine with testing showed improvement in all scores, but significant improvement occurred only in tests assessing f more complete tasks. This potentially suggests that the effects of carbamazepine on decreasing neuron excitability may impair information circuitry in the front areas of the brain. However, in patients' studies, c testing scores never fell below the normal range (Riva & Devoti, 1999).

3.3.9.D Motor dysfunction

1) Summary

a) Carbamazepine has been associated with episodes of dystonia possibly due to its antagonism of dop Tegretol(R), 2002b); (Bradbury & Bentick, 1982; Larazo, 1982)(Crosley & Swender, 1979; Jacome, 1979

2) Literature Reports

a) Four episodes of dystonia in 3 children with generalized tonic-clonic seizures occurred in association carbamazepine use. Carbamazepine dosage was increased to a maximum of 25 milligrams/kilogram/da symptoms beginning 2 to 3 weeks after start of therapy. Symptoms subsided within 3 weeks following di second course of carbamazepine in 1 child resulted in dystonia (Crosley & Swender, 1979).

b) Carbamazepine produces dyskinesias similar to those induced by neuroleptic agents (Chadwick et al asterixis and cerebellar syndrome is reported in a 66-year-old patient receiving doses of 800 to 1200 mil decreasing the dose to 800 milligrams daily, the asterixis improved markedly and only minor nystagmus discontinuation of therapy, asterixis and nystagmus subsided completely.

c) Treatment with carbamazepine in ordinary doses can cause motor impairment in children (Braathen e Nineteen children were tested while receiving carbamazepine and 6 months later without treatment. Sign improvements were found in response speed (p less than 0.05), composite fine-motor tests (p less than test battery (p less than 0.05).

3.3.9.E Movement disorder

1) Summary

a) The appearance or worsening of tics has been reported in 9 cases. With the withdrawal of carbamaze patients with a previous history, the tics did not resolve, suggesting the drug may trigger the onset of Tou Tics did subside in patients without a history of movement disorders after discontinuation of carbamazep (Robertson et al, 1993; Kurlan et al, 1989; Neglia et al, 1984).

2) Literature Reports

a) The appearance or worsening of tics was reported in 3 patients with underlying movement disorders chorea, tardive dyskinesia and tourette's syndrome) following initiation of low doses of carbamazepine (K The tics included vocalizations, facial tics and generalized motor tics; these disappeared or returned to b discontinuation of the drug.

b) Three similar cases of a syndrome like Tourette's associated with carbamazepine for control of seizu reported (Neglia et al, 1984). Tics and vocalizations did not resolve upon discontinuation of the carbama that the drug might trigger the onset of Tourette's syndrome in susceptible patients.

c) Transient facial tics were reported in 3 children with no previous history of involuntary movements (R 1993). The tics, characterized by abnormal movements of the eyes and mouth, began about two weeks carbamazepine and despite therapeutic serum levels. In 2 of the cases the tics gradually subsided after continuous therapy; in the third case, carbamazepine was discontinued with resolution of symptoms.

3.3.9.F Myoclonus

1) Summary

a) Myoclonus was reported secondary to carbamazepine. Withdrawal of therapeutic levels of carbamaz involuntary movements (Nanba & Maegaki, 1999; Aguglia et al, 1987).

2) Literature Reports

a) A case of epileptic negative myoclonus is reported in a 7- year-old child treated with carbamazepine f childhood epilepsy with centrotemporal spikes. Carbamazepine was increased to 300 milligrams per day frequency did not decrease. In addition, several weeks after beginning carbamazepine treatment, the pa brief episodes of loss of tone in one or both arms, accompanied by eye blinking. Electroencephalograms spike and wave discharges that tended to spread diffusely. This activity ceased when carbamazepine wa (Nanba & Maegaki, 1999).

b) A further report of myoclonus secondary to carbamazepine was described in a 11-year-old boy with b epilepsy (Aguglia et al, 1987). Nonepileptic myoclonus and tic-like movements were observed after 2 we carbamazepine therapy (15 milligrams/kilogram/day). Withdrawal of the drug resulted in resolution of inv movements within several days; rechallenge with carbamazepine again produced myoclonic symptoms. occurred in the presence of therapeutic serum levels of carbamazepine.

3.3.9.G Neuroleptic malignant syndrome

1) Summary

a) A case of neuroleptic malignant syndrome (NMS) induced by carbamazepine was reported in a schiz a history of classic NMS secondary to antipsychotics (O'Griofa & Voris, 1991).

2) Literature Reports

a) A case of neuroleptic malignant syndrome (NMS) induced by carbamazepine was reported in a schiz a history of classic NMS secondary to antipsychotics (O'Griofa & Voris, 1991). Following 3 weeks of carb milligrams 3 times daily (serum level 10.8 micrograms/milliliter), the patient developed fever, increased c phosphokinase, tachycardia, hypertension, diaphoresis and leukocytosis; there was no evidence of musc Symptoms of NMS resolved within 10 days following discontinuation of the carbamazepine despite conti intramuscular lorazepam and amobarbital.

3.3.9.H Neurological finding

1) Summary

a) Other central nervous system effects that have been reported carbamazepine therapy include headac disturbances, confusion, peripheral neuritis, and paresthesias, (Bradbury & Bentick, 1982)(Lazaro, 1982 O'Donnell, 1984)(Aguglia et al, 1987; Silverstein et al, 1982; Shields & Saslow, 1983; Kurlan et al, 1989; (R), 2002b).

2) Symptoms of vertigo, drowsiness, unsteadiness and dizziness are relatively common side effects of carba Other central nervous system effects that have been reported include aseptic meningitis, headache, speech confusion, depression with agitation, psychosis, mania, nystagmus, visual hallucinations, peripheral neuritis, worsening of tics, dystonic reactions such as dyskinesias and myoclonus, and neuroleptic malignant syndrom seizures in children has also occurred. Patients with chronic focal epilepsy who exhibited cerebellar atrophy c resonance imaging were at increased risk of cerebellar adverse effects of carbamazepine.

3.3.9.I Nystagmus

1) Summary

a) Nystagmus occurs often with therapeutic levels of carbamazepine (Prod Info Tegretol(R), 2002b; Rar (Weeler et al, 1982).

2) Literature Reports

a) In a controlled trial, nystagmus occurred in 52% of 35 adult epileptic patients treated with carbamaze sufficient to maintain therapeutic serum concentrations (Ramsay et al, 1983a). Nystagmus was consider effect and did not interfere with daily functioning and in some cases was transient. Nystagmus did not ne discontinuation in any patient. Nystagmus may also occur in overdosage or acute toxic reactions (Fraunf 1982).

b) DOWNBEAT NYSTAGMUS was reported following several weeks of carbamazepine therapy in a 23- (Wheeler et al, 1982). The occurrence of nystagmus was associated with a high unbound concentration (2.6 micrograms/milliliter). Downbeat nystagmus with oscillopsia and reduced visual acuity has also beer patients taking carbamazepine with blood levels of 9 to 12 micrograms/milliliter. Symptoms reversed upo reduction (Chrousos et al, 1987).

c) Patients with chronic focal epilepsy who exhibited cerebellar atrophy on magnetic resonance imaging increased risk of cerebellar adverse effects of carbamazepine. These patients exhibited gaze-evoked ny than 0.001), dizziness (p less than 0.008), and ataxia of stance (p less than 0.02) at significantly lower se concentrations as compared to patients without cerebellar atrophy (Specht et al, 1997).

3.3.9.J Seizure

1) Summary

a) Carbamazepine increases the risk of exacerbation of seizures in children and adolescents (Prasad et al, 1986; Snead & Hosey, 1985). Patients developing uncontrolled, generalized seizures during carbama should be examined for possible carbamazepine exacerbation of epilepsy (Dhuna et al, 1991).

2) Literature Reports

a) Exacerbation of seizures may occur in children receiving carbamazepine monotherapy (Prasad et al, 1998; Shields & Saslow, 1983). Exacerbations occur when children with absence seizures are erroneous carbamazepine. Patients have experienced increased absences or myoclonic jerking. One study noted t children (28.5%) beginning carbamazepine therapy experienced a clinical or electroencephalographic de seizure disorder regardless of type (Prasad et al, 1998).
b) Fifteen children were evaluated with complex partial seizures where 1 or more seizure type was exac carbamazepine therapy (Snead & Hosey, 1985). The most common seizure type exacerbated by the dru atypical absence seizures in 11 children. in 4 patients, more frequent and severe generalized convulsive the use of video-electroencephalographic monitoring enabled evaluation of risk factors for seizures induc carbamazepine. a bilaterally synchronous spike and wave discharge of 2.5 to 3 cycles/second was consi an increase in atypical absence seizures with carbamazepine. generalized bursts of spikes and slow wav cycles/second were suggestive of a risk of increased generalized convulsive seizures. A generalized par wave discharge was observed in all children who had exacerbated seizures induced by carbamazepine.
c) It is suggested that carbamazepine be used cautiously to treat a complex partial component of mixed in children, as the risk of seizure exacerbation was approximately 12% in this series of patients. Children of generalized absence or atypical absence seizures appear to be at a particularly high risk. The drug sh when generalized, synchronous, spike and wave discharges of 2.5 to 3 cycles/second are observed rega clinical manifestation. Prolonged video-EEG monitoring is suggested prior to carbamazepine therapy in c seizure disorders to identify patients at risk of developing seizure exacerbation during treatment. The occ worsening of atypical absence or generalized convulsive seizures following the addition of carbamazepir be an indication that seizure activity may be a result of carbamazepine rather than the natural history of Hosey, 1985).
d) Myoclonic, atypical absence and/or atonic (minor motor) seizures were reported within a few days of carbamazepine treatment for epilepsy in 5 children (3 to 11 years of age) (Shields & Saslow, 1983). With resulted in resolution of symptoms in 2 children, whereas in 2 others, minor motor seizures resolved in 3 the remaining child, seizures persisted, and this child was later found to have ceroid lipofuscinosis. The a that carbamazepine can in some cases precipitate or exacerbate minor motor seizures and their occurre days of initiation of therapy requires withdrawal of the drug.
e) Exacerbation of epilepsy was reported in 26 adolescents and children receiving carbamazepine (Horr epileptic syndromes were affected by carbamazepine: childhood absence seizures; focal symptomatic, fi epilepsy; Lennox-Gastaut syndrome; and severe myoclonic epilepsy of infancy. New-onset absence seiz of the 26 patients, and 3 patients with established absence seizures experienced absence status. It is su caution be exercised when carbamazepine is administered to children or adolescents with absence or m Patients developing uncontrolled, generalized seizures during carbamazepine therapy should be examin carbamazepine exacerbation of epilepsy. Withdrawal of the drug in these patients may result in marked i
f) Seizure exacerbation was attributed to high levels of carbamazepine-10,11-epoxide in a series of 6 pa condition unexpectedly deteriorated (So et al, 1994). In all 6 cases, the patients were taking other drugs serum carbamazepine- epoxide levels. Status epilepticus did not respond to intravenous phenytoin, and after withholding carbamazepine. While routine monitoring of serum carbamazepine-epoxide levels is no the authors suggest obtaining a level when the cause of seizure exacerbation or drug toxicity is not appa
g) The development of frequent complex partial seizures and nonepileptic multifocal myoclonus was rep month-old child started on carbamazepine therapy for generalized tonic-clonic seizures previously unres phenobarbital and valproic acid. Carbamazepine blood levels reached 8.2 micrograms/milliliter and carba epoxide levels were 8.9 micrograms/milliliter. Within 24 hours of carbamazepine discontinuation, seizure myoclonus disappeared within 5 days. The authors postulate that symptoms may have related to toxic co the epoxide metabolite (Dhuna et al, 1991).

3.3.9.K Somnolence

1) Summary

a) Marked drowsiness is a common adverse effect of carbamazepine therapy (Prod Info Tegretol(R), 20 1997; Smith, 1991; Levy et al, 1985).

2) Literature Reports

a) Daytime sleepiness was worse in carbamazepine patients as compared with controls (Bonanni et al, carbamazepine monotherapy (n=26) and controls (n=12) were tested for sleepiness using the multiple sl Compared with controls, the carbamazepine group showed statistically significant shorter sleep latencies 0.001).
b) Profound drowsiness was reported in a 19-month-old boy receiving carbamazepine for seizure activit receiving carbamazepine 100 milligrams 4 times a day (35 milligrams/kilogram/day) which produced sev 17 days. Serum levels of carbamazepine were within therapeutic range upon admission. Further investig normal behavior when serum levels of carbamazepine had decreased to 4 micrograms/milliliter (10 hours dose) and severe drowsiness occurred immediately following a test dose of 100 mg carbamazepine (Lev
c) Carbamazepine 800 mg daily in combination with phenytoin 500 mg daily was prescribed for symptor neuralgia in a 66-year-old woman. Maximum blood levels were 2.6 micrograms/milliliter and 16.5 microg respectively. After 2 weeks of combined therapy, the patient developed drowsiness, confusion, staggerin disorientation and confusion. The EEG indicated diffuse cerebral dysfunction. Within 48 hours of drug dis encephalomyelopathy disappeared and facial pain returned. A retrial of carbamazepine resulted in hyper spasticity without evidence of mental status change. Discontinuation resulted in complete resolution of sy 1991).

3.3.10 Ophthalmic Effects

Disorder of oculomotor system

Eye / vision finding

Oculogyric crisis

Retinopathy

3.3.10.A Disorder of oculomotor system

1) Summary

a) Oculomotor disturbances have been reported with carbamazepine therapy (Prod Info Tegretol(R), 20

3.3.10.B Eye / vision finding

1) Summary

a) Diplopia, esotropia, blurred vision and impaired visual contrast sensitivity occasionally occur with carb therapy (Fukuo et al, 1998; Tomson et al, 1988; Fraunfelder & Meyer, 1982; Livingston et al, 1974). In ac opacities and conjunctivitis have been reported; a direct causal relationship has not been established (Pr (R), 2002b)

2) The following ocular effects have been reported during carbamazepine therapy: blurred vision, transient d oculomotor disturbances. In addition, lens opacities and conjunctivitis have been reported; a direct causal rel been established. An oculogyric crisis has been reported in 1 case and ophthalmoplegia was reported in 2 pa elevated carbamazepine blood levels. Visual disturbances are reversible and may clear without reduction of c however, such problems are most common with high doses and typically respond to dosage decreases.

3) Literature Reports

a) An 11-year-old boy with head trauma and postsurgical convulsions developed diplopia associated wit his carbamazepine had been increased to 700 milligrams per day and his level was 12.5 micrograms/mil examination he was also noted to have esotropia and lateral gaze nystagmus. Carbamazepine was decr milligrams and the symptoms disappeared (Fukuo et al, 1998).

b) Blurred vision, most often manifested as diplopia, occurs occasionally during therapy with carbamaze figures have varied from 0% of patients in 1 series (n=280) (Andersen et al, 1983) to as many as 17% wi another 5.5% with transient blurred vision in another series (n=255) (Livingston et al, 1974). Visual distur reversible and may clear without reduction of drug dosage although such problems are most common wi typically respond to dosage decreases. Vision changes generally are not serious; a small number of lens resembling cataracts have been reported, but an association with carbamazepine is unproved (Fraunfelc 1982).

c) Impaired visual contrast sensitivity has been reported in a study of 27 epileptic patients receiving carb monotherapy. These patients had no subjective complaints of visual disturbance and critical flicker-fusion not affected. The effect upon visual contrast sensitivity appeared to be dose-related, with higher blood le greater impairment (Tomson et al, 1988).

3.3.10.C Oculogyric crisis

1) Summary

a) A case report of an oculogyric crisis in an 8-year-old girl was also reported with carbamazepine thera 1979).

2) Literature Reports

a) One case of oculogyric crisis in a 8-year-old girl was reported (Fallat & Norris, 1979). Oculogyric crisis carbamazepine was added to her regimen of phenytoin and phenobarbital. There was temporary cessati when treated with 25 milligrams of oral diphenhydramine and permanent cessation when the carbamaze completely withdrawn. The highest serum level of carbamazepine recorded was 4.3 micrograms/milliliter

3.3.10.D Retinopathy

1) Summary

a) Two cases of retinopathy in patients treated with long-term carbamazepine therapy have been report Syversen, 1986).

2) Literature Reports

a) Two cases of retinopathy in patients treated with long-term carbamazepine therapy have been report Syversen, 1986). Despite the absence of systemic toxicity, both patients developed decreases in visual a disturbances. Examination revealed lesions of the retinal pigment epithelium, which partially resolved in discontinuation of the drug.

3.3.11 Otic Effects

Auditory dysfunction

Ear and auditory finding

3.3.11.A Auditory dysfunction

1) Summary

a) Several case reports of a lowered pitch perception shift have been identified following the administrat carbamazepine (Kobayaski et al, 2001)(Kashihara et al, 1998).

2) Literature Reports

a) In two separate case reports, a 17-year-old girl and a 10-year-old boy experienced a downwards pitcl of one semitone after receiving carbamazepine 400 milligrams per day. In addition to carbamazepine, th receiving sulpiride and bromazepam, and the boy was taking imipramine and bromazepam. The girl noti two days following the carbamazepine, and the boy noticed the pitch perception change 3 to 4 hours afte drug. Neither patient demonstrated any other signs of carbamazepine toxicity. The girl's pitch perception one week after discontinuing carbamazepine, and the boy stopped complaining of the pitch perception c remaining on carbamazepine (Kobayashi et al, 2001).

b) Within 3 days of beginning carbamazepine 200 milligrams (mg)/day, an 18-year-old woman with gene noticed a false lowering of perceived pitch (Kashihara et al, 1998). She noted false pitches of the telepho sounds, and mechanical noises. After 2 weeks, her carbamazepine dose was increased to 300 mg and s TINNITUS (noted in approximately 0.2% of carbamazepine patients). Carbamazepine was subsequently auditory symptoms disappearing in 2 days.

3.3.11.B Ear and auditory finding

1) Several cases of lowered pitch perception shift have been reported in association with carbamazepine the

3.3.12 Psychiatric Effects

Mania

Psychiatric sign or symptom

Psychotic disorder

Suicidal thoughts

3.3.12.A Mania

1) Summary

a) Carbamazepine has been associated with mania in a few cases (Prod Info Tegretol(R), 2002b; Kurla Aguglia et al, 1987; Drake & Peruzzi, 1986; Reiss & O'Donnell, 1984; Reiss & O'Donnell, 1984); (Shields 1983; Bradbury & Bentick, 1982)(Lazaro, 1982; Silverstein et al, 1982).

2) Literature Reports

a) Mania attributable to carbamazepine was described in 2 children (Reiss & O'Donnell, 1984). In 1 chil had also developed after receiving imipramine and dextroamphetamine. The authors suggest that, due t similarities between carbamazepine and tricyclic antidepressants, this reaction may be similar to that ind antidepressants.

b) Carbamazepine was associated with the occurrence of an acute manic state in a 40-year-old seizure days of therapy for complex partial seizures (200 milligrams 4 times a day). Withdrawal of the drug result of psychiatric symptoms within the ensuing 24 hours. Inadvertent readministration of carbamazepine 200 times a day reproduced acute manic symptoms, which again subsided upon withdrawal of the drug. It is carbamazepine may have produced a paradoxical effect; the patient recalled brief euphoric episodes foll occurrence of seizures, at which time carbamazepine was administered, and exacerbation or prolongatic cerebral dysfunction may have occurred (Drake & Peruzzi, 1986).

3.3.12.B Psychiatric sign or symptom

1) Psychiatric effects that have been reported with carbamazepine therapy include depression with agitation and visual hallucinations.

3.3.12.C Psychotic disorder

1) Summary

a) Acute adverse behavioral changes were noted with both the initiation and withdrawal of carbamazepi Depression with agitation has also been reported (Heh et al, 1988); (Reiss &O'Donnell, 1984)(Silverstein Berger, 1971).

2) Literature Reports

a) Acute adverse behavioral changes were reported in 7 children following initiation of carbamazepine th
et al, 1982). Symptoms of irritability, agitation, insomnia, aggressive outbursts, delirium, confusion, and h
appeared within 4 days to several weeks after initiation of therapy. Serum concentrations at the time of th
ranged from 5.8 to 11.8 micrograms/milliliter. The 3 most severe reactions occurred in children who were
retarded, suggesting that prior psychopathological problems may predispose to adverse reactions. In all
behavior changes resolved upon drug discontinuation, and 5 of the 7 patients were eventually able to tol
when lower doses were used.
b) Abrupt discontinuation of carbamazepine 600 to 800 mg daily resulted in exacerbations of psychotic s
including paranoia, hostility and agitation in 2 of 20 schizophrenic patients treated with carbamazepine in
an antipsychotic. The authors postulate the possibility of a withdrawal syndrome caused by carbamazepi
rebound or a hyperdopaminergic state (Heh et al, 1988).
c) At least 1 case of visual hallucinations has been reported secondary to carbamazepine therapy (Berg
year-old female developed visual hallucinations after 2 weeks of carbamazepine 100 milligrams 4 times a
neuralgia. Specifically, she complained of strangers in her apartment and insects on walls. The patient w
hospital and all drugs were discontinued including pentazocine, corticosteroids, carisoprodol, and analge
Hallucinations disappeared gradually and the neuralgia did not occur. A test dose of carbamazepine 60 m
a day was administered and visual hallucinations recurred within 2 days. They again subsided when the
withdrawn.

3.3.12.D Suicidal thoughts

1) Data reviewed by the US Food and Drug Administration suggest an increased risk of suicidal behavior or
in patients receiving therapy with antiepileptic drugs (AEDs). The analysis included 199 placebo-controlled cli
covering 11 different AEDs used for several different indications such as epilepsy, selected psychiatric illness
conditions, including migraine and neuropathic pain syndromes. The analysis included 27,863 patients treate
16,029 patients who received placebo, and patients were aged 5 years and older. There were 4 completed su
patients in the AED treatment groups versus (vs) none in the placebo groups. Suicidal behavior or ideation oc
patients in the AED treatment groups compared to 0.22% of patients in the placebo groups. This corresponde
2.1 per 1000 (95% confidence interval, 0.7 to 4.2) more patients in the AED treatment groups having suicidal
ideation than the placebo groups. The increased risk of suicidality was noted at 1 week after starting an AED
at least 24 weeks. When compared to placebo, results were generally consistent among the drugs and were
demographic subgroups. Patients treated for epilepsy, psychiatric disorders, or other conditions were all at ar
suicidality compared to placebo. Closely monitor patients treated with AEDs for emergence or worsening of d
suicidality and other unusual changes in behavior, which may include symptoms such as anxiety, agitation, h
hypomania (US Food and Drug Administration, 2008).

3.3.13 Renal Effects

Drug-induced tubulointerstitial nephritis, acute

Kidney finding

Necrotizing arteritis, Granulomatous

Renal failure

Urogenital finding

3.3.13.A Drug-induced tubulointerstitial nephritis, acute

1) Summary

a) Infrequent cases of tubulointerstitial nephritis and tubular necrosis have occurred with therapeutic car
(Hogg et al, 1981; Jubert et al, 1994).

2) Literature Reports

a) A case of acute renal failure secondary to tubulointerstitial nephritis in a 7-year-old boy receiving carb
reported (Hogg et al, 1981). Because of worsening control of grand mal seizures, carbamazepine 200 m
milligrams/kilogram/day) was initiated, phenobarbital was discontinued, and the dosage of phenytoin was
25 days treatment with carbamazepine, he developed a fever and patchy erythematous rash. Relevant la
included bilirubin 0.9 nanograms/decaliter, SGOT 89 International units/liter, alkaline phosphatase 393 In
units/liter, and a white blood cell count of 3500/cubic millimeter with a normal differential. His carbamaze
decreased, but 3 days later, spiking fevers occurred with development of a generalized swelling and eryt
over his entire body. Over the next 7 days, urinalysis revealed 1+ proteinuria with coarse granular casts.
increased to 3.4 nanograms/decaliter. Urine output decreased and the patient became anuric over the ne
Peritoneal dialysis was begun. Sonography revealed enlarged kidneys and renal biopsy showed tubular
infiltration of lymphocytes and plasma cells. High dose parenteral methylprednisolone was begun and co
with gradual improvement leading to a return of renal function to normal over the following 4 weeks.

3.3.13.B Kidney finding

1) Summary

a) Urinary frequency, acute urinary retention, oliguria, azotemia, albuminuria, glycosuria, elevated bun, a in the urine have been reported in patients receiving carbamazepine (Prod Info Tegretol(R), 2002b).

3.3.13.C Necrotizing arteritis, Granulomatous

1) Summary

a) CASE REPORT- Granulomatous necrotizing angiitis accompanying acute renal failure was describec male with schizophrenia following carbamazepine therapy (150 milligrams daily) for approximately 3 mor 1989). The patient developed a skin eruption initially, followed by acute renal failure. On admission, signi and eosinophilia were observed, suggesting an allergic reaction. Renal biopsy demonstrated granulomat angiitis, differing from classic periarteritis nodosa and hypersensitivity angiitis. The patient was also rece zometapine and profenamine. After withdrawal of all drugs and with conservative therapy renal function i gradually. A carefully performed provocation test identified carbamazepine as the causative agent.

3.3.13.D Renal failure

1) Summary

a) Renal failure has been reported in patients. Acute renal failure was described in a 59-year-old male w carbamazepine 200 to 400 milligrams four times daily for 8 weeks for trigeminal neuralgia. Also, a case c hypersensitivity reaction to carbamazepine was described in a 35-year-old woman with late-onset epilep Tegretol(R), 2002b; Nicholls & Yasin, 1972); (Ray- Chaudhuri et al, 1989).

2) Literature Reports

a) A 79-year-old man developed kidney failure within 4 weeks of starting carbamazepine therapy for cor seizures. He first manifested a rash (within 2 weeks), which led to discontinuation of all other medication his carbamazepine dose to 200 milligrams (mg) twice daily. Two weeks later, his rash had worsened anc hospitalized. Carbamazepine was replaced by sodium valproate and he was given topical hydrocortisone rash. Laboratory results showed liver dysfunction, which improved over the next 6 days. However, he wa acute renal failure. Biopsy showed a giant cell granuloma. He became anuric and was treated with hemc steroids. He was discharged 15 days after admission with normal liver function, normal renal function, re rash, and on prednisone 60 mg, which was eventually reduced and withdrawn (Hegarty et al, 2002).

b) Acute renal failure was described in a 59-year-old male who had received carbamazepine 200 to 400 times daily for 8 weeks for trigeminal neuralgia (Nicholls & Yasin, 1972). The patient developed symptom sweating, and passing of dark urine. The eyes and face became swollen, and the patient passed large v urine. BUN was 285 milligrams/100 milliliters and serum creatinine was 6.5 milligrams/100 milliliters. Urir trace of protein and some hyaline casts. The drug was withdrawn and the patient rapidly improved, not r and BUN levels fell to 60 milligrams/100 milliliters in the next 2 weeks and serum electrolytes normalized revealed a non-specific tubular damage. A similar case has been reported (Prod Info Tegretol(R), 2002b 1993).

c) A hypersensitivity reaction to carbamazepine, characterized by generalized erythroderma, a severe le hyponatremia, marked eosinophilia, and renal failure, was described in a 35-year-old woman with late-or receiving carbamazepine therapy for approximately 3 weeks (Ray-Chaudhuri et al, 1989). The patient im withdrawal of carbamazepine and steroid therapy; however, introduction of sodium valproate resulted in new skin rash, leukocytosis, and eosinophilia; valproate was discontinued. The patient was not treated fu anticonvulsants, and seizures did not recur. This appears to be the first report of this type of reaction to c

3.3.13.E Urogenital finding

1) Renal failure, urinary frequency, acute urinary retention, oliguria, azotemia, albuminuria, glycosuria, eleva deposits in the urine, and impotence have been reported in patients receiving carbamazepine. Ejaculatory fai granulomatous necrotizing angitis has also been reported. Infrequent cases of tubulointerstitial nephritis and have occurred.

2) When compared to healthy controls (n=41), valproic acid treated men with generalized epilepsy (n=27) ha volumes (p=0.01). Within the same study however, the testicular volumes of carbamazepine treated men with (n=15) or oxcarbazepine treated men with generalized epilepsy (n=18) did not differ from controls. When furtl valproic acid treated men with abnormal sperm morphology had smaller testicular volumes than control wher volumes of valproic acid treated men with normal sperm were similar to controls (Isojarvi et al, 2004).

3.3.14 Reproductive Effects

Impotence

Semen finding

3.3.14.A Impotence

1) Summary

a) Sexual dysfunction has been reported in patients receiving carbamazepine (Prod Info Tegretol(R), 20

2) Literature Reports

a) A 61-year-old man developed ejaculatory failure and associated loss of sensation of orgasm shortly a taking carbamazepine (Leris et al, 1997). His symptoms returned to normal after discontinuation of carba returned upon rechallenge.

3.3.14.B Semen finding

1) Antiepileptic agents have been associated with changes in sperm morphology and motility. A lower freque morphologically normal sperm was found in carbamazepine treated men with partial epilepsy (n=15), in valpr men with generalized epilepsy and in oxcarbazepine treated men with partial epilepsy (n=18) (p less than 0.0 carbamazepine and valproic acid and p less than 0.05 for oxcarbazepine) compared to healthy controls (n=4 significant decrease in the frequency of motile sperm was also found with all treatment groups combined whe healthy controls (p less than 0.05). Within the various treatment groups, valproic acid treated patients had a s significant decrease in the frequency of motile sperm than in the control group (p less than 0.05). Carbamaze had high frequencies of abnormally low sperm concentration (p less than 0.001) and poorly motile sperm (p l when compared to controls (Isojarvi et al, 2004).

3.3.15 Respiratory Effects

Cryptogenic organizing pneumonia

Pulmonary eosinophilia

Pulmonary hypersensitivity

3.3.15.A Cryptogenic organizing pneumonia

1) A 49-year-old woman developed bronchiolitis obliterans organizing pneumonia (BOOP) secondary to carb induced hypogammaglobulinemia after two years of carbamazepine therapy for epilepsy. The woman presen progressive exertional dyspnea and prolonged productive cough. BOOP was diagnosed via computerize tom and transbronchial biopsy. Laboratory analysis revealed severe hypogammaglobulinemia including immunog milligrams/deciliter (mg/dL), Ig A 20 mg/dL, and Ig M 51 mg/dL. After carbamazepine withdrawal, gammaglob and roentgenogram findings improved (Tamada et al, 2007).

2) A 52-year-old woman developed Bronchiolitis obliterans organizing pneumonia (BOOP) and lupus while ta carbamazepine (Milesi-Lecat et al, 1997). Her symptoms included facial erythema, arthralgia, dyspnea and m rounded masses and nodules. BOOP was diagnosed via pulmonary histologic examination. Antinuclear antib antihistone antibodies were present without antibodies to double-stranded DNA. All symptoms disappeared 1 carbamazepine withdrawal.

3.3.15.B Pulmonary eosinophilia

1) Summary

a) A few cases of pulmonary eosinophilia have been described following carbamazepine therapy (Tolmi Lewis & Rosenbloom, 1982).

2) Literature Reports

a) Pulmonary eosinophilia was described in an 8-year-old girl following carbamazepine (elixir) 300 millig approximately 12 weeks. The patient presented with eczema and wheezing; a chest X-ray revealed colla of the right middle lobe accompanied by a diffuse increase in bronchovascular markings. The absolute e was 11 x 10(9)/liter. valproic acid was substituted for carbamazepine, and the eosinophil count dropped later; the patient recovered in 1 month. Rechallenge with 20 mg of oral carbamazepine elixir resulted in a expiratory flow rate, wheezing, and pruritus (Tolmie et al, 1983).

b) A hypersensitivity reaction to carbamazepine was described in an 8-year-old boy who received carba milligrams orally, twice daily for approximately 5 weeks. The child developed symptoms of both pulmona asthma and fever, rash, lymphadenopathy, and hepatosplenomegaly. Symptoms improved within 3 days carbamazepine (Lewis & Rosenbloom, 1982).

3.3.15.C Pulmonary hypersensitivity

1) Summary

a) Acute pulmonary hypersensitivity was reported in patients receiving carbamazepine (Prod Info Tegret et al, 1994; Tolmie et al, 1983; Lewis & Rosenbloom, 1982; Cullinan & Bower, 1975).

2) Literature Reports

a) A case of acute pulmonary hypersensitivity was reported in a 55-year-old woman receiving carbamaz milligrams (mg) twice daily for trigeminal neuralgia (Cullinan & Bower, 1975). After 5 weeks of drug thera developed symptoms of shortness of breath, cough, and skin rash on the forearms, thighs and trunk. Exa chest disclosed crackling RALES throughout both lungs associated with a white blood cell count of 17,40 millimeter (mm(3)) with 58% eosinophils. Carbamazepine was discontinued and the patient was treated corticosteroids and diphenhydramine 25 mg every 6 hours. Within 1 to 2 weeks, the patient improved an

with a white blood cell count of 8,100 per mm(3) (8% eosinophils). Three months after discharge, the pat and blood studies were normal.

3.3.16 Other

Summary

Angioedema

Desensitization therapy

Drug withdrawal

Toxic shock syndrome

3.3.16.A Summary

1) OTHER EFFECTS

a) Withdrawal of carbamazepine was found to increase the risk of rebound seizures.

3.3.16.B Angioedema

1) Carbamazepine-associated angioedema and maculopapular eruptions occurred in a 27 year-old Indian w history of postpartum psychosis. The patient presented with symptoms of mania and aggressive behavior an carbamazepine 400 milligrams each day after failing to adequately respond to lithium and valproic acid. Carb discontinued on the second day after she developed mild palpebral edema, itching, and discoloration of the s giddiness, syncope, vomiting, and fever. Her palpebral edema became worse on the third day. Her blood cou white blood cells of 13,800 cells/cubic millimeter, with 70% neutrophils, 27% lymphocytes, 3% eosinophils, 0 0% basophils. Her serum chemistry was essentially normal with the exception of serum sodium (133 milliequ A dermatological examination indicated she had angioedema and maculopapular rash. The angioedema resp treatment with pheniramine and oral hydroxyzine hydrchloride, and her skin rash resolved gradually. The autl subsidence of angioedema with carbamazepine cessation and continued use of her other drugs suggests tha did not account or contribute to this adverse reaction (Elias et al, 2006).

3.3.16.C Desensitization therapy

1) Summary

a) The use of desensitization to carbamazepine was described in a 12-year-old epileptic boy with multip allergies (Smith & Newton, 1985).

2) Literature Reports

a) The use of desensitization to carbamazepine was described in a 12-year-old epileptic boy with multip allergies. Desensitization was accomplished by initiating 0.1 milligrams (mg) carbamazepine daily and do every 2 days until the patient had reached a therapeutic dosage of 200 milligrams twice daily (Smith & N

3.3.16.D Drug withdrawal

1) Summary

a) Withdrawal of carbamazepine was found to increase the risk of rebound seizures in patients with refra epilepsies who had incompletely controlled seizures compared to rebound seizure occurrence rates in pa from other antiepileptic drugs (DeToledo et al, 2000).

2) Literature Reports

a) Withdrawal of carbamazepine was found to increase the risk of rebound seizures in patients with refra epilepsies who had incompletely controlled seizures compared to rebound seizure occurrence rates in pa from other antiepileptic drugs (AEDs); patients who had NOT had seizures for several years on carbama seemed not to have a higher risk of recurring seizures than patients who had used other AEDs. The stud seizure occurrence rates in patients with epilepsy who had all AEDs discontinued during an 8-week perio converted to gabapentin monotherapy and observed on gabapentin for 26 weeks (n=275). Seizure rates the first 2 weeks after discontinuation of CBZ, and the state of activation of seizures was found to possib 10 weeks. Patients discontinuing CBZ had more seizures and earlier seizures than patients tapered from VALPROATE. When CBZ was part of combination treatment, the sequence in which CBZ was withdrawn inconsequential (ie, CBZ withdrawn first versus CBZ withdrawn second). No new types of seizures were CBZ withdrawal (DeToledo et al, 2000).

3.3.16.E Toxic shock syndrome

1) Summary

a) A case of pseudo-toxic shock syndrome was attributed to carbamazepine in a 13-year-old girl after 1 for temporal lobe seizures (Burnstein et al, 1983).

2) Literature Reports

a) A case of pseudo-toxic shock syndrome was attributed to carbamazepine in a 13-year-old girl after 1 for temporal lobe seizures (Burnstein et al, 1983). One week prior to admission, the patient experienced malaise, vomiting, anorexia and a facial rash had progressed to the entire body. Diarrhea, elevations in h tests and white blood cells in the urine were observed. S aureus was recovered from the patient's blood Leukopenia was also present. The patient was treated with methicillin IV and became afebrile within 48 h with oral carbamazepine resulted in recurrence of original symptoms including a spiking fever. The mech development of the S aureus bacteremia is unclear. The authors ruled out the possibility of staphylococc

3.4 Teratogenicity/Effects in Pregnancy/Breastfeeding

A) Teratogenicity/Effects in Pregnancy

1) U.S. Food and Drug Administration's Pregnancy Category: Category D (Prod Info TEGRETOL(R)-XR extende tablets, 2007) (All Trimesters)

a) There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be accep risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs car ineffective).

2) Australian Drug Evaluation Committee's (ADEC) Category: D(Australian Drug Evaluation Committee, 1999)

a) Drugs which have caused, are suspected to have caused, or may be expected to cause an increased inci fetal malformations or irreversible damage. These drugs may also have adverse pharmacological effects. Ac should be consulted for further details.

See Drug Consult reference: PREGNANCY RISK CATEGORIES

3) Crosses Placenta: Yes

4) Clinical Management

a) Retrospective reviews suggest that teratogenic effects are associated with the use of anticonvulsants in c therapy. If therapy is to be continued, monotherapy is preferred for pregnant women (Prod Info TEGRETOL(R release oral tablets, 2007). Carbamazepine can cause fetal harm when administered to a pregnant woman. W childbearing potential should be counseled to weigh the benefits of therapy against the risks. Antiepileptic dru discontinued abruptly in patients taking the drug to prevent major seizures due to the strong possibility of pre epilepticus with the danger of hypoxia and threat to life. Standard prenatal care of childbearing women taking should include currently accepted tests including a fetal echocardiograph during the first trimester to detect p defects (Diav-Citrin et al, 2001).

5) Literature Reports

a) Reports indicate an increased risk of neural-tube defects, cardiovascular defects, and urinary tract defects hypoplasia of the nose, anal atresia, meningomyelocele, ambiguous genitalia, congenital heart disease, hype hypoplasia of the nails, congenital hip dislocation, spina bifida, and inguinal hernia have also been reported (A possible risk of birth defects with the folic acid antagonist, carbamazepine, has been found when used duri trimester of pregnancy (Hernandez-Diaz et al, 2000). A negative relationship between serum folate and serur concentrations has been found, suggesting that folate deficiency may play a role in carbamazepine teratoger 1998).

b) If phenytoin or carbamazepine (or any prodrugs) are used in pregnant women, there is a substantially incr teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is largely o the levels of the reactive epoxide metabolites (Finnell et al, 1992g; Van Dyke et al, 1991g; Buehler et al, 199 epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with each otl other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hydrola valproic acid, progabide, and lamotrigine. Such combinations increase the risk of major birth defects 3- to 4-f monotherapy and about 10-fold over background rates.(Spina et al, 1996f; Ramsay et al, 1990g; Bianchetti e

c) In a large retrospective cohort study (n=1411), an increased risk of major congenital abnormalities was ob offspring of women treated with carbamazepine (relative risk (RR) 2.6) or valproate (RR 4.1) monotherapy du trimester of pregnancy. Risk was unaffected by the type of seizure disorder, but in the case of valproate and was dependent upon the dose used. The risk for phenobarbital was significantly increased when other antiep or caffeine were added (RR 2.5) or when all were combined (RR 5.1). Significant associations were observed tube defects and valproate alone (RR 4.0, p=0.03) and when combined with other antiepileptic medications (I specifically with carbamazepine (RR 8.1, p=0.01). In addition, the risk of hypospadia was higher with valproat p=0.05) or combined with other antiepileptic drugs (RR 4.8, p=0.03) (Samren et al, 1999).

d) The results of a prospective study involving 210 pregnant women suggest that carbamazepine treatment the risk of major congenital abnormalities when used in the first trimester of pregnancy. The data was gathere Teratogen Information Service between January 1989 and March 1999. The 210 carbamazepine-exposed pr compared with 629 controls. Sixty-eight percent of the women in the carbamazepine group were treated throu The relative risk (RR) of major congenital anomalies was 2.24 for women in the carbamazepine group (p= 0.0 birth weights were also noted (mean 3046 grams versus 3277 grams; p= 0.000). The prevalence of congenita was 2.9% in the treatment group, compared with 0.7% in the control group. As a result, the investigators recc echocardiography in women treated with carbamazepine in the first trimester (Diav-Citrin et al, 2001).

e) A case of radial microbrain form of microencephaly in a 35-week-old premature infant exposed to carbam was reported. The mother had a history of seizures for which she was receiving carbamazepine 600 mg/day pregnancy. The last carbamazepine level, measured 18 months prior to delivery, was within the therapeutic r mcg/mL). No other levels were obtained and no seizures were recorded during the pregnancy. At birth, facial were observed in the infant. An echocardiogram showed normal cardiac structure, but reduced contractility. C revealed a grossly undersized but histologically normal brain. Due to an extremely poor prognosis, life suppo The absence of trauma, infection, or vascular disease suggests that the disorder was related to impaired neu

Although causality cannot be definitively determined, the occurrence of multiple birth defects associated with raises the possibility that carbamazepine exposure may have contributed to the pathogenesis in this infant (H 1999).

f) A pregnant, 44-year-old woman ingested 24 carbamazepine 200 mg tablets and developed mild clinical to 28.5 mcg/mL). Last menstrual period, pelvic exam and sonography indicated she was 3 to 4 weeks postconc of ingestion, which correlated with the time period of the neural tube closure. Maternal alpha-fetoprotein level 16 weeks gestation and sonography at 20 weeks suggested spina bifida. The pregnancy was electively termi showed a fetus with a large open myeloschisis from T 11 to L 5 and a hypoplastic left cerebral hemisphere (L

B) Breastfeeding

1) American Academy of Pediatrics Rating: Maternal medication usually compatible with breastfeeding. (Anon, 2(

2) World Health Organization Rating: Compatible with breastfeeding. Monitor infant for side effects. (Anon, 2002)

3) Thomson Lactation Rating: Infant risk cannot be ruled out.

a) Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk wh breastfeeding. Weigh the potential benefits of drug treatment against potential risks before prescribing this dr breastfeeding.

4) Clinical Management

a) The World Health Organization considers carbamazepine compatible with breast-feeding, but recommenc infant for jaundice, drowsiness, poor suckling, vomiting, and poor weight gain (Anon, 2002). Carbamazepine for use during the breast-feeding period (Froescher et al, 1984).

5) Literature Reports

a) Carbamazepine and the epoxide metabolite transfers to breast milk. The concentration ratio of breast milk plasma is nearly 0.4 for carbamazepine and 0.5 for the epoxide. Estimated doses transferred to the newborn feeding range from 2 to 5 mg/day for carbamazepine and 1 to 2 mg/day for the epoxide. Due to the potential adverse reactions in nursing infants from carbamazepine, a decision should be made regarding discontinuing discontinuing the medication, taking into account the importance for the use of the medication for the mother TEGRETOL(R)-XR extended-release oral tablets, 2007).

b) A lower milk:maternal plasma ratio was reported in women treated with multiple, unspecified anticonvulsa 1979). Carbamazepine levels in milk were equal to 39.4% of maternal serum concentration (milk equal to 1.9 equal to 4.3 mcg/mL; n= 3). These amounts were considered pharmacologically insignificant. No adverse effe the nursing infants in any of these reports (Kaneko et al, 1979; Niebyl et al, 1979; Pynnonen et al, 1977; Pynı 1975); however, such effects were not systematically sought.

c) In four women treated with carbamazepine and phenytoin the approximate milk to serum ratio of carbama (Wilson et al, 1980; Pynnonen et al, 1977; Pynnonen & Sillanpaa, 1975). The metabolite 10,11-epoxy carban measured. Milk levels of the epoxide were approximately equal to serum levels, but the epoxide was not dete nursing infants' serum for undetermined reasons. Maternal plasma concentrations assayed at 0.5 to 3.2 mcg/ lower than the therapeutic range of 6 to 8 mcg/mL (Gilman et al, 1980).

d) One case of cholestatic hepatitis in a breast-fed infant has been reported in association with maternal use carbamazepine. Symptoms resolved following cessation of breast-feeding (Anon, 2001; Frey et al, 1990; Cha nursing infant is expected to ingest between 2% to 7.2% of the lowest weight-adjusted therapeutic dose (Iqba another report, breast-fed newborns developed serum carbamazepine levels between 15% to 65% of matern Perel, 1998) Breast milk concentrations are reported to be approximately 24% to 69% of that found in matern usual infant serum levels of 0.4 mcg/mL (Pynnonen et al, 1977).

6) Drug Levels in Breastmilk

a) Parent Drug

1) Milk to Maternal Plasma Ratio

a) 0.24-0.69 (Kok et al, 1982; Nau et al, 1982; Neibly et al, 1979; Pynnonen & Sillanpaa, 1975; Pyn

3.5.1.A Acetaminophen

1) Interaction Effect: an increased risk of acetaminophen hepatotoxicity

2) Summary: The hepatotoxicity of acetaminophen may be related to the formation of toxic metabolites in the carbamazepine, an enzyme inducer, is given concurrently with high and frequent doses of acetaminophen, th metabolism of acetaminophen may result in an increased level of hepatotoxic metabolites. In support of this t observed that patients who receive enzyme-inducing agents do not recover as well from an acetaminophen o patients who are not taking enzyme-inducing drugs. The significance of this interaction at therapeutic doses o administered intermittently appears low. In addition, acetaminophen has been shown to have lower bioavailal patients receiving enzyme-inducing agents (Perucca & Richens, 1979).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: At usual therapeutic oral doses of acetaminophen and carbamazepine, no special r required.

7) Probable Mechanism: increased metabolism of acetaminophen resulting in abnormally high levels of hepa metabolites

8) Literature Reports

a) A 17-year-old female with a history of anorexia nervosa and who was receiving carbamazepine 300 r stabilization ingested acetaminophen 7800 mg in a suicide attempt. Upon admission to the hospital, her were significantly elevated and her serum acetaminophen level was 15 mcg/mL. Treatment with acetylcy initiated and her acetaminophen level decreased in the expected manner. However, eight days later, she

transplant because of fulminant hepatic failure that was believed to be due to a combination of low body malnutrition, and carbamazepine therapy. A small portion of acetaminophen is metabolized by the cytoch system to toxic metabolites which are then detoxified by glutathione. Carbamazepine is known to induce P450 system, and her malnutrition status depleted her glutathione concentrations. These two factors res concentration of acetaminophen toxic metabolites, resulting in liver failure (Young & Mazure, 1998).

3.5.1.B Acetylcysteine

1) Interaction Effect: subtherapeutic carbamazepine levels
2) Summary: One woman experienced decreased carbamazepine trough levels three days after starting N-a therapy, which led to three consecutive tonic-clonic seizures. It was proposed that high doses of N-acetylcyst the clearance of carbamazepine and its metabolites to inactive derivatives, leaving the patient at an increase activity (Simonart et al, 1998a). Closely monitor carbamazepine levels in patients also receiving N-acetylcyste
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Use caution when prescribing N-acetylcysteine to patients who take carbamazepine of N-acetylcysteine and carbamazepine may cause decreased carbamazepine plasma concentrations resulti risk of seizures. Closely monitor carbamazepine levels in patients also receiving N-acetylcysteine.
7) Probable Mechanism: increased clearance of carbamazepine
8) Literature Reports
a) A 59-year-old female being treated for two years with carbamazepine 800 mg daily had serum trough mcg/mL. Lamotrigine was added to her therapeutic regimen to allow a slow withdrawal of carbamazepine lamotrigine increased to 75 mg daily, the patient developed fever, lymphadenopathy, conjunctivitis, and r eruptions on the face and upper torso. Carbamazepine trough level at this time was 11.1 mcg/mL. The p diagnosed with lamotrigine-induced hypersensitivity, and N-acetylcysteine 2 g every six hours was initiat clinical improvement. However, on the third day of N-acetylcysteine therapy, the patient had three tonic-c within five hours. Although her carbamazepine dose had not changed, the trough level was 8.1 mcg/mL. that the high doses of N-acetylcysteine increased the clearance of carbamazepine and its metabolites to derivatives, leaving the patient at an increased risk for seizure activity (Simonart et al, 1998).

3.5.1.C Activated Charcoal

1) Interaction Effect: decreased carbamazepine exposure
2) Summary: In a cross-over study involving six healthy volunteers, activated charcoal 8 g administered imm carbamazepine 400 mg resulted in a decrease in the carbamazepine absorption by 90%. Maximum concentr decreased from 2.7 mg/L to 0.28 mg/L, and the area under the concentration-time curve (AUC) of carbamaze mg/L/h to 11 mg/L/h (Neuvonen et al, 1988). This drug interaction may make activated charcoal useful in cas carbamazepine overdose, but should be kept in mind when using activated charcoal in therapy concurrently v carbamazepine.
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Since activated charcoal binds carbamazepine in the gastrointestinal tract, administ two hours before or four to six hours after activated charcoal. If this is not possible, separate administration ti possible. During concurrent therapy, monitor carbamazepine serum levels closely and observe the patient for response to carbamazepine.
7) Probable Mechanism: reduced carbamazepine absorption

3.5.1.D Adenosine

1) Interaction Effect: a higher degree of heart block
2) Summary: Carbamazepine has been reported to increase the degree of heart block that may be produced Adenosine exerts its effect by decreasing conduction through the AV node, and may cause a short-lasting firs third-degree block. Therefore, higher degrees of heart block induced by adenosine may occur in the presence carbamazepine (Prod Info Adenocard(R), 2002).
3) Severity: major
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: If possible, carbamazepine should be withheld for at least five half-lives (approxima prior to the use of adenosine.
7) Probable Mechanism: additive effects

3.5.1.E Alprazolam

1) Interaction Effect: decreased alprazolam effectiveness
2) Summary: The addition of carbamazepine 600 mg daily to a patient stabilized on alprazolam resulted in a decrease in alprazolam concentration (43 ng/mL vs 20 ng/mL) (Arana et al, 1988a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for signs of benzodiazepine clinical effectiveness. Concurrent use of carbar

alprazolam may require higher doses of alprazolam. The dose of alprazolam should be decreased if carbama discontinued.
7) Probable Mechanism: increased hepatic metabolism
8) Literature Reports
a) Combined therapy with alprazolam and carbamazepine was reported to result in significant reduction plasma levels, corresponding with clinical deterioration, in a 32-year-old male with atypical bipolar disord attacks (Arana et al, 1988). The patient was receiving oral lithium carbonate 1200 mg daily with oral alpr daily prior to the initiation of carbamazepine. Carbamazepine 300 to 600 mg daily orally was used to con impulsivity and psychosis; the lithium was discontinued. It is speculated that carbamazepine reduced alp levels by induction of hepatic microsomal enzymes. More studies are required to evaluate this interactior mechanisms.

3.5.1.F Amitriptyline
1) Interaction Effect: decreased amitriptyline effectiveness
2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease ar levels (Leinonen et al, 1991h; Brown et al, 1988b).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for clinical efficacy of the amitriptyline therapy and for any signs of toxicity c Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.
7) Probable Mechanism: increased amitriptyline metabolism
8) Literature Reports
a) A study examined the effect of carbamazepine on amitriptyline levels in 8 psychiatric inpatients treate amitriptyline dosage of 137.5 mg daily. All patients were treated for a minimum of 7 days prior to measur antidepressant concentrations. Carbamazepine was added in a mean dose of 593 mg continued over a patients receiving combination therapy, serum amitriptyline and nortriptyline concentrations were signific and 40% respectively) than in patients receiving amitriptyline alone, although the ratio of amitriptyline to remained relatively unchanged (Leinonen et al, 1991g).

3.5.1.G Amoxapine
1) Interaction Effect: decreased amoxapine concentration
2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease ar levels (Leinonen et al, 1991e; Brown et al, 1990c). Although not reported for amoxapine, a similar interaction
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for clinical efficacy of the amoxapine therapy and for any signs of toxicity of Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.
7) Probable Mechanism: increased amoxapine metabolism
8) Literature Reports
a) Concomitant administration of imipramine and carbamazepine to children with attention deficit disorde reported to result in a 50% decrease in the total plasma concentration of imipramine plus desipramine (E Carbamazepine probably enhances the hepatic microsomal metabolism of imipramine and other tricyclic by inducing hepatic enzymes (Moody et al, 1977a). Although not reported specifically for amoxapine, be potential for a similar interaction exists. Patients on chronic Carbamazepine therapy may require increas tricyclic antidepressants.

3.5.1.H Amprenavir
1) Interaction Effect: reduced amprenavir efficacy due to reduced amprenavir serum concentrations
2) Summary: Coadministration of carbamazepine and amprenavir may result in reduced amprenavir serum c Dose adjustments of amprenavir may be necessary to maintain antiviral efficacy of amprenavir (Prod Info Ag
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Clinicians may want to consider using alternative medication to carbamazepine in p amprenavir therapy. However, if it becomes necessary to give these agents concurrently, upward adjustment dosing may be needed to maintain antiviral effectiveness.
7) Probable Mechanism: induction of cytochrome P450 3A4-mediated amprenavir metabolism

3.5.1.I Anisindione
1) Interaction Effect: decreased anticoagulant effectiveness
2) Summary: Concomitant carbamazepine and warfarin therapy has been reported to result in a decreased a effect, secondary to the induction of hepatic metabolism of the anticoagulant (Massey, 1983a; Cohen & Arms Koch-Weser & Koch-Weser, 1975a; Kendall & Boivin, 1981a; Hansen et al, 1971b). A similar effect may occu
3) Severity: moderate

4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving oral anticoagulant therapy, the prothrombin time ratio or INR (i normalized ratio) should be closely monitored with the addition and withdrawal of treatment with carbamazep reassessed periodically during concurrent therapy. Adjustments of the anisindione dose may be necessary in the desired level of anticoagulation.
7) Probable Mechanism: increased anisindione metabolism

3.5.1.J Aprepitant

1) Interaction Effect: reduced plasma aprepitant concentrations and decreased aprepitant efficacy
2) Summary: Coadministration of aprepitant with drugs that strongly induce cytochrome P450 3A4 activity, s carbamazepine, may result in reduced plasma concentrations of aprepitant and decreased efficacy of aprepit EMEND(R) oral capsules, 2008).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concomitant administration of aprepitant and carbamazepine may result in reducec concentrations of aprepitant and may decrease the efficacy of aprepitant (Prod Info EMEND(R) oral capsules
7) Probable Mechanism: induction of cytochrome P450 3A4-mediated metabolism of aprepitant by carbamaz

3.5.1.K Aripiprazole

1) Interaction Effect: decreased aripiprazole concentrations
2) Summary: Coadministration of carbamazepine 200 milligrams (mg) twice daily with aripiprazole 30 mg on the maximum concentration (Cmax) and the area under the concentration-time curve (AUC) values of both a active metabolite, dehydro-aripiprazole, by approximately 70%. Aripiprazole is partly metabolized by cytochro (CYP3A4) enzymes. Coadministration with carbamazepine, a potent CYP3A4 inducer, could increase aripipr causing decreased blood concentrations. The dose of aripiprazole should be doubled when it is administered carbamazepine. If therapy with carbamazepine is discontinued, the dose of aripiprazole should then be decre ABILIFY(R) oral tablets, oral solution, 2005).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Coadministration of aripiprazole and carbamazepine has resulted in decreased arip concentrations. The dose of aripiprazole should be doubled when it is administered concurrently with carbam with carbamazepine is discontinued, the dose of aripiprazole should then be decreased.
7) Probable Mechanism: induction of CYP3A4-mediated aripiprazole metabolism

3.5.1.L Armodafinil

1) Interaction Effect: decreased armodafinil exposure or plasma levels
2) Summary: Armodafinil is partially metabolized by the CYP3A enzyme system. Use caution with the coadm armodafinil with other drugs that are potent inducers of CYP3A4, such as carbamazepine, as this could resul exposure or plasma levels of armodafinil (Prod Info NUVIGIL(TM) oral tablets, 2007). Also, monitor patient's armodafinil if these 2 agents are used concurrently.
3) Severity: minor
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution with the coadministration of armodafinil and carbamazepine as this ma decreased armodafinil exposure or levels (Prod Info NUVIGIL(TM) oral tablets, 2007). Monitor patient respon these 2 agents are used concurrently.
7) Probable Mechanism: induction of CYP3A-mediated armodafinil metabolism

3.5.1.M Atracurium

1) Interaction Effect: decreased atracurium duration of action
2) Summary: The effects of carbamazepine on the neuromuscular blocking effects of atracurium have been well-controlled studies. The effect of atracurium was significantly shortened in patients taking carbamazepine phenytoin or valproic acid, compared to patients not taking anticonvulsants (Tempelhoff et al, 1990a). Other reported that carbamazepine had no effect on the onset time or duration of atracurium (Spacek et al, 1997a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Monitor patients for an appropriate clinical response to the neuromuscular blocker. intervals or higher doses of atracurium may be needed in patients receiving carbamazepine.
7) Probable Mechanism: increased atracurium metabolism
8) Literature Reports
a) Researchers studied the effect of carbamazepine on the onset and duration of neuromuscular blocka atracurium. Three groups of patients were studied; 21 nonepileptic patients, 14 epileptic patients treated carbamazepine alone, and 18 epileptic patients receiving carbamazepine and either phenytoin or valproi receiving carbamazepine had been maintained for many years. All patients were treated with atracurium

intravenously following standard induction of anesthesia. The time to onset of neuromuscular blockade w different for the three groups of patients. However, time to recovery of baseline and train-of-four respons shorter for the two groups receiving carbamazepine (Tempelhoff et al, 1990).

b) Carbamazepine had no effect on the neuromuscular blockade induced by atracurium in one study. Af induction of anesthesia, 0.5 mg/kg of atracurium was administered in two groups of patients, with eight p carbamazepine and ten patients not receiving carbamazepine. The average duration of carbamazepine t weeks. There was no significant difference between the two groups in lag time, onset time, or time to rec neuromuscular blockade induced by atracurium (Spacek et al, 1997).

3.5.1.N Azithromycin

1) Interaction Effect: increased serum carbamazepine levels

2) Summary: Although some macrolide antibiotics interfere with hepatic metabolism of carbamazepine, azith the semisynthetic macrolides that does not inactivate cytochrome P450, and, therefore, does not interact with (Periti et al, 1992a; Hopkins, 1991a). It is suggested, however, that elevations of serum carbamazepine level the concomitant use of azithromycin, and that careful monitoring of patients is advised by the manufacturer (P Zithromax(R), 2001).

3) Severity: minor

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Until further data are available regarding drug interactions with azithromycin and ca careful monitoring of patients is advised.

7) Probable Mechanism: unknown

8) Literature Reports

a) Although quite variable in their ability to produce enzyme inhibition, the macrolide antibiotics have be significant drug interactions. They can be classified into three groups: 1) erythromycins and troleandomy nitrosoalkanes leading to inactive cytochrome P450- metabolite complexes, 2) clarithromycin, flurithromy midecamycin, miocamycin, and roxithromycin form complexes to a smaller degree and seldom cause dr and 3) azithromycin, dirithromycin, rokitamycin, and spiramycin do not affect cytochrome P450 and, ther produce drug interactions (Periti et al, 1992).

b) In a toleration and safety profile of azithromycin assessing 3995 patients, no pharmacokinetic interac observed with carbamazepine, cimetidine, methylprednisolone, theophylline, or warfarin (Hopkins, 1991)

3.5.1.O Betamethasone

1) Interaction Effect: decreased betamethasone effectiveness

2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, al, 1982b). Although not specifically reported for betamethasone, a similar interaction could be expected.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Monitor therapeutic efficacy of betamethasone. An increase in the steroid dosage m after three to five days of concurrent carbamazepine therapy.

7) Probable Mechanism: increased betamethasone metabolism

3.5.1.P Bortezomib

1) Interaction Effect: reduced efficacy of bortezomib

2) Summary: Carbamazepine may induce the metabolism of bortezomib. Monitor patients closely for reduce CYP3A4 inducers (ie, carbamazepine) are coadministered with bortezomib (Prod Info VELCADE(R) injection

3) Severity: moderate

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: The concomitant use of bortezomib and CYP3A4 inducers (ie, carbamazepine) may bortezomib efficacy. Monitor patients if bortezomib and carbamazepine are coadministered (Prod Info VELCA 2008).

7) Probable Mechanism: induction of CYP3A4-mediated bortezomib metabolism by carbamazepine

3.5.1.Q Bromperidol

1) Interaction Effect: decreased bromperidol efficacy

2) Summary: Concurrent administration of carbamazepine and bromperidol may decrease plasma concentra bromperidol and its reduced metabolite by inducing their metabolism. However, when carbamazepine and br coadministered in schizophrenic patients, clinical improvement was seen. This indicates that these two agent some pharmacodynamic synergism (Otani et al, 1997a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: established

6) Clinical Management: Monitor patients for bromperidol efficacy. When given concomitantly with carbamaz bromperidol may need to be increased.

7) Probable Mechanism: induction of bromperidol metabolism by carbamazepine

8) Literature Reports

a) In one study, 13 schizophrenic patients were given bromperidol 12 mg to 24 mg daily for 1 to 20 weel addition of carbamazepine 400 mg daily for 4 weeks. Carbamazepine reduced plasma concentrations of and reduced bromperidol by 37% and 23%, respectively, at four weeks. It appeared that the induction by was fastest during the first week of cotherapy, but maximal effects were seen at four weeks. The authors cytochrome P450 3A4 isoenzymes may be involved in this process, since carbamazepine is known to in CYP 3A4. Although carbamazepine and bromperidol coadministration resulted in decreased plasma con bromperidol, the Clinical Global Impression scores were decreased significantly, indicating that some ph synergism exists between carbamazepine and bromperidol which results in clinical improvement (Otani e

3.5.1.R Buprenorphine

1) Interaction Effect: decreased buprenorphine plasma concentrations
2) Summary: Buprenorphine is primarily metabolized by the CYP3A4 isoenzyme system. Coadministration o inducer, such as carbamazepine, may result in increased clearance and reduced plasma concentrations of b concomitant use of buprenorphine and carbamazepine is warranted, dosage adjustment may be necessary (buprenorphine hcl injection, 2004) along with increased monitoring for buprenorphine withdrawal signs and s et al, 2003).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing buprenorphine to patients who take carbamazepine. of buprenorphine and carbamazepine may cause reduced buprenorphine plasma concentrations. If concurre dosage adjustments should be considered (Prod Info buprenorphine hcl injection, 2004). Increased monitorin signs and symptoms is also recommended when buprenorphine is coadministered with carbamazepine (Brid
7) Probable Mechanism: induction of CYP3A4-mediated buprenorphine metabolism by carbamazepine

3.5.1.S Bupropion

1) Interaction Effect: decreased bupropion effectiveness
2) Summary: Since bupropion is extensively metabolized by the cytochrome P450 enzyme system, the coad bupropion with other drugs that are inducers of the CYP450 system may affect its clinical activity. Carbamaze the metabolism of bupropion, resulting in decreased efficacy of bupropion (Prod Info Wellbutrin XL(TM), 2003
3) Severity: minor
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Care should be taken when administering bupropion with carbamazepine. Monitor t bupropion efficacy.
7) Probable Mechanism: induction of bupropion metabolism by carbamazepine

3.5.1.T Caspofungin

1) Interaction Effect: reduced caspofungin plasma levels
2) Summary: Enhanced clearance of caspofungin may occur during concomitant therapy with carbamazepin drug clearance. Patients may require an increase in dose to 70 mg caspofungin daily (Prod Info CANCIDAS(2008).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: When caspofungin is coadministered with inducers of drug clearance, such as carb consider using a daily dose of 70 mg of caspofungin (Prod Info CANCIDAS(R) IV infusion, 2008).
7) Probable Mechanism: enzyme induction by carbamazepine
8) Literature Reports

a) Combined use of carbamazepine and caspofungin, an inducer of drug clearance, may result in a sign caspofungin plasma levels. This is based on regression analyses of pharmacokinetic data. It is not know clearance mechanism involved in caspofungin disposition may be inducible (Prod Info CANCIDAS(R) IV

3.5.1.U Cimetidine

1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: The effects of cimetidine on carbamazepine plasma concentration may be temporary. Possible limitation of carbamazepine auto-induction may occur (Macphee et al, 1984; Dalton et al, 1985a; Dalton et al, 1985a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Consider obtaining plasma carbamazepine levels two to four days after starting or c cimetidine. Usual therapeutic levels are 6 mg/L to 12 mg/L; however, the relationship between plasma levels variable. Patients should also be cautioned that transient signs of carbamazepine toxicity may occur during th cimetidine therapy. An alternative H-2 blocker that has not been reported to cause this interaction, such as ra famotidine, might be considered.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports

a) In a single dose study, cimetidine pretreatment increased the carbamazepine area under the curve by elimination half-life by 18% (Dalton et al, 1985). It is possible that this is due to decreased metabolism se inhibition of hepatic microsomal enzymes by cimetidine (Telerman-Toppet et al, 1981); however, others l significant alterations in steady-state plasma concentrations of carbamazepine or its metabolite with con administration of cimetidine (Sonne et al, 1983; Levine et al, 1985).
b) Cimetidine 400 mg three times daily significantly increased steady-state carbamazepine plasma level days. However, carbamazepine levels decreased to pretreatment levels by the seventh day of cimetidine Carbamazepine side effects appeared in most patients within 24 hours following cimetidine initiation, but next 48 to 72 hours. The investigators concluded that dosage adjustments appear unnecessary, but that warned of the appearance of carbamazepine side effects for the first 3 to 5 days after beginning cimetidi 1986).
c) A case of carbamazepine toxicity was reported in an elderly man receiving carbamazepine 200 mg th isoniazid 300 mg daily, and cimetidine 400 mg twice daily. Two days after initiating this drug combinatior developed nausea, vomiting, dizziness, and epigastric pain. Carbamazepine serum concentrations were receiving this combination of therapy should have close monitoring of carbamazepine concentrations (Ga

3.5.1.V Cisatracurium

1) Interaction Effect: resistance to neuromuscular blocking action
2) Summary: Some medications, including carbamazepine, may enhance resistance to the neuromuscular b nondepolarizing agents such as cisatracurium (Prod Info Nimbex(R), 1999). Dose adjustments of cisatracuriu when these agents are being used concurrently.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The dose of cisatracurium may need to be adjusted upward in patients receiving co carbamazepine.
7) Probable Mechanism: unknown

3.5.1.W Cisplatin

1) Interaction Effect: decreased carbamazepine plasma concentrations
2) Summary: A 36-year old epileptic female undergoing antineoplastic therapy with doxorubicin and cisplatin subtherapeutic carbamazepine and valproic acid concentrations which resulted in tonic-clonic seizures. Altho mechanism is unknown, possible causes include decreased absorption or accelerated elimination of carbama Voogd-van der Straaten, 1988c).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Anticonvulsant levels should be closely monitored in patients receiving antineoplast doxorubicin or cisplatin. Doses of carbamazepine may need to be increased.
7) Probable Mechanism: decreased absorption or accelerated elimination of carbamazepine
8) Literature Reports
a) A 36-year old female epileptic patient requiring cisplatin and doxorubicin therapy for papillary adenoc experienced tonic-clonic seizures after two days of antineoplastic treatment. Plasma concentrations of ca valproic acid, and phenytoin were all determined to be subtherapeutic (0.5 mg/L, 24.3 mg/L, and 0.3 mg/ One month later, she was controlled on phenytoin 450 mg daily, carbamazepine 1200 mg daily, and valp daily. During her second course of cisplatin and doxorubicin, she again suffered a tonic-clonic seizure. P concentrations of her anticonvulsants were phenytoin 0.2 mg/L, carbamazepine 3.5 mg/L, and valproic a Three days following her chemotherapy, plasma concentrations of the anticonvulsants had returned to th values. During her sixth and final chemotherapy course, carbamazepine levels remained low (1.4 mg/L) all 15 days of the course (Neef & de Voogd-van der Straaten, 1988b).

3.5.1.X Clarithromycin

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo seizures, coma)
2) Summary: Clarithromycin has been reported to elevate the serum levels of carbamazepine (Prod Info Biax resulting in the clinical symptoms of lethargy, fatigue, blurred vision, nausea, confusion, and ataxia (Tatum & Albani et al, 1993a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Decreasing the carbamazepine dose by approximately 25% is advised at the initiati clarithromycin therapy with further modification according to clinical symptoms and serum carbamazepine tro concentrations. Consider monitoring carbamazepine plasma levels.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) Carbamazepine toxicity with an increase in serum level associated with the addition of clarithromycin 35-year-old female diagnosed with complex partial seizures (Tatum & Gonzalez, 1994). She was mainta carbamazepine 200 mg three times daily with an approximate steady-state level of 8.3 mcg/mL. With dev

upper respiratory infection, clarithromycin 500 mg two times daily was initiated. Symptoms of lethargy, fa vision, nausea, "muddled thoughts", and ataxia occurred within a few hours of the first dose. A carbamaz of 15.5 mcg/mL was obtained 26 hours after the first clarithromycin dose. The symptoms of toxicity resol level returned to baseline within 36 hours of discontinuing carbamazepine and clarithromycin.

b) A 29 year-old male was diagnosed with simple partial seizures since the age of 11 years and was ma carbamazepine 400 mg two times daily with an approximate steady-state level of 8 mcg/mL (Albani et al addition of clarithromycin increased the serum level to 12.7 mcg/mL, measured at the end of the clarithro despite decreasing carbamazepine (300 mg two times daily); yet, he did not notice any adverse symptor elevated serum level. Upon completion of the therapy, he was placed on the previous carbamazepine do the level returned to baseline.

c) Clarithromycin 500 mg was given concurrently with either oral carbamazepine 400 mg or placebo twi healthy volunteers in a randomized, double-blind study. The mean area under the concentration-time cu carbamazepine was increased and the formation of the 10,11-epoxide metabolite was significantly reduc significant change in carbamazepine pharmacokinetics (Sturgill & Rapp, 1992). Whether this would lead significant effect is unknown.

d) Macrolide antibiotics have been implicated in severe drug interactions, but there are differences amo not all are responsible for drug interactions. They can be classified into 3 groups: 1) erythromycins and t form nitrosoalkanes leading to inactive cytochrome P450-metabolite complexes, 2) clarithromycin, flurith josamycin, midecamycin, miocamycin, and roxithromycin form complexes to a smaller degree and are le drug interactions, and 3) azithromycin, dirithromycin, rokitamycin, and spiramycin do not affect cytochron therefore, would not be expected to interfere with drugs metabolized by this enzyme system (Periti et al,

3.5.1.Y Clobazam

1) Interaction Effect: decreased carbamazepine parent drug and/or increased active metabolite concentratio

2) Summary: Studies that investigated the effect of clobazam on carbamazepine have shown variable effects and active metabolite concentrations, including increases in carbamazepine levels (Franceschi et al, 1983), c et al, 1986a), and no significant change (Sennoune et al, 1992; Munoz et al, 1990a). Carbamazepine effects been shown to include decreased plasma levels and area under the concentration-time curve (AUC) of cloba levels and AUC of norclobazam (the active metabolite) (Bun et al, 1990; Jawad et al, 1984; Levy et al, 1983; 1992).

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor carbamazepine serum concentrations and seizure control.

7) Probable Mechanism: increased hepatic metabolism

8) Literature Reports

a) Concomitant administration of clobazam and carbamazepine has been reported to result in a 14% re parent drug carbamazepine plasma concentrations; changes to active metabolites were not noted (Schm

b) Metabolite/parent drug plasma ratios were studied in 15 patients with seizure disorders on carbamaz and five patients receiving both clobazam and carbamazepine. Carbamazepine plasma concentrations w groups, but clobazam-treated patients demonstrated higher concentrations of metabolites, particularly th metabolite. This suggested induction of carbamazepine metabolism, probably by induction of cytochrom resulting increases in carbamazepine epoxidation (Munoz et al, 1990).

3.5.1.Z Clomipramine

1) Interaction Effect: decreased clomipramine effectiveness

2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease ar levels (Leinonen et al, 1991f; Brown et al, 1990d). Although not reported for clomipramine, a similar interactic

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Monitor for clinical efficacy of the clomipramine therapy and for any signs of toxicity carbamazepine. Serum levels of both agents should be considered when either agent is added or discontinue appropriate dosage adjustments made accordingly.

7) Probable Mechanism: increased clomipramine metabolism

8) Literature Reports

a) Concomitant administration of imipramine and carbamazepine to children with attention deficit disord reported to result in a 50% decrease in the total plasma concentration of imipramine plus desipramine (E Carbamazepine enhances the hepatic microsomal metabolism of imipramine and other tricyclic antidepr inducing hepatic enzymes (Moody et al, 1977b). Although not reported specifically for clomipramine, be a potential for a similar interaction exists. Patients on chronic carbamazepine therapy may require increase tricyclic antidepressants.

3.5.1.AA Clonazepam

1) Interaction Effect: reduced plasma levels of clonazepam

2) Summary: Clonazepam and carbamazepine cotherapy has resulted in decreased clonazepam serum con may be a result of carbamazepine enzyme induction (Sunaoshi et al, 1988a; Lai et al, 1978a). One study invo administration to epileptic patients maintained on carbamazepine either alone or in combination with other an

determined that clonazepam administration did not influence serum concentrations of carbamazepine (Johan 1977a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Clonazepam levels should be monitored whenever carbamazepine is added or with therapy, or when the carbamazepine dose is changed. Also monitor the patient for seizure control.
7) Probable Mechanism: induction of clonazepam hepatic metabolism
8) Literature Reports
a) The effect of carbamazepine on clonazepam plasma levels during chronic administration were evalua healthy volunteers (Lai et al, 1978). Subjects were given clonazepam 1 mg once daily for 29 consecutive carbamazepine 200 mg was coadministered on days 8 to 29. Clonazepam plasma levels reached a stea to the initiation of carbamazepine therapy. After the addition of carbamazepine, plasma clonazepam leve 5 to 15 days to a level 19% to 37% less than their prior steady-state concentrations. Carbamazepine als clonazepam half-life. The proposed mechanism for this drug interaction is enzyme induction caused by c
b) The effects of clonazepam on serum levels of phenytoin, phenobarbital, and carbamazepine were stu epileptic patients who were receiving one or two of these drugs (Johannessen et al, 1977). Clonazepam was added to their therapeutic regimens and anticonvulsant levels were determined weekly for at least s nine patients receiving carbamazepine either as monotherapy or combined with another anticonvulsant, plasma concentrations averaged 8.1 mcg/mL prior to clonazepam and 8.3 mcg/mL after clonazepam the concluded that clonazepam has an insignificant effect on plasma concentrations of carbamazepine.
c) Concurrently administered clonazepam and carbamazepine were investigated in epileptic children (S 1988). The steady-state plasma concentration of clonazepam was determined in 66 epileptic children wh both carbamazepine and clonazepam. These levels were compared to the plasma levels of clonazepam children who were receiving clonazepam as monotherapy. In another group of 12 children, some of whor the previous groups, carbamazepine was added to their pre-existing regimen of clonazepam. Another gr was maintained on clonazepam and carbamazepine, and their therapeutic regimen was changed to clon plasma levels were determined four or more weeks after maintaining the same dose and regimen. When plasma levels of clonazepam, children who received clonazepam monotherapy had a mean level of 30.9 children who were receiving therapy with clonazepam and carbamazepine had a mean level of 26.2 ng/r carbamazepine was added to clonazepam monotherapy, steady-state plasma concentrations of clonaze from 47.5 ng/mL to 35.1 ng/mL. Conversely, when children who were receiving clonazepam and carbam switched to clonazepam monotherapy, plasma levels of clonazepam increased from 28.6 ng/mL to 34.4

3.5.1.AB Clorgyline

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures
2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(Info Tegretol(R), 1998e; Thweatt, 1986e). However, there is preliminary evidence that the combination of car an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995k; Barker & Ecclestor controlled studies are needed.
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of if the clinical situation permits, before carbamazepine therapy is initiated.
7) Probable Mechanism: unknown
8) Literature Reports
a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics) (Ketter et al, 1995j). In addition to their regular carbamazepine and four patients received phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylc maximum dose 55 mg daily) for a mean duration combination therapy of 52.2 days. During MAOI coadm concentrations of carbamazepine and lithium did not change significantly from baseline values. Self-rate not substantially different. Four patients (three on phenelzine and one on tranylcypromine) responded to were subsequently discharged.
b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984j).
c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru case (Joffe et al, 1985e). Conversely, five patients on tranylcypromine needed a mean daily dose of carb mg to achieve a carbamazepine blood level of 8.0-11.1 mcg/mL (Barklage et al, 1992e). Four other patie

phenelzine only required a mean daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9

3.5.1.AC Clozapine

1) Interaction Effect: an increased risk of bone marrow suppression, asterixis, or decreased serum clozapine
2) Summary: Clozapine and carbamazepine both have the potential to cause bone marrow suppression, incl agranulocytosis (Prod Info Clozaril(R), 2002). Asterixis (flapping tremor) has also been reported in patients u concurrent therapy with carbamazepine and clozapine (Rittmannsberger, 1996c). In addition, a therapeutic d study revealed significantly lower clozapine concentrations when carbamazepine was added to therapy (Jerli The mechanism may be due to carbamazepine induction of clozapine metabolism through cytochrome P450 studies are needed to further evaluate the pharmacokinetic and clinical effects of combining these agents.
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Avoid concurrent use; an alternative anticonvulsant agent should be considered. If these agents is necessary, monitor patients for decreased response to clozapine and agranulocytosis. Lower clozapine or carbamazepine may be required.
7) Probable Mechanism: additive bone marrow-suppressive effects and neurotoxicity; induction of clozapine
8) Literature Reports

a) One agranulocytosis fatality has been reported in association with the use of a multi-drug regimen wh clozapine, carbamazepine, clonazepam, benztropine, and lithium (Gerson & Lieberman JA Friedenberg, exhibited pancytopenia which is not characteristic of clozapine-induced agranulocytosis.

b) Over a three-year period, some drug combinations caused a greater risk of asterixis (flapping tremor) regimen of multiple psychopharmacologic agents (Rittmannsberger, 1996b). With regard to the agents c clozapine, and lithium, incidence of asterixis was greatest in those patients that were on at least two of t Out of ten patients developing asterixis, five patients received carbamazepine and clozapine as part of m and in two cases carbamazepine and clozapine were the sole psychopharmacologic agents. In all cases the drugs were within normal therapeutic ranges, suggesting an additive effect of combination therapy ra of a single agent.

c) Therapeutic drug monitoring data showed a 50% lower clozapine concentration/dose (C/D) ratio whe carbamazepine was taken compared to clozapine alone. The clozapine C/D ratio was inversely correlate carbamazepine. An additional analysis of eight patients confirmed that upon addition of carbamazepine t regimen, clozapine concentrations decreased significantly. The mean C/D ratio during monotherapy was cotherapy with carbamazepine fell to 0.30. The change in clozapine metabolism was suggested to be du carbamazepine induction of cytochrome P450 3A4 (Jerling et al, 1994).

3.5.1.AD Cortisone

1) Interaction Effect: decreased cortisone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, al, 1982a). Although not specifically reported for cortisone, a similar interaction could be expected.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of the corticosteroid. An increase in the steroid dosage after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased cortisone metabolism

3.5.1.AE Cyclosporine

1) Interaction Effect: reduced cyclosporine serum levels and potentially increased risk for organ rejection
2) Summary: In a number of case reports, the concomitant use of cyclosporine and carbamazepine resulted cyclosporine levels (Soto Alvarez et al, 1991; Yee & McGuire, 1990a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Within the first two to three weeks of initiating or discontinuing carbamazepine thera cyclosporine levels and adjust cyclosporine dosage as necessary; therapeutic trough levels range from 150 transplant, to 50 to 100 mcg/L thereafter; also monitor for signs of organ rejection.
7) Probable Mechanism: increased cyclosporine metabolism

3.5.1.AF Dalfopristin

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo seizures, coma)
2) Summary: Quinupristin/dalfopristin is a potent inhibitor of cytochrome P450 3A4 enzymes and may cause carbamazepine concentrations when administered concurrently. Because carbamazepine possesses a narro window, carbamazepine concentrations should be closely monitored during therapy with quinupristin/dalfopri carbamazepine should be adjusted accordingly (Prod Info Synercid(R) I.V., 1999).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable

6) Clinical Management: Monitor the trough carbamazepine concentrations when therapy with quinupristin/d administered concurrently. Dose reductions of carbamazepine may be required. Also monitor the patient for e carbamazepine toxicity.
7) Probable Mechanism: inhibition of cytochrome P450 3A4-mediated carbamazepine metabolism

3.5.1.AG Danazol
1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: Concomitant use of danazol and carbamazepine has led to significant increases in carbamaze resulted in toxicity (Kramer et al, 1986a; Zielinski et al, 1987; Hayden & Buchanan, 1991).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for symptoms of carbamazepine toxicity when danazol is added to therapy. carbamazepine levels should also be considered with the addition or discontinuation of danazol and dosage a accordingly.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) In a case report of a patient on carbamazepine 600 mg daily, the concurrent use of danazol 600 mg c carbamazepine level 60%, the area under the concentration-time curve (AUC) 148%, half-life 120%, and clearance approximately 60% within a month. Evaluation of the interaction by stable isotope technique re danazol inhibits carbamazepine metabolism, specifically the epoxide-trans-diol pathway (Kramer et al, 19

3.5.1.AH Darunavir
1) Interaction Effect: increased carbamazepine plasma concentrations and potential toxicity
2) Summary: Coadministration of carbamazepine with darunavir/ritonavir, an inhibitor of CYP450 enzymes, r inhibition of CYP3A-mediated carbamazepine metabolism, resulting in significantly increased carbamazepine concentrations and potential toxicity. In a pharmacokinetic drug interaction study, concurrent administration o and darunavir/ritonavir significantly increased plasma concentrations of carbamazepine. No significant chang pharmacokinetic parameters were noted. If coadministration of carbamazepine and darunavir/ritonavir is nec monitoring of carbamazepine concentrations and dose titration is recommended to attain the desired clinical initiating coadministration of darunavir/ritonavir and carbamazepine, no dose adjustment of either darunavir/ri carbamazepine is required (Prod Info PREZISTA(R) film coated oral tablets, 2008).
3) Severity: major
4) Onset: unspecified
5) Substantiation: established
6) Clinical Management: Coadministration of carbamazepine and darunavir/ritonavir may result in significant carbamazepine plasma concentrations due to inhibition of CYP3A-mediated carbamazepine metabolism by c coadministration of carbamazepine and darunavir/ritonavir is necessary, clinical monitoring of carbamazepine and dose titration is recommended to attain the desired clinical response. When initiating coadministration of and carbamazepine, no dose adjustment of either darunavir/ritonavir or carbamazepine is required (Prod Info film coated oral tablets, 2008).
7) Probable Mechanism: inhibition of CYP3A-mediated carbamazepine metabolism
8) Literature Reports
a) In a pharmacokinetic drug interaction study, concurrent administration of carbamazepine and darunav significantly increased plasma concentrations of carbamazepine. Subjects (n=16) were administered car mg twice daily concurrently with darunavir 600 mg/ritonavir 100 mg twice daily. Carbamazepine Cmax w (Least squares (LS) mean ratio 1.43; 90% confidence interval (CI), 1.34 to 1.53), AUC was increased 45 1.45; 90% CI, 1.35 to 1.57), and Cmin was increased 54% (LS mean ratio 1.54; 90% CI, 1.41 to 1.68). N changes in darunavir pharmacokinetic parameters were noted (Prod Info PREZISTA(R) film coated oral

3.5.1.AI Dasatinib
1) Interaction Effect: decreased dasatinib plasma concentrations
2) Summary: Dasatinib is a CYP3A4 substrate. Coadministration of a strong CYP3A4 inducer, such as carba dasatinib should be avoided as this may result in decreased dasatinib plasma concentrations leading to subth dasatinib levels. Consider using alternative therapeutic agents with low enzyme induction potential for coadm dasatinib. If concomitant use of dasatinib and carbamazepine is clinically warranted, a dasatinib dose increas considered and the patient should be monitored carefully for signs/symptoms of dasatinib toxicity (myelosupp retention, diarrhea, hemorrhage, or skin rash) (Prod Info SPRYCEL(R) oral tablets, 2008).
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant administration of carbamazepine, a strong CYP3A4 inducer, and CYP3A4 substrate, as this may result in decreased dasatinib plasma concentrations and consequently, subth Consider using alternative therapeutic agents with low enzyme induction potential for coadministration with d if concomitant use with carbamazepine is clinically warranted, consider increasing the dasatinib dose and mo closely for dasatinib toxicity (myelosuppression, fluid retention, diarrhea, hemorrhage, or skin rash) (Prod Info oral tablets, 2008).
7) Probable Mechanism: induction of CYP3A4-mediated dasatinib metabolism

3.5.1.AJ Dehydroepiandrosterone

1) Interaction Effect: reduced effectiveness of carbamazepine

2) Summary: Dehydroepiandrosterone (DHEA) in a single case report was noted to cause mania in a patient personal or family history of bipolar disorder (Markowitz et al, 1999a). Elevated DHEA levels have been found mental disorders; DHEA suppression has lead to improvement in psychotic symptoms (Howard, 1992a). Pati medication for bipolar disorder or patients with a personal and/or family history of bipolar disorder should not further data is available to characterize this drug-herb interaction.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: If carbamazepine is being used for manic symptoms, concomitant use of dehydroep (DHEA) may cause a return of symptoms. Patients with a personal or family history of bipolar disorder should avoid DHEA use.

7) Probable Mechanism: proserotonergic activity of dehydroepiandrosterone may predispose patients to mar dehydroepiandrosterone is a precursor to androgenic steroids, which in high doses may precipitate mania

8) Literature Reports

a) A 68-year-old male with no documented psychiatric history initiated dehydroepiandrosterone (DHEA) (mg) daily and increased the dose to 200 to 300 mg daily for 6 months. Within 3 months, family members of odd behavior with prominent symptoms of agitation, delusional thinking, decreased sleep and appetite sprees. The patient was not taking any prescribed medication but did ingest alcohol in amounts up to 1 c Another 3 months elapsed, leading to involuntary inpatient admission secondary to rapid, loud, pressured grandiose thoughts. At admission, the patient reported that he had decreased alcohol intake to 2 beers c concerns about his behavior changes. There was no family history of bipolar disorder. Urinary drug scree Over the seven-day hospital stay, with the institution of valproic acid 500 mg twice daily, the patient's beh patterns improved, and the patient believed DHEA led to his symptoms. There were no ethanol withdraw patient was discharged with follow-up care from his primary care physician with a diagnosis of substance disorder (Markowitz et al, 1999).

b) A 13-year-old male decompensated with a subsequent two-year period of emotional problems accom use of LSD, hashish, barbiturates, and alcohol. His mental status included bizarre, disorganized, delusio auditory and visual hallucinations, paranoia, lack of attention to personal hygiene, agitation, and combati diagnosed with chronic paranoid schizophrenia; schizophrenia, chronic undifferentiated type, and schizo excited type. He was resistant to daily doses of trifluoperazine 40 mg, chlorpromazine 400 mg, and imipr was also resistant to combination therapy with chlorpromazine 400 mg with thiothixene 80 mg, thioridazi perphenazine 48 mg with lithium carbonate 1200 mg, clonazepam 4 mg, and carbamazepine 1200 mg d DHEA level exceeded 900 mcg/dL. A seven-day suppression test with dexamethasone 1 mg orally at be normal DHEA level of 200 mcg/dL. By day 5, psychosis improved and the patient was well-oriented, con was making good eye contact. Once dexamethasone was discontinued, rapid decompensation and floric despite "substantial amounts of psychotropic medications." DHEA increased to 536 mcg/dL. The author elevated DHEA levels were associated with florid psychosis resistant to conventional antipsychotic thera 1992).

3.5.1.AK Delavirdine

1) Interaction Effect: decreased trough plasma delavirdine concentrations

2) Summary: Pharmacokinetic data on eight patients suggested that coadministration of phenytoin, phenoba carbamazepine with delavirdine results in substantial reductions in trough plasma delavirdine concentrations 90%). Coadministration of delavirdine with any of these drugs is not recommended (Prod Info RESCRIPTOR 2006).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Coadministration of delavirdine and carbamazepine is not recommended, due to th reduction in plasma delavirdine concentrations seen with concurrent use.

7) Probable Mechanism: induction of delavirdine metabolism

3.5.1.AL Desipramine

1) Interaction Effect: increased carbamazepine toxicity, decreased desipramine effectiveness

2) Summary: The concomitant use of carbamazepine and desipramine has been reported to increase carbar concentrations and decrease desipramine concentrations (Lesser, 1984; Brown et al, 1990a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for clinical efficacy of the desipramine therapy and for any signs of toxicity c Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.

7) Probable Mechanism: increased desipramine metabolism, decreased carbamazepine metabolism

3.5.1.AM Dexamethasone

1) Interaction Effect: decreased dexamethasone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, Carbamazepine does interfere with the dexamethasone suppression test (Privitera et al, 1982c).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of the corticosteroid. An increase in the steroid dosage after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased dexamethasone metabolism

3.5.1.AN Dicumarol
1) Interaction Effect: decreased anticoagulant effectiveness
2) Summary: Concomitant carbamazepine and warfarin therapy has been reported to result in a decreased a effect, secondary to the induction of hepatic metabolism of the anticoagulant (Massey, 1983c; Cohen & Arms Koch-Weser & Koch-Weser, 1975c; Kendall & Boivin, 1981c; Hansen et al, 1971e). A similar effect may occu
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving oral anticoagulant therapy, the prothrombin time ratio or INR (i normalized ratio) should be closely monitored with the addition and withdrawal of treatment with carbamazep reassessed periodically during concurrent therapy. Adjustments of the dicumarol dose may be necessary in c the desired level of anticoagulation.
7) Probable Mechanism: increased dicumarol metabolism

3.5.1.AO Diltiazem
1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: Concomitant administration of carbamazepine and diltiazem may increase carbamazepine leve 72%, resulting in toxicity (Prod Info Tiazac(TM), 1996; Shaughnessy & Mosley, 1992a; Brodie & Macphee, 19 al, 1986; Eimer & Carter, 1987a; Bahls et al, 1991).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor carbamazepine serum levels and clinical signs of carbamazepine toxicity. U levels are 6-12 mg/L; adjust dose accordingly. Nifedipine does not appear to interact with carbamazepine and considered as an alternative to diltiazem.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) Concomitant carbamazepine and diltiazem administration may produce elevated serum carbamazepi in neurotoxicity (Brodie & Macphee, 1986; Eimer & Carter, 1987; Ahmad, 1990; Shaughnessy & Mosley, case report, diltiazem 60 mg three times daily elevated the carbamazepine level by 40% higher than bas clinical signs of carbamazepine toxicity. Nifedipine 20 mg three times daily did not produce any adverse Macphee, 1986). In another case report, a patient with a stable carbamazepine dose (800 mg daily) and concentration (8.5 to 10.1 mg/L) was started on diltiazem 30 mg three times a day for atrial fibrillation. Ap weeks later, the patient was admitted to the hospital with mental slowing and speech difficulties. The ser level the next day was 15.5 mg/L. Carbamazepine was consequently reduced to 300 mg daily, which pro level of 8.3 mg/L and resolution of the mental disturbances (Eimer & Carter, 1987). Competitive inhibitior system by diltiazem may be the most likely cause of the elevated carbamazepine serum concentrations.

3.5.1.AP Dothiepin
1) Interaction Effect: decreased dothiepin effectiveness
2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease se antidepressant levels (Leinonen et al, 1991l; Brown et al, 1990i). Although not reported for dothiepin, a simila occur.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor for clinical efficacy of the dothiepin therapy and for any signs of toxicity of c Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.
7) Probable Mechanism: increased dothiepin metabolism
8) Literature Reports
a) Concomitant administration of imipramine and carbamazepine to children with attention deficit disorde reported to result in a 50% decrease in the total plasma concentration of imipramine plus desipramine (E Carbamazepine probably enhances the hepatic microsomal metabolism of imipramine and other tricyclic by inducing hepatic enzymes (Moody et al, 1977d). Although not reported specifically for dothiepin, be av potential for a similar interaction exits. Patients on chronic carbamazepine therapy may require increase antidepressants.

3.5.1.AQ Doxacurium

1) Interaction Effect: decreased doxacurium duration of action

2) Summary: It has been demonstrated that in patients taking carbamazepine for at least one month prior to neuromuscular blockers, the recovery time after being given neuromuscular blockers was about 65% faster w control patients (Ornstein et al, 1991a; Prod Info Nuromax(R), 1994).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: Monitor patients for an appropriate clinical response to the neuromuscular blocker. intervals or higher doses of doxacurium may be needed in patients receiving carbamazepine.

7) Probable Mechanism: unknown

8) Literature Reports

a) Twenty-seven adult neurosurgical patients participated in a study to determine the effects of doxacuri neuromuscular blockade. Patients were divided into three equal groups, with nine patients having been c therapy for at least one week, nine patients having been on carbamazepine therapy for at least one weel patients serving as controls. All subjects received a bolus intravenous dose of doxacurium 60 mcg/kg du with nitrous oxide, fentanyl, and droperidol. The onset of paralysis was prolonged by 49% in the phenyto not altered in the carbamazepine group. Recovery times were significantly shortened in both anticonvuls recovering approximately twice as fast as the controls. Times from doxacurium administration to 75% rec follows: control group, 203 minutes; phenytoin group, 97 minutes; carbamazepine group, 80 minutes. Sir recovery times were seen for 5%, 25%, 50%, and 90% recovery. Once the recovery from paralysis starte more quickly in the anticonvulsant groups. The 25% to 75% recovery index was increased by 67% in the group and 53% in the phenytoin group when compared to controls (Ornstein et al, 1991).

3.5.1.AR Doxepin

1) Interaction Effect: decreased doxepin effectiveness and possibly increased carbamazepine toxicity (diplop dizziness, tremor)

2) Summary: The concomitant use of carbamazepine and antidepressants has been reported to decrease do (Leinonen et al, 1991d).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for clinical efficacy of the doxepin therapy and for any signs of toxicity of ca Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.

7) Probable Mechanism: increased doxepin metabolism

8) Literature Reports

a) The effect of carbamazepine on doxepin levels were examined in 17 psychiatric inpatients who were minimum of 7 days prior to measurement of baseline antidepressant concentrations. The average daily d was 201.5 mg. Carbamazepine was added in a mean dose of 593 mg and continued over a 4-week perio concentrations were decreased to 46% in patients receiving combination therapy compared to patients r alone (Leinonen et al, 1991c).

3.5.1.AS Doxorubicin Hydrochloride

1) Interaction Effect: decreased carbamazepine plasma concentrations

2) Summary: A 36-year old epileptic female undergoing antineoplastic therapy with doxorubicin and cisplatin subtherapeutic carbamazepine, phenytoin, and valproic acid concentrations which resulted in tonic-clonic sei the exact mechanism is unknown, possible causes include decreased absorption or accelerated elimination o (Neef & de Voogd-van der Straaten, 1988e).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Anticonvulsant levels should be closely monitored in patients receiving antineoplast doxorubicin or cisplatin. Doses of carbamazepine may need to be increased.

7) Probable Mechanism: decreased absorption or accelerated elimination of carbamazepine

8) Literature Reports

a) A 36-year old female epileptic patient requiring cisplatin and doxorubicin therapy for papillary adenoc experienced tonic-clonic seizures after two days of antineoplastic treatment. Plasma concentrations of ca valproic acid, and phenytoin were all determined to be subtherapeutic (0.5 mg/L, 24.3 mg/L, and 0.3 mg/ One month later, she was controlled on phenytoin 450 mg daily, carbamazepine 1200 mg daily, and valp daily. During her second course of cisplatin and doxorubicin, she again suffered a tonic-clonic seizure. P concentrations of her anticonvulsants were phenytoin 0.2 mg/L, carbamazepine 3.5 mg/L, and valproic a Three days following her chemotherapy, plasma concentrations of the anticonvulsants had returned to th values. During her sixth and final chemotherapy course, carbamazepine levels remained low (1.4 mg/L) all 15 days of the course (Neef & de Voogd-van der Straaten, 1988d).

3.5.1.AT Doxorubicin Hydrochloride Liposome

1) Interaction Effect: decreased carbamazepine plasma concentrations

2) Summary: Although no formal drug interaction studies have been done with doxorubicin hydrochloride lipo may interact with drugs known to interact with the conventional formulation of doxorubicin (Prod Info Doxil(R) old epileptic female undergoing antineoplastic therapy with doxorubicin and cisplatin experienced subtherape carbamazepine, phenytoin, and valproic acid concentrations which resulted in tonic-clonic seizures. Although mechanism is unknown, possible causes include decreased absorption or accelerated elimination of carbama Voogd-van der Straaten, 1988a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Anticonvulsant levels should be closely monitored in patients receiving antineoplast doxorubicin or cisplatin. Doses of carbamazepine may need to be increased.
7) Probable Mechanism: decreased absorption or accelerated elimination of carbamazepine
8) Literature Reports
a) A 36-year old female epileptic patient requiring cisplatin and doxorubicin therapy for papillary adenoc experienced tonic-clonic seizures after two days of antineoplastic treatment. Plasma concentrations of ca valproic acid, and phenytoin were all determined to be subtherapeutic (0.5 mg/L, 24.3 mg/L, and 0.3 mg/ One month later, she was controlled on phenytoin 450 mg daily, carbamazepine 1200 mg daily, and valp daily. During her second course of cisplatin and doxorubicin, she again suffered a tonic-clonic seizure. P concentrations of her anticonvulsants were phenytoin 0.2 mg/L, carbamazepine 3.5 mg/L, and valproic a Three days following her chemotherapy, plasma concentrations of the anticonvulsants had returned to th values. During her sixth and final chemotherapy course, carbamazepine levels remained low (1.4 mg/L) all 15 days of the course (Neef & de Voogd-van der Straaten, 1988).

3.5.1.AU Doxycycline

1) Interaction Effect: decreased doxycycline effectiveness
2) Summary: Chronic carbamazepine therapy may decrease the half-life of doxycycline by 50% (Neuvonen e et al, 1974).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor clinical effectiveness of doxycycline therapy in patients concurrently receivi increased doxycycline dosage might be considered.
7) Probable Mechanism: may increase metabolism doxycycline

3.5.1.AV Efavirenz

1) Interaction Effect: decreased efavirenz plasma concentrations and/or carbamazepine plasma concentratio
2) Summary: Coadministration of carbamazepine and efavirenz resulted in lowered exposures and plasma c both carbamazepine and efavirenz. However, as no dosing recommendations can be made, use of an alterna anticonvulsant should be considered in patients receiving efavirenz (Prod Info SUSTIVA(R) oral capsules, tab
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: established
6) Clinical Management: The concomitant use of carbamazepine and efavirenz has resulted in reduced plas of carbamazepine and efavirenz. An alternative anticonvulsant should be considered in patients receiving efa adjusted dosing recommendations are available for carbamazepine (Prod Info SUSTIVA(R) oral capsules, tal
7) Probable Mechanism: unknown
8) Literature Reports
a) Coadministration of carbamazepine and efavirenz resulted in decreased exposure and plasma conce carbamazepine in pharmacokinetic studies. In 12 subjects, efavirenz (600 mg orally daily for 14 days) de plasma Cmax, AUC, and Cmin of carbamazepine (200 mg/day for 3 days, 200 mg twice daily for 3 days, for 29 days) by an average of 20% (90% confidence interval (CI), 15 to 24%), 27% (90% CI, 20 to 33%), 24 to 44%), respectively. In 14 subjects, carbamazepine (200 mg/day for 3 days, 200 mg twice daily for 3 mg/day for 15 days) decreased the plasma Cmax, AUC, and Cmin of efavirenz (600 mg orally daily for 3 average of 21% (90% confidence interval (CI), 15 to 26%), 36% (90% CI, 32 to 40%), and 47% (90% CI, respectively. (Prod Info SUSTIVA(R) oral capsules, tablets, 2008).

3.5.1.AW Ergocalciferol

1) Interaction Effect: decreased systemic ergocalciferol (vitamin D) exposure
2) Summary: Coadministration of carbamazepine and vitamin D may reduce exposure to vitamin D and may events related to vitamin D deficiency, including hypocalcemia and secondary hyperparathyroidism. If carban vitamin D are used concomitantly, additional vitamin D supplementation may be necessary (Prod Info FOSAM oral tablets, 2008). Monitoring the patient for signs and symptoms of vitamin D deficiency (ie, hypocalcemia a hyperparathyroidism) may be warranted.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Concomitant administration of carbamazepine and vitamin D may reduce exposure to increased ergocalciferol clearance. Consider additional vitamin D supplementation if these agents are used

(Prod Info FOSAMAX PLUS D(TM) oral tablets, 2008). Monitor the patient for adverse events related to vitam including signs and symptoms of hypocalcemia and secondary hyperparathyroidism.
7) Probable Mechanism: increased catabolism of vitamin D

3.5.1.AX Erlotinib
1) Interaction Effect: increased erlotinib clearance and reduced erlotinib exposure
2) Summary: Erlotinib is primarily metabolized by the CYP3A4 isozyme. Coadministration of erlotinib and rifa inducer, decreased the erlotinib AUC by approximately 67% to 80%, which is equivalent to an erlotinib dose c mg in non-small cell lung cancer patients; it also significantly increased erlotinib clearance. Although not direc concomitant use of erlotinib and carbamazepine, also a CYP3A4 inducer, could result in a similar interaction therefore be avoided. If concomitant use is clinically warranted, an increase in erlotinib dose as tolerated at 2 should be considered, while monitoring patient safety. If the erlotinib dose is increased, the dose should be re immediately to the indicated starting dose upon discontinuation of carbamazepine (Prod Info TARCEVA(R) o
3) Severity: major
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of erlotinib and carbamazepine as this may result in decreas exposure and efficacy. However, if concomitant use is clinically warranted, consider an increase in erlotinib d 2 week intervals and monitor patient's safety. If the erlotinib dose is increased, reduce it immediately to the in dose upon discontinuation of carbamazepine (Prod Info TARCEVA(R) oral tablets, 2007).
7) Probable Mechanism: induction of CYP3A4-mediated erlotinib metabolism by carbamazepine

3.5.1.AY Erythromycin
1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: Erythromycin decreases the hepatic clearance of carbamazepine causing elevated carbamaze concentrations and possible toxicity (Hendrick et al, 1983a; MacNab et al, 1987a; Miles & Tennison, 1989a; V 1987a; Wroblewski et al, 1986).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: The combination of carbamazepine and macrolide antibiotics should be avoided an given to an alternative antibiotic. If the combination is necessary, carbamazepine levels should be obtained w adding or discontinuing erythromycin and dosage adjustments made accordingly.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) Toxicity following concomitant administration of carbamazepine and erythromycin was reported in six (Goulden et al, 1986). Toxicity occurred in less than two days with erythromycin therapy in five patients; the interaction was not observed until the eighth day of erythromycin therapy when the dose was double mg/kg/day. Carbamazepine serum concentrations decreased to baseline levels within 8 to 12 hours of di erythromycin, suggesting that normalization of carbamazepine metabolism occurs rapidly.
b) It is suggested that erythromycin inhibits the metabolism of carbamazepine in liver (cytochrome P450 al, 1983). Concomitant administration of erythromycin and carbamazepine in healthy volunteers resulted increases in carbamazepine half-life and 24-hour postdose serum concentrations, as well as decreases i oral clearance (Miles & Tennison, 1989). Decreases in maximum carbamazepine-10,11-epoxide serum c area under concentration-time curve (AUC), and the carbamazepine-10,11-epoxide to carbamazepine ra observed during combined therapy. In this study, carbamazepine was given in daily doses of 300 mg to 4 17 consecutive days; subjects were given placebo erythromycin every six hours on days 12, 13 and 14, t base 250 mg every six hours for the final three days. It is suggested that erythromycin significantly inhibi metabolic pathway required for transformation of carbamazepine to carbamazepine-10,11-epoxide. Wide variability was seen in this study; individual changes in oral clearance ranged from plus 23% to minus 41 unpredictability of this interaction. Close patient monitoring is advised when these two agents are given c when one agent is discontinued.
c) Increases in carbamazepine serum concentrations were observed in four children during concurrent e carbamazepine therapy. All children developed signs of toxicity (nausea, vomiting, ataxia, dizziness) with initiation of erythromycin therapy, which subsided after erythromycin was discontinued and was associat in carbamazepine serum concentrations. The authors suggest that erythromycin inhibits the metabolism The onset of the interaction generally occurred three to four days after addition of erythromycin to the ca regimen (Hendrick et al, 1983).
d) Concomitant carbamazepine and erythromycin stearate therapy was reported to result in carbamazep SIADH in a 41-year-old epileptic woman (Carranco et al, 1985).
e) A further report of the interaction between erythromycin ethylsuccinate and carbamazepine was desc old girl with tonic-clonic seizures (Zitelli et al, 1987). The patient had been maintained on carbamazepine (serum level 12 mcg/mL) and developed symptoms of carbamazepine toxicity (vomiting, lethargy, ataxia, cogwheeling movements) after five days of erythromycin ethylsuccinate therapy (250 mg four times daily increases in carbamazepine serum levels to 26 mcg/mL. Following withdrawal of erythromycin, serum co carbamazepine returned to normal levels, with resolution of symptoms. This article also provides a brief r clinically-relevant erythromycin drug interactions.
f) Two cases describing the interaction of carbamazepine and erythromycin in children resulting in carba

were reported by (Woody et al, 1987). The authors suggest that parents should be advised of the interac
medications are frequently prescribed independently by pediatrician and neurologist.
g) Concomitant administration of erythromycin and carbamazepine was reported to result in sinus arrest
10-year-old boy secondary to carbamazepine toxicity (MacNab et al, 1987). The patient recovered follow
therapy and the EKG normalized when carbamazepine serum levels returned to the therapeutic range. T
preexisting cardiac symptoms.

3.5.1.AZ Estazolam

1) Interaction Effect: decreased estazolam plasma concentrations and reduced effectiveness
2) Summary: Carbamazepine is a potent inducer of cytochrome P450-3A4 and estazolam metabolism is cata
coadministration of carbamazepine and estazolam would therefore be expected to reduce estazolam plasma
levels (Prod Info ProSom(TM), 2004).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Monitor for signs of benzodiazepine clinical ineffectiveness. Concurrent use of carb
estazolam may require higher doses of estazolam. The dose of estazolam should be decreased if carbamaze
discontinued.
7) Probable Mechanism: carbamazepine induction of CYP3A-isoform mediated estazolam metabolism

3.5.1.BA Ethinyl Estradiol

1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness
2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa
contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 198
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf
use of alternate methods of birth control may be necessary.
7) Probable Mechanism: increased metabolism of contraceptive steroids
8) Literature Reports
a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima
phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr
et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate
receiving oral contraceptives. Increasing the dose of ethinyl estradiol or mestranol in oral contraceptives
breakthrough bleeding and decrease the risk of conception. However, higher doses of estrogens may als
of vascular side effects, primarily in patients where enzyme induction does not occur. It is recommended
estrogen and progestin be given initially in patients receiving an enzyme inducing anticonvulsant; howev
pregnancy is a special concern, a moderate dose formulation (50 mcg ethinyl estradiol) should be consid
breakthrough bleeding occurs with low-dose contraception, progressive increases in the dose of mestran
(up to 80 mcg) should be considered. If spotting occurs, it is suggested that the contraceptive not be disc
rather that a traditional method of barrier contraception be initiated during the remainder of that cycle. Sv
dose oral contraceptive is recommended if enzyme inducing anticonvulsants are discontinued in women
moderate or high-dose contraceptives.
b) Carbamazepine reduced the area under the plasma concentration time curve (AUC) of ethinyl estrad
4 women taking carbamazepine 300 to 600 mg daily within 8 to 12 weeks of initiation of therapy. Norges
also significantly reduced to 29% to 57% of baseline. The authors suggest that breakthrough bleeding ca
most women with use of oral contraceptives containing 80 to 100 mcg ethinyl estradiol (Crawford et al, 1
c) Accidental pregnancy occurred in a 20-year-old epileptic who was using phenytoin 400 mg daily plus
400 mg daily (Haukkamaa, 1986). The plasma concentration of levonorgestrel in this patient was very lo
pg/mL) when compared to controls (325 +/- 135 pg/mL). Carbamazepine appears to decrease plasma le
concentrations by enhancing the hepatic metabolism of the steroid via enzyme induction. Levonorgestrel
relied upon as the sole means of contraception in patients on anticonvulsant therapy.

3.5.1.BB Ethosuximide

1) Interaction Effect: decreased ethosuximide serum concentrations
2) Summary: Two studies have documented that ethosuximide disposition is altered during carbamazepine t
decreased steady-state plasma concentrations, decreased half-life, and increased clearance of ethosuximide
1996a; Warren et al, 1980a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Patients receiving concurrent therapy with carbamazepine and ethosuximide may a
serum ethosuximide concentrations compared to patients not taking carbamazepine, leading to a decreased
If these two agents are used together, careful evaluation of clinical response and serum drug level monitoring
7) Probable Mechanism: carbamazepine induction of cytochrome P450 enzymes
8) Literature Reports
a) In a study of 22 volunteers, the effects of chronic epileptic medication on the pharmacokinetics of eth

evaluated. The study consisted of 10 epileptic patients undergoing chronic treatment with carbamazepin phenobarbital, and 12 healthy control subjects taking no chronic medications. Each subject received a si dose of ethosuximide after an overnight fast. Patients on chronic epileptic therapy had a decreased mea half-life of 29.0 +/- 7.8 hours compared to 53.7 +/- 14.3 hours for control subjects. Patients on chronic ep had higher oral clearance values and slightly decreased apparent volume of distribution values compare patients. The authors postulate that the mechanism of action was due to antiepileptic medication inductic CYP3A (Giaccone et al, 1996).

b) The disposition of ethosuximide was demonstrated to be altered by carbamazepine therapy (Warren Concomitant therapy with carbamazepine 200 mg daily and ethosuximide 250 mg twice daily resulted in ethosuximide steady-state plasma concentrations. The clearance of ethosuximide was shown to increas concomitant decrease in serum half-life. Thus carbamazepine induced the metabolism of ethosuximide a adjustments may be required during concomitant therapy.

3.5.1.BC Etonogestrel

1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness

2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 198

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf use of alternate methods of birth control may be necessary.

7) Probable Mechanism: increased metabolism of contraceptive steroids

8) Literature Reports

a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate receiving oral contraceptives. Increasing the dose of ethinyl estradiol or mestranol in oral contraceptives breakthrough bleeding and decrease the risk of conception. However, higher doses of estrogens may als of vascular side effects, primarily in patients where enzyme induction does not occur. It is recommended estrogen and progestin be given initially in patients receiving an enzyme inducing anticonvulsant; howev pregnancy is a special concern, a moderate dose formulation (50 mcg ethinyl estradiol) should be consic breakthrough bleeding occurs with low-dose contraception, progressive increases in the dose of mestrar (up to 80 mcg) should be considered. If spotting occurs, it is suggested that the contraceptive not be disc rather that a traditional method of barrier contraception be initiated during the remainder of that cycle. Sv dose oral contraceptive is recommended if enzyme inducing anticonvulsants are discontinued in women moderate or high-dose contraceptives.

b) Carbamazepine reduced the area under the plasma concentration time curve (AUC) of ethinyl estrad 4 women taking carbamazepine 300 to 600 mg daily within 8 to 12 weeks of initiation of therapy. Norges also significantly reduced to 29% to 57% of baseline. The authors suggest that breakthrough bleeding ca most women with use of oral contraceptives containing 80 to 100 mcg ethinyl estradiol (Crawford et al, 1

c) Accidental pregnancy occurred in a 20-year-old epileptic who was using phenytoin 400 mg daily plus 400 mg daily (Haukkamaa, 1986). The plasma concentration of levonorgestrel in this patient was very lo pg/mL) when compared to controls (325 +/- 135 pg/mL). Carbamazepine appears to decrease plasma le concentrations by enhancing the hepatic metabolism of the steroid via enzyme induction. Levonorgestrel relied upon as the sole means of contraception in patients on anticonvulsant therapy.

3.5.1.BD Etravirine

1) Interaction Effect: decreased etravirine plasma concentrations

2) Summary: Carbamazepine and etravirine should not be coadministered. The combination of carbamazepi may result in significant decreases in etravirine plasma concentrations due to CYP3A4-mediated induction of carbamazepine (Prod Info INTELENCE(TM) oral tablets, 2008).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Carbamazepine and etravirine should not be coadministered. Concomitant use of c etravirine may result in decreased etravirine plasma concentrations and loss of therapeutic effect of etravirine CYP3A4-mediated induction of etravirine by carbamazepine (Prod Info INTELENCE(TM) oral tablets, 2008).

7) Probable Mechanism: induction of CYP3A4-mediated metabolism of etravirine by carbamazepine

3.5.1.BE Etretinate

1) Interaction Effect: decreased etretinate effectiveness

2) Summary: A case report described a possible interaction between carbamazepine and etretinate (Moham Concurrent use resulted in the lack of etretinate efficacy; withdrawal of carbamazepine was followed by the e response to etretinate.

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Monitor for therapeutic efficacy of etretinate. If no clinical response is seen, and etr necessary, consideration might be given to changing to an alternative anticonvulsant regimen.
7) Probable Mechanism: induction of etretinate metabolism
8) Literature Reports
a) A 15-year-old girl with epilepsy and pityriasis rubra pilaris was being treated with carbamazepine 200 acid 100 mg/d when etretinate 30 mg/d was added to her therapy. After 2 months of therapy no clinical ir seen, and none of the usual cutaneous side effects of etretinate were noted. Etretinate was discontinued was gradually withdrawn and the valproic acid dose increased to 350 mg/d. Etretinate 30 mg/d was resta weeks a good clinical response and dry lips and mouth, a common side effect, were seen. No etretinate concentrations were reported, and rechallenge was not attempted (Mohammed, 1992).

3.5.1.BF Evening Primrose

1) Interaction Effect: reduced anticonvulsant effectiveness
2) Summary: Theoretically, evening primrose oil may reduce the effectiveness of anticonvulsants by lowering threshold. Evening primrose oil is contraindicated in patients with epilepsy (Barber, 1998; Newall et al, 1996).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Avoid concomitant use of evening primrose oil with anticonvulsants.
7) Probable Mechanism: evening primrose oil may reduce the seizure threshold

3.5.1.BG Everolimus

1) Interaction Effect: loss of everolimus efficacy
2) Summary: Drugs such as carbamazepine, which is a cytochrome CYP3A4 inducer, may increase the met everolimus, causing decreased everolimus plasma concentrations. Caution should be used when these two a concomitantly. Dosage increase of everolimus is recommended (Prod Info AFINITOR(R) oral tablets, 2009).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Monitor the patient closely or perform additional tests to determine effectiveness of Dosage increase of everolimus is recommended (Prod Info AFINITOR(R) oral tablets, 2009).
7) Probable Mechanism: induction of cytochrome CYP3A4-mediated everolimus metabolism

3.5.1.BH Felbamate

1) Interaction Effect: decreased carbamazepine or felbamate effectiveness
2) Summary: Felbamate reduces carbamazepine levels (Albani et al, 1991a; Graves et al, 1989a; Wilensky e carbamazepine decreases felbamate levels (Prod Info Felbatol(R), 2000a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Consider monitoring carbamazepine levels following the addition of felbamate thera carbamazepine concentrations may be reduced, there is an increase in the active metabolite (carbamazepine concentration, such that the overall effectiveness of carbamazepine may not change.
7) Probable Mechanism: increased carbamazepine or felbamate metabolism
8) Literature Reports
a) The manufacturer reports that a 50% increase in felbamate clearance and a 40% decrease in felbam trough concentration occurs when carbamazepine is added to felbamate therapy. Additionally, felbamate decrease in the steady-state plasma concentrations of carbamazepine and an increase in the steady-sta epoxide plasma concentration (Prod Info Felbatol(R), 2000).
b) Four patients who were receiving carbamazepine, phenytoin, and felbamate have been described. Fo discontinuation of phenytoin, felbamate clearance decreased 21%. Carbamazepine dosage was reduced additional felbamate clearance of 16.5% (Wagner et al, 1991).
c) Felbamate has been reported to increase carbamazepine metabolism. The effect of felbamate 3000 r carbamazepine levels in four patients on monotherapy was studied. Carbamazepine levels had previous at 4 to 12 mcg/mL with dosages of 800 to 1800 mg carbamazepine daily. Carbamazepine levels were re of 25% with concurrent use; this effect was evident within one week of initiation of felbamate and plateau weeks. Felbamate appeared to reduce carbamazepine concentrations and increase carbamazepine-epo concentrations without affecting free fraction (Albani et al, 1991). Similar results were reported in anothe al, 1989).
d) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially i teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large related to the levels of the reactive epoxide metabolites (Buehler et al, 1990d; Van Dyke et al, 1991d; Fir The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hyc valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987d; Ramsay et al, 1990d; Spina et al, 1996 combinations increase the risk of major birth defects 3- to 4-fold over monotherapy and about 10-fold ove rates.

3.5.1.BI Felodipine

1) Interaction Effect: decreased felodipine effectiveness

2) Summary: Several studies have shown that concurrent use carbamazepine with some but not all calcium (nimodipine, felodipine) has resulted in decreased levels of the calcium channel blocker (Capewell et al, 1987 1988a; Woodcock et al, 1991; Tartara et al, 1991a).

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor clinical response to felodipine with dose adjustments as needed to achieve cardiovascular response. Nifedipine does not appear to interact with carbamazepine and may be considered to felodipine.

7) Probable Mechanism: increased felodipine metabolism

8) Literature Reports

a) Three groups of eight subjects were studied (Tartara et al, 1991). Group 1 was comprised of healthy had epileptic patients treated at least four months with carbamazepine, phenobarbital, phenytoin (all enz a combination, and group 3 included epileptic patients treated for at least four months with sodium valpro the control group, nimodipine AUCs averaged a 7-fold decrease in the enzyme inducer group, probably d first-pass metabolism. The nimodipine AUCs were increased by 50% in the valproate-treated group.

b) Maximum plasma concentrations of felodipine were considerably lower in 10 epileptic patients (1.6 nr anticonvulsant therapy (phenytoin, carbamazepine, phenobarbital) than in 12 healthy volunteers (8.7 nm administration of oral felodipine 5 mg twice daily for four days to both groups (Capewell et al, 1987). The the felodipine plasma concentration-time curve at 12 hours postdose was reduced from 33 nmol/L/hr in t nmol/L/hr in epileptics on anticonvulsant medications (Saltiel et al, 1988).

3.5.1.BJ Fentanyl

1) Interaction Effect: decreased plasma concentrations of fentanyl

2) Summary: Induction of fentanyl metabolism by carbamazepine, a cytochrome P450 inducer, may cause ir of fentanyl (Prod Info Duragesic(R), 2001).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Caution is advised when administering fentanyl to patients receiving carbamazepin adjustments should be considered if necessary.

7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of fentanyl

3.5.1.BK Fluconazole

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vor seizures, coma)

2) Summary: Several cases of carbamazepine toxicity attributed to the coadministration of fluconazole have (Finch et al, 2002a; Nair & Morris, 1999a; Ulivelli et al, 2004). Fluconazole inhibits cytochrome P450 3A4 enz for carbamazepine metabolism. A similar interaction has also been reported between fluconazole and phenyt

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Consider monitoring carbamazepine levels and symptoms of carbamazepine toxicit addition of fluconazole.

7) Probable Mechanism: fluconazole inhibition of cytochrome P450 3A4-mediated carbamazepine metabolis

8) Literature Reports

a) A 33-year-old male with mental retardation and a history of seizures had been taking carbamazepine times daily for more than five years. His last carbamazepine concentration before the initiation of flucona 11.1 mcg/mL, which was consistent with his past levels. Fluconazole 150 mg daily, ciprofloxacin 250 mg oral steroid taper were prescribed for a skin eruption which was thought to be candidiasis. Ciprofloxacin after two days since no clinical improvement was noted. By the end of the third day of fluconazole therap lethargic and unarousable to painful stimuli. A carbamazepine concentration was measured at 24.5 mcg/ was discontinued and carbamazepine was held for 24 hours. By the next day, the carbamazepine conce mcg/mL and his symptoms had resolved. He was restarted on his prior dose of carbamazepine and four level of 11.7 mcg/mL (Nair & Morris, 1999).

b) Fluconazole, an inhibitor of the cytochrome P450 enzyme system (CYP450), inhibits the metabolism but undergoes metabolism itself via the CYP3A4 isoenzyme. A 38-year-old mentally retarded male was hospital because of coffee ground emesis. His medications included lansoprazole, ranitidine, carbamaze three times a day and 400 mg at bedtime), cisapride, clonazepam, docusate, lactulose, dantrolene, and tablet. The serum carbamazepine level on admission was 6 mcg/mL. The patient seized and when seizu carbamazepine dose increased to 1000 mg/day with no further seizure activity. On hospital day 24, fluco initiated at 200 mg/day for severe tinea cruris. Three days later fluconazole was increased to 400 mg/da culture was positive for candida albicans. After 10 days of fluconazole therapy the carbamazepine level The patient showed no signs of toxicity. Carbamazepine was decreased to 200 mg four times daily which therapeutic carbamazepine levels. He was discharged on day 45 of hospitalization. This case report sug elevations in carbamazepine serum concentrations can occur with concomitant fluconazole therapy (Finc

c) Addition of fluconazole to a stable drug regimen containing carbamazepine resulted in an increased c plasma level with associated symptoms of carbamazepine toxicity (ataxia, nystagmus, diplopia, nausea, year-old female with a history of partial epilepsy had been taking carbamazepine 1600 mg/day, lamotrigi and barbexaclone 100 mg/day for many years without incident. The carbamazepine plasma level drawn to initiation of fluconazole was approximately 7.5 mcg/mL. Fluconazole was initiated at 150 mg/day for tr corporis. On the first day of fluconazole administration the patient noted episodes of blurred vision and d head movements. After 11 days of fluconazole therapy the patient complained of severe diplopia, oscillo vomiting and gait instability. Lamotrigine and barbexaclone plasma levels remained mostly unchanged, b carbamazepine plasma level increased to approximately 18.5 mcg/mL. Neurological exam revealed a ga nystagmus and smooth pursuit impairment. Twenty four hours after fluconazole withdrawal, carbamazep decreased to approximately 8 mcg/mL and neurological symptoms improved (Ulivelli et al, 2004).

3.5.1.BL Flunarizine

1) Interaction Effect: increased carbamazepine serum levels and possible toxicity (ataxia, nystagmus, diplop vomiting, apnea, seizures, coma)
2) Summary: Among patients comedicated with flunarizine and carbamazepine, a mean increase of 0.22 mc carbamazepine serum levels was noted (Pledger et al, 1994a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Continue routine monitoring of carbamazepine serum levels. Some dose adjustmer both clinical symptoms and laboratory findings suggest carbamazepine toxicity.
7) Probable Mechanism: unknown
8) Literature Reports

a) During a 24-week trial of adjunctive flunarizine added to regimens consisting of either carbamazepine both, only patients in the group receiving carbamazepine-flunarizine showed a modest increase in mean serum levels of 0.22 mcg/mL compared to baseline. A parallel placebo-carbamazepine group showed a 0.57 mcg/mL (Pledger et al, 1994).

3.5.1.BM Fluoxetine

1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: The addition of fluoxetine to carbamazepine therapy has increased carbamazepine concentrati effects, including diplopia, blurred vision, dizziness, and tremors in some reports (Grimsley et al, 1991a; Gerr Pearson, 1990b). Conversely, no changes in steady state carbamazepine levels have been reported with the fluoxetine (Spina et al, 1993c). Symptoms of serotonin syndrome (hypertension, hyperthermia, myoclonus, m changes) have also been reported with this combination (Dursun et al, 1993a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Due to the potential to increase carbamazepine levels, patients should be monitore carbamazepine toxicity when fluoxetine is added to therapy. Carbamazepine levels should be considered wit weeks of adding or discontinuing fluoxetine, with dosage adjustments made as indicated.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports

a) An interaction between fluoxetine and carbamazepine was reported in six normal volunteers (Grimsle Carbamazepine was given for 28 days, and fluoxetine was added to the regimen on day 7. The addition daily to carbamazepine 400 mg daily resulted in an increase in the area under the concentration-time cu carbamazepine and carbamazepine-epoxide and a decrease in clearance of carbamazepine. No signific observed in absorption, volume of distribution or elimination rate constant, indicating that fluoxetine inhib of carbamazepine.

b) The effect of fluoxetine 20 mg daily was studied for three weeks in eight epileptic patients who were s carbamazepine therapy (Spina et al, 1993b). Steady-state plasma levels of carbamazepine and its epoxi were not significantly changed with concurrent use of fluoxetine. These results differ from previous repor speculate that chronic carbamazepine administration may have resulted in enzyme induction that caused of fluoxetine, thereby lowering the chances of a metabolic interaction. Unfortunately fluoxetine levels wer

c) An interaction between fluoxetine and carbamazepine was reported in two patients receiving chronic dosages of 600 mg and 1000 mg daily respectively. Within 7 to 10 days of initiation of fluoxetine 20 mg c developed symptoms of carbamazepine toxicity. Symptoms disappeared within two weeks in one patient carbamazepine dosage reduction by 200 mg daily; in the other patient, fluoxetine was discontinued with resolution within two weeks (Pearson, 1990a).

d) Two cases of parkinsonism were reported after fluoxetine was added to an existing carbamazepine r patient, a 74-year old man, developed symptoms three days after fluoxetine 20 mg per day was added t month regimen of carbamazepine 200 mg twice daily. The patient developed cogwheel rigidity, a mask-li parkinsonian gait. After discontinuation of fluoxetine and treatment with dexetimide, the patient showed c hypertonia of the arms 17 days later. The other patient, a 53-year old woman, developed parkinsonian s fluoxetine 20 mg per day was added to an existing regimen of carbamazepine 200 mg twice daily. The p been taking thioridazine 275 mg per day which was stopped when fluoxetine was added. The patient dev rigidity and a mask-like face nine days after initiation of fluoxetine therapy (Gernaat et al, 1991).

e) A female patient experienced a drug interaction 14 days after she had fluoxetine 20 mg added to a re carbamazepine 200 mg daily. The patient presented with symptoms of serotonin syndrome, such as unc shivering, agitation, incoordination, myoclonus, hyperreflexia, and diaphoresis. The patient also had leuk thrombocytopenia. After discontinuation of fluoxetine, all symptoms of serotonin syndrome and hematolo resolved over the next 72 hours (Dursun et al, 1993).

3.5.1.BN Fluvoxamine

1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: Several cases have been reported in which fluvoxamine appeared to cause increased carbama symptoms of carbamazepine toxicity (Martinelli et al, 1993; Fritze et al, 1991b). However, one study of eight e found no such increase in carbamazepine levels with three weeks of concurrent use (Spina et al, 1993a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Due to the potential to increase carbamazepine levels, patients should be monitore carbamazepine toxicity when fluvoxamine is added to therapy. Carbamazepine levels should be considered v discontinuing fluvoxamine, with dosage adjustments made as indicated.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports

a) The addition of fluvoxamine to a constant dosage of carbamazepine in three patients caused an incre carbamazepine levels resulting in symptoms of toxicity (Fritze et al, 1991a). The authors concluded that inhibition of carbamazepine metabolism. However, (Spina et al, 1993) found no increase in carbamazepi epileptic patients who were given fluvoxamine 100 mg daily or fluoxetine 20 mg daily with carbamazepin

3.5.1.BO Fosamprenavir

1) Interaction Effect: reduced effectiveness of fosamprenavir due to reduced serum concentrations
2) Summary: Fosamprenavir is a prodrug of amprenavir and is susceptible to amprenavir-associated drug in Coadministration of carbamazepine and fosamprenavir may result in reduced amprenavir serum concentratio LEXIVA(R) oral solution, oral tablets, 2009).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution when prescribing carbamazepine to patients who take fosamprenavir. of carbamazepine and fosamprenavir may cause reduced amprenavir plasma concentrations (Prod Info LEX solution, oral tablets, 2009).
7) Probable Mechanism: induction of CYP3A4-mediated amprenavir metabolism

3.5.1.BP Fosaprepitant

1) Interaction Effect: decreased plasma concentrations and efficacy of aprepitant
2) Summary: Fosaprepitant is a prodrug of aprepitant, which is a CYP3A4 substrate. Coadministration of wit inducer, such as carbamazepine, should be approached with caution as this may lead to decreased aprepita concentrations and efficacy (Prod Info EMEND(R) IV injection, 2008).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Use caution if carbamazepine and fosaprepitant are coadministered as this may lea aprepitant levels and decreased efficacy (Prod Info EMEND(R) IV injection, 2008).
7) Probable Mechanism: induction of CYP3A4-mediated aprepitant metabolism

3.5.1.BQ Fosphenytoin

1) Interaction Effect: decreased/increased phenytoin concentrations, decreased carbamazepine concentratio
2) Summary: Fosphenytoin is a prodrug of phenytoin and the same interactions that occur with phenytoin are occur with fosphenytoin (Prod Info Cerebyx(R), 1999). Concurrent use of phenytoin and carbamazepine may carbamazepine levels (Zielinski & Haidukewych, 1987b; Randall & Tett, 1993a). The addition of carbamazepi therapy may decrease (Hansen et al, 1971d) or increase (Browne et al, 1988a) phenytoin levels.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Serum levels of both phenytoin and carbamazepine should be measured after initia discontinuation of either agent, with appropriate dosage adjustment made accordingly. Serum levels should a following dosage adjustments and periodically thereafter.
7) Probable Mechanism: altered metabolism
8) Literature Reports

a) Twenty-four epileptic patients who were stabilized on phenytoin (PHT) and had carbamazepine (CBZ drug regimen were studied (Zielinski et al, 1985). The mean phenytoin level increased from 13.89 +/- 4.6 (35.9% increase). The effect of carbamazepine on phenytoin in an individual is unpredictable; 12 of the s change in phenytoin levels while the other 12 patients showed an average increase of 81.3% in phenyto Five of the patients with increased levels had symptoms of acute phenytoin toxicity.

b) Concomitant administration of carbamazepine and phenytoin has been reported to result in a dual int simultaneous effects of inhibition of phenytoin metabolism by carbamazepine and induction of carbamaz by phenytoin. The result is potential phenytoin intoxication and significant reductions of carbamazepine p concentrations to subtherapeutic levels. These dual effects appear to be especially significant when phe levels approach a change from linear to saturation kinetics. It is suggested that the interaction may be av minimized by adjusting phenytoin plasma levels to approximately 13 mcg/mL prior to the addition of carb regimen or increasing carbamazepine doses (Zielinski & Haidukewych, 1987).
c) Factors influencing simultaneous plasma concentrations of carbamazepine and its epoxide metabolite (McKauge et al, 1981) and it was found that plasma carbamazepine concentrations were significantly lov taking carbamazepine and phenytoin than those taking carbamazepine alone. In contrast to another stuc epoxide levels were unaltered (Pynnonen et al, 1980). Other researchers studied carbamazepine plasma four groups of epileptic patients on a variety of anticonvulsants (Christiansen & Dam, 1973). Their results administration of phenytoin or phenobarbital to patients receiving carbamazepine results in a significant carbamazepine plasma concentration when compared to patients receiving carbamazepine alone. It sho however, that some subjects in the trial were treated with carbamazepine for only one week prior to the i phenytoin. Carbamazepine has been shown to induce its own metabolism for up to 30 days after the initi thus lowering carbamazepine plasma concentration (Pynnonen et al, 1980). This may account for some carbamazepine plasma concentration in subjects also receiving phenytoin.
d) A prospective controlled study of the effects of reduction and discontinuation of phenytoin and carbar levels of concomitant antiepileptic drugs was conducted (Duncan et al, 1991). Phenytoin discontinuation 48% increase in total carbamazepine concentration and a 30% increase in free carbamazepine concentr change in carbamazepine epoxide concentrations. The authors suggest that phenytoin is a strong induce enzymes metabolizing carbamazepine to carbamazepine epoxide, but has less of an effect on the epoxi enzyme. This results in elevations in carbamazepine-epoxide/carbamazepine ratios in patients on conco Conversely, when carbamazepine was discontinued, phenytoin concentrations decreased by a mean of change in free fraction. The authors propose that this may result from inhibition of phenytoin metabolism carbamazepine. There appeared to be no impact on protein binding of either drug. Similar results were r researchers in 49 patients on concomitant phenytoin and carbamazepine therapy (Ramsay et al, 1990a)
e) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially i teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large related to the levels of the reactive epoxide metabolites (Buehler et al, 1990f; Van Dyke et al, 1991f; Finr The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hyc valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987f; Ramsay et al, 1990f; Spina et al, 1996e combinations increase the risk of major birth defects 3- to 4-fold over monotherapy and about 10-fold ove rates.

3.5.1.BR Ginkgo

1) Interaction Effect: decreased anticonvulsant effectiveness
2) Summary: In a case report, 2 patients with epilepsy previously well controlled by valproate sodium develo of seizures after ingesting ginkgo extract. Seizure control was regained after ginkgo was withdrawn (Granger developed seizures after exposure to 4'-O-methylpyridoxine arising from ingestion of ginkgo seeds (Yagi et a compound 4'-O-methylpyridoxine, a neurotoxin, is found in ginkgo seeds (used as food in Japan) as well as i ginkgo component from which commercially available extracts are derived (Arenz et al, 1996a). The majority products should not contain sufficient amounts of 4'-O-methylpyridoxine to cause seizures. However, ginkgo commonly assayed to assure that 4'-O-methylpyridixone is not contained in the commercial product. Of conc instances where, depending on the harvest season and the potential introduction of contamination, 4'-O-meth be present in sufficient amounts to be problematic in vulnerable populations (eg, infants or those with known
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Avoid concomitant use of ginkgo and anticonvulsants in patients with epilepsy. If se the first time or recur in patients previously controlled by anticonvulsant medication, inquire about the use of g extract. If possible, an assay should be conducted on the specific product to ascertain if 4'-O-methylpyridoxin
7) Probable Mechanism: neurotoxin 4'-O-methylpyridoxine (found in leaves and seeds of ginkgo biloba) may
8) Literature Reports

a) The serum of a 21-month-old patient with gin-nan food poisoning was assayed for 4'-O-methylpyridox serum concentration was 0.9 micrograms/milliliter (mcg/mL) at 8.5 hours after ingesting ginkgo seeds, de mcg/mL at 15.5 hours. The authors concluded that the 4'-O-methylpyridoxine content was responsible fo convulsions and loss of consciousness observed. They further observed that infants are particularly vuln 1993).

b) Four to six milligrams of the neurotoxin 4'-O-methylpyridoxine have been isolated from 2 kilograms of leaves which is the source of commercially-available products. Highest amounts were found in seeds (85 (mcg)/seed) and leaves (5 mcg/leaf) derived from the tree at the end of July and beginning of August. Th seed can contain 105.15 mcg/gram dry weight, but this is reduced to 0.75-1.32 mcg/gram dry weight wh unprocessed seed coats contain from 5.44-7.15 mcg/gram dry weight. The neurotoxin in ginkgo leaf was medications and it was even detectable in homeopathic preparations. Specifically, 8.13 mcg/mL of 4'-O-r was found in Tebonin Forte(R), 9.77 mcg/mL in Rokan(R), 3.80 mcg/mL in Kaveri Forte(R), and 7.18 mc

(R). Based on recommended daily intake, this translates into a maximum daily intake of 4'-O-methylpyrid
mcg, 58.62 mcg, 11.40 mcg, and 43.08 mcg for Tebonin Forte(R), Rokan(R), Kaveri Forte(R), and Gingi
respectively. Among the homeopathic products, Ginkgo biloba Urtinktur Hanosan(R) and Ginkgo biloba
contained 0.301 mcg/mL and 0.589 mcg/mL of 4'-O-methylpyridoxine, respectively. However, the author
amount contained in medicinal extracts of ginkgo leaves may be too low to be of clinical significance. Co
the variance in 4'-O-methylpyridoxine content depending on the season during which the ginkgo was har
al, 1996).

c) Seizures recurred in 2 patients, both with epilepsy that was well controlled prior to ingesting ginkgo bi
patients (an 84-year-old woman and a 78-year-old man) had been free of seizures for at least 18 months
therapy with Gb 120 milligrams daily to treat cognitive decline. Both patients developed seizures within 2
beginning Gb therapy, and both remained seizure-free (without changing anticonvulsant therapy) after di
(Granger, 2001).

3.5.1.BS Haloperidol

1) Interaction Effect: decreased haloperidol effectiveness

2) Summary: In a case report, the addition of carbamazepine to patients stabilized with haloperidol resulted i
of haloperidol levels by 60%. Two other case reports and a clinical study supported this finding, while a third
(Kahn et al, 1990a; Arana et al, 1986a; Fast et al, 1986; Klein et al, 1984; Hesslinger et al, 1999a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for the therapeutic efficacy of haloperidol following the addition of carbama
haloperidol dosage may be required in some clinical situations.

7) Probable Mechanism: increased cytochrome P450 2D6 and 3A4-mediated haloperidol metabolism

8) Literature Reports

a) Serum haloperidol levels of 14 schizophrenic patients dropped an average of 50% when carbamazep
their therapy. Haloperidol doses ranged from 2 mg to 20 mg daily and the carbamazepine dose was adju
of 8 to 12 mcg/mL. The drop in haloperidol levels resulted in the worsening of one patient's condition. Tw
significant symptom reduction while on carbamazepine, despite the decrease in the haloperidol levels. T
may have been due to direct effects of the carbamazepine, or as a secondary effect due to the lowering
levels. The authors recommend monitoring serum medication levels when administering haloperidol in c
carbamazepine (Kahn et al, 1990).

b) Serum haloperidol levels of seven patients treated for psychosis fell when carbamazepine was addec
Haloperidol doses ranged from 10 mg to 40 mg daily and carbamazepine doses ranged from 400 mg to
After carbamazepine was added, haloperidol levels decreased by 19% to 100%. The two patients whose
undetectable levels had a marked worsening of symptoms. Careful monitoring should take place if carba
to haloperidol therapy (Arana et al, 1986).

c) Concomitant administration of haloperidol and carbamazepine as reported to result in neurotoxicity (c
speech, concentration difficulties) in a 37-year-old woman with cerebral palsy and dipolar disorder (Brayl
1987). Withdrawal of carbamazepine resulted in subsidence of symptoms on this second occasion. It is s
interaction occurred at the level of the CNS, as opposed to toxic effects of either drug alone, as carbama
levels were subtherapeutic during the toxic episodes and due to the fact that carbamazepine is reported
haloperidol metabolism. In addition, the patient received higher doses of carbamazepine following withdr
without the occurrence of toxic effects. Cerebral palsy may have been a predisposing factor to the intera

d) Twenty-seven schizophrenic patients enrolled in a study to determine the effects of carbamazepine a
the plasma levels of haloperidol and the psychopathologic outcome. Following a four-day washout perioc
assigned to receive treatment for four weeks with haloperidol monotherapy, haloperidol with carbamazep
with valproic acid. Doses of haloperidol remained stable throughout the study, and the doses of carbama
valproic acid were titrated to a plasma level of 6 to 12 mg/L and 50 to 100 mg/L, respectively. When adm
carbamazepine, haloperidol plasma levels decreased by 45% (from 7.6 ng/mL to 4.6 ng/mL) over the 28
Decreases in the rating scores on the Positive subscale of the Positive and Negative Syndrome Scale (p
significant during the carbamazepine phase of the study, indicating that the coadministration of carbama
haloperidol may worsen the clinical outcome compared to haloperidol monotherapy (Hesslinger et al, 19

3.5.1.BT Hydrochlorothiazide

1) Interaction Effect: hyponatremia

2) Summary: Concomitant administration of carbamazepine and diuretics (hydrochlorothiazide or furosemide
reported to result in symptomatic hyponatremia in epileptic patients (Yassa et al, 1987). It is felt that a synerg
diuretics and carbamazepine is responsible for occurrence of the hyponatremia, and that epileptic patients m
to developing this complication than are patients with affective disorders, due to the higher doses of carbama
in epilepsy.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor electrolytes during concurrent therapy. Consider discontinuing the diuretic
alternative anticonvulsant if appropriate.

7) Probable Mechanism: additive hyponatremic effects

3.5.1.BU Hydrocortisone

1) Interaction Effect: decreased hydrocortisone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, al, 1982). Although not specifically reported for hydrocortisone, a similar interaction could be expected.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of the corticosteroid. An increase in the steroid dosage after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased hydrocortisone metabolism

3.5.1.BV Imatinib

1) Interaction Effect: decreased plasma levels of imatinib
2) Summary: Concurrent administration of imatinib and carbamazepine may result in a significant decrease i imatinib due to induction of CYP3A4-mediated imatinib metabolism. Caution is advised when these two agen coadministered. Alternatives to carbamazepine, with less enzyme induction potential, should be considered. ' used concurrently with carbamazepine, consider an increase in imatinib dose by at least 50% to maintain the and monitor clinical response closely (Prod Info GLEEVEC(R) oral tablets, 2005).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Coadministration of imatinib and carbamazepine, a CYP3A4 inducer, may result in reduction in exposure to imatinib. Caution is advised when these two agents are coadministered. Consider us carbamazepine with less enzyme induction potential. However, if imatinib is used concurrently with carbamaz increase in imatinib dose by at least 50% to maintain therapeutic efficacy and monitor clinical response close
7) Probable Mechanism: induction of cytochrome P450 3A4-mediated metabolism of imatinib by carbamaze

3.5.1.BW Imipramine

1) Interaction Effect: decreased imipramine effectiveness
2) Summary: In a retrospective study of 36 children suffering from hyperactivity secondary to attention deficit antidepressant levels (imipramine and its metabolite desipramine) were decreased by 50% in children receivi compared to levels obtained with imipramine alone (Brown et al, 1990h).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for clinical efficacy of the imipramine therapy and for any signs of toxicity of Serum levels of both agents should be considered when either agent is added or discontinued, with appropria adjustments made accordingly.
7) Probable Mechanism: increased imipramine metabolism
8) Literature Reports
a) In a retrospective study, of 36 children with attention deficit hyperactivity disorder, the average plasm imipramine was significantly lower in patients treated with carbamazepine concurrently. The average dos was 1.3 mg/kg in patients receiving imipramine alone, compared to an imipramine dose of 1.8 mg/kg in p both imipramine and carbamazepine. The plasma level of imipramine, desipramine, and total tricyclic ant plasma levels were significantly lower in patients treated with carbamazepine concurrently. The dose of i need to be increased if carbamazepine is added to therapy and the dose of imipramine may need to be carbamazepine is stopped (Brown et al, 1990g).
b) Combination therapy with carbamazepine decreases steady-state total serum concentrations of imipr concentrations of desipramine. Thirteen patients were treated with imipramine 2 mg/kg/day for 3 weeks, carbamazepine 400 mg/day was added. The ratios of total concentrations of imipramine to desipramine and two weeks after carbamazepine intake (0.7 +/- 0.41 versus 0.63 +/- 0.36; p greater than 0.05). Free imipramine and desipramine were elevated after the addition of carbamazepine. Despite lowever imiprar desipramine total concentrations, the combination treatment with carbamazepine in depressed patients i tolerated. Dosage increase of imipramine does not appear to be necessary in the depressed patients inc (Szymura-Oleksiak et al, 2001).

3.5.1.BX Indinavir

1) Interaction Effect: decreased indinavir plasma concentrations and an increased risk of antiretroviral therap
2) Summary: Inducers of cytochrome P450 3A4 enzymes, including carbamazepine, may decrease the plasi of indinavir during concurrent therapy. Decreased plasma concentrations of indinavir may cause antiretrovira Caution should be observed when these two drugs are given together. If alternative therapy is not possible, c adjustments, therapeutic drug monitoring, and close clinical observation should be utilized to reduce adverse consequences (Prod Info Crixivan(R), 2004; Hugen et al, 2000a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Concurrent treatment with indinavir and carbamazepine should be undertaken caut patient for an adequate response to indinavir therapy. Alternatives to carbamazepine therapy should be cons

7) Probable Mechanism: induction of cytochrome P450 3A4-mediated indinavir metabolism
8) Literature Reports
a) A 48-year-old HIV-positive male was started on triple therapy consisting of indinavir 800 mg every eig lamivudine 150 mg twice daily, and zidovudine 200 mg three times daily with a resulting undetectable HI later. Because of the development of postherpetic neuralgia, carbamazepine 200 mg daily was initiated a approximately 10 weeks. His indinavir concentrations drawn during carbamazepine therapy were 25% ar population values, whereas before carbamazepine was started, they were slightly below the lower limit o population curve. Two weeks following the discontinuation of carbamazepine, the HIV-RNA was detectal to lamivudine therapy was observed in a blood sample. A further increase in HIV-RNA prompted his anti to be switched to nevirapine, didanosine, and zidovudine. Carbamazepine is an inducer of the cytochrom enzyme system, while indinavir is a substrate of this pathway. Decreased indinavir concentrations cause between indinavir and carbamazepine is the most likely explanation for the increased HIV-RNA and the c lamivudine resistance in this patient (Hugen et al, 2000).

3.5.1.BY Influenza Virus Vaccine

1) Interaction Effect: increased carbamazepine serum concentrations
2) Summary: Influenza vaccine has been reported to cause a decrease in the elimination and an increase in carbamazepine, resulting in an increase in the carbamazepine plasma concentration (Jann & Fidone, 1986a; 1990). It has been proposed that the immune response after influenza vaccination may cause a depression o P450 isoenzymes responsible for oxidation of carbamazepine (Robertson, 2002a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: The majority of patients might experience only a transient and slight increase in car levels. No routine monitoring appears necessary.
7) Probable Mechanism: decreased cytochrome P450-mediated metabolism of carbamazepine
8) Literature Reports
a) In a study conducted on mentally retarded residents who were receiving single-drug anticonvulsant th vaccine resulted in increased levels of phenytoin, phenobarbital, and carbamazepine. Prior to vaccinatio carbamazepine concentration was 6.17 mcg/mL. Serum carbamazepine concentrations were measured to vaccination (day 0), and on days 7, 14, and 28. On day 7, the mean carbamazepine concentration hac 6.89 mcg/mL. By day 14 and 28, concentrations had increased and decreased to 9.04 mcg/mL and 8.65 respectively. Similar increases in plasma concentrations were observed in patients receiving phenobarbi The proposed mechanism for the increased carbamazepine concentration is that influenza vaccine decre of hepatic enzymes which are responsible for carbamazepine metabolism (Jann & Fidone, 1986).
b) Influenza vaccination may significantly increase carbamazepine blood levels. A report describes a ca carbamazepine toxicity that developed 13 days after administration of the influenza vaccine. A female 14 old complained of ataxia and increased lethargy. Her drug regimen included carbamazepine for partial c and gabapentin. Thirteen days prior to her complaints the patient received the inactivated influenza vacc manufactured by Aventis Pasteur, Inc (Swiftwater, PA). Thirteen days later the child complained of naus subsequently vomited. She was dizzy, had slurred speech, became lethargic and poorly responsive. In th department her CBZ level was 27.5 mcg/mL and a urine drug screen was positive for TCAs and cocaine intubated, received IV fluids and activated charcoal. Four days after admission her CBZ level was 9.1 mc recovered and remains seizure free on her former dose of CBZ (400 mg am and 600 mg pm) and gabap TID). The author concludes that the patients immune response after influenza vaccination caused a depr isoenzymes responsible for oxidation of CBZ. This resulted in a rise in CBZ levels and observed CBZ tox instances of CBZ toxicity may be secondary to inhibition of hepatic clearance by interferon production (R

3.5.1.BZ Iproniazid

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures
2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(Info Tegretol(R), 1998b; Thweatt, 1986b). However, there is preliminary evidence that the combination of car an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995e; Barker & Eccleston controlled studies are needed.
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of if the clinical situation permits, before carbamazepine therapy is initiated.
7) Probable Mechanism: unknown
8) Literature Reports
a) A double-blind study was conducted in ten inpatients with depression that had proven refractory to mu therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc

carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and discharged (Ketter et al, 1995d).

b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984d).

c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru presented (Joffe et al, 1985b). Conversely, five patients on tranylcypromine were reported to need a mea carbamazepine 1040 mg to achieve a carbamazepine blood level of 8.0-11.1 mcg/mL. Four other patient phenelzine only required a mean daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9 et al, 1992b).

3.5.1.CA Irinotecan

1) Interaction Effect: substantially decreased exposure to irinotecan and its active metabolite SN-38 and may irinotecan efficacy

2) Summary: Concomitant use of carbamazepine and irinotecan has resulted in a substantially decreased ex irinotecan and its active metabolite SN-38 in both adult and pediatric patients. This decreased exposure is du carbamazepine induction of CYP3A4-mediated metabolism of irinotecan and may decrease the efficacy of iri An alternative non-enzyme inducing anticonvulsant should be considered. Substitution should be implemente weeks prior to initiation of irinotecan therapy (Prod Info Camptosar(R) Injection, 2004).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Consider a non-enzyme inducing anticonvulsant alternative for those patients requi therapy. Begin substitution at least 2 weeks prior to initiation of irinotecan therapy. The appropriate starting d for patients on CYP3A4 inducing anticonvulsants has not yet been established.

7) Probable Mechanism: induction of CYP3A4-mediated irinotecan metabolism

3.5.1.CB Isocarboxazid

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures

2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Info Marplan(R), 1998). Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure ac Parnate(R), 1995h; Prod Info Tegretol(R), 1998i; Thweatt, 1986i). However, there is preliminary evidence tha of carbamazepine and an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 19 Eccleston, 1984s). Further controlled studies are needed.

3) Severity: contraindicated

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of if the clinical situation permits, before carbamazepine therapy is initiated.

7) Probable Mechanism: unknown

8) Literature Reports

a) A double-blind study was conducted in ten inpatients with depression who had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and discharged (Ketter et al, 1995r).

b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984r).

c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru case (Joffe et al, 1985i). Conversely, five patients on tranylcypromine needed a mean daily dose of carb mg to achieve a carbamazepine blood level of 8.0-11.1 mcg/mL (Barklage et al, 1992i). Four other patier phenelzine only required a mean daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9

3.5.1.CC Isoniazid

1) Interaction Effect: elevated carbamazepine levels and toxicity (ataxia, nystagmus, diplopia, headache, vor seizures, coma)

2) Summary: Concomitant carbamazepine and isoniazid therapy has been reported to produce increases in serum concentrations and toxicity at isoniazid doses of 200 mg daily or more (Block, 1982a; Wright et al, 198 changes were noted in 10 of 13 epileptics following the addition of isoniazid 200 mg daily to their maintenanc therapy (Valsalan & Cooper, 1982). Carbamazepine may increase isoniazid liver toxicity (Wright et al, 1982a)

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: Watch for signs of carbamazepine toxicity such as nausea, vomiting, drowsiness ar consider monitoring serum carbamazepine levels following the addition of isoniazid; lower carbamazepine do required. Conversely, if isoniazid is discontinued or the dosage reduced, carbamazepine levels should be mo dose adjusted accordingly. Usual anticonvulsant levels are 6-12 mg/L.

7) Probable Mechanism: decreased carbamazepine metabolism

8) Literature Reports

a) Five days after concurrent use of carbamazepine with isoniazid 300 mg daily, a patient presented wit headache, vomiting, drowsiness, and confusion. Carbamazepine serum levels had increased from 5 mcg mcg/mL. The patient was also receiving phenytoin, with levels increasing from 13 to 18 mcg/mL; this was in the therapeutic range and not related to an interaction with carbamazepine. Upon withdrawal of the iso carbamazepine level decreased to 6 mcg/mL within seven days, and the phenytoin level remained at 18 patient's symptoms disappeared at day 2. However, it is difficult to rule out the effects of phenytoin as a p toxicity, since some patients may present with toxic symptoms at these serum concentrations (Block, 198

b) Administration of isoniazid to a patient receiving chronic carbamazepine therapy resulted in significar carbamazepine clearance as well as delayed isoniazid-induced hepatotoxicity. This was presumably rela carbamazepine's microsomal enzyme metabolism by isoniazid and increased metabolism of isoniazid to metabolite (acetylhydrazine) by carbamazepine (Wright et al, 1982).

c) One study reported a case of carbamazepine toxicity following the addition of antituberculosis medica anticonvulsant medication. Carbamazepine levels had previously been 8.5 to 9.5 mcg/mL without eviden Isoniazid 300 mg daily was well tolerated for three days prior to the introduction of rifampin 600 mg daily. of initiation of rifampin, the patient developed nausea, ataxia, confusion and drowsiness. The carbamaze noted to be 16.9 mcg/mL. The authors suggest that rifampin may have augmented the enzyme inhibiting isoniazid, resulting in carbamazepine toxicity (Fleenor et al, 1991).

3.5.1.CD Itraconazole

1) Interaction Effect: loss of itraconazole efficacy

2) Summary: Concomitant administration of itraconazole and carbamazepine has resulted in subtherapeutic concentrations and therapeutic failure (Hay et al, 1988; Tucker et al, 1992a). Itraconazole is a known inhibito P450 3A4 enzyme system, which is the major isoform responsible for the metabolism of carbamazepine. Bas metabolic pathways, it seems possible that itraconazole could inhibit the metabolism of carbamazepine, resu plasma concentrations of carbamazepine (Prod Info Sporonox(R), 2002; Prod Info Tegretol(R), 1997). Howev not been reported to date.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Monitor antifungal therapy for clinical efficacy; larger itraconazole doses may be rec situations.

7) Probable Mechanism: induction by carbamazepine of cytochrome P450 3A4-mediated itraconazole metab

8) Literature Reports

a) Interactions between azole antifungals and rifampin, phenytoin, and carbamazepine have been descr 1992). Twelve patients receiving a combination of these agents for systemic mycoses experienced drug resulted in substantial decreases in the azole serum concentrations. All four of the patients who received concurrent phenytoin or carbamazepine failed to respond to the antifungal therapy or suffered a relapse These four patients had undetectable or substantially lower serum concentrations of the azole compared measured during therapy with the azole alone.

3.5.1.CE Ixabepilone

1) Interaction Effect: decreased ixabepilone plasma concentrations

2) Summary: Ixabepilone is a CYP3A4 substrate. Coadministration of a strong CYP3A4 inducer, such as car ixabepilone may result in decreased ixabepilone plasma concentrations leading to subtherapeutic ixabepilone using alternative therapeutic agents with low enzyme induction potential for coadministration with ixabepilone IXEMPRA(TM) IV injection, 2007).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Concomitant administration of carbamazepine, a strong CYP3A4 inducer, and ixabe substrate, may result in decreased ixabepilone plasma concentrations and consequently, subtherapeutic leve

alternative therapeutic agents with low enzyme induction potential for coadministration with ixabepilone (Proc (TM) IV injection, 2007).
7) Probable Mechanism: induction of CYP3A4-mediated ixabepilone metabolism

3.5.1.CF Ketoconazole
1) Interaction Effect: increased carbamazepine serum levels
2) Summary: Ketoconazole, a CYP 3A4 enzyme system inhibitor, can inhibit the metabolism of carbamazepi plasma carbamazepine levels would be expected (Prod Info Tegretol(R), 2002).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: If carbamazepine and ketoconazole are administered together, carefully monitor se carbamazepine levels and monitor the patient for signs and symptoms of toxicity.
7) Probable Mechanism: inhibition of CYP 3A4 mediated metabolism of carbamazepine

3.5.1.CG Lamotrigine
1) Interaction Effect: reduced lamotrigine efficacy, loss of seizure control, and a potential risk of neurotoxicity nystagmus, ataxia)
2) Summary: The clearance of lamotrigine may double during concomitant therapy with carbamazepine (Goa Rambeck & Wolf, 1993; Ramsay et al, 1991a; Mikati et al, 1989a; Jawad et al, 1987a). In addition, increased concentrations of carbamazepine-10,11-epoxide (an active metabolite of carbamazepine) and neurotoxicity h during concomitant administration of carbamazepine and lamotrigine (Wolf, 1992; Warner et al, 1992). Other found that lamotrigine had no effect on either carbamazepine or its metabolite (Schapel et al, 1991; Pisani et & Boreus, 1997a). While lamotrigine has no appreciable effect on the steady-state carbamazepine concentra carbamazepine decreases the lamotrigine steady-state level by 40% (Prod Info Lamictal(R), 2003).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor seizure control and follow patients for signs of neurotoxicity (nausea, vertig ataxia). Anticipate a possible need to increase lamotrigine doses and/or reduce carbamazepine doses. It may to monitor the serum concentration of both carbamazepine and its metabolite, carbamazepine-10,11-epoxide effects have been associated with carbamazepine-10,11- epoxide serum levels above 9 micromoles/liter. Wh combination with an enzyme-inducing antiepileptic agent, the manufacturer recommends an initial lamotrigine once daily for the first two weeks for adult patients, followed by 50 mg twice daily for the third and fourth weel 100 mg daily every two weeks to a total daily dose of 300 mg to 500 mg administered in two divided doses.
7) Probable Mechanism: hepatic induction by carbamazepine of lamotrigine metabolism; possible alteration elimination by lamotrigine
8) Literature Reports
a) While lamotrigine alone has a steady-state elimination half-life of between 25 to 37 hours, coadminist carbamazepine reduces the half-life to approximately 14 or 15 hours (Binnie et al, 1986; Jawad et al, 198 Lamotrigine clearance ranged from 0.021 to 0.035 L/h/kg (0.35 to 0.59 mL/min/kg) in healthy volunteers alone (Cohen et al, 1987; Posner et al, 1989; Posner et al, 1991). Comparable values during combinatio from 0.044 to 0.084 L/h/kg (0.73 to 1.4 mL/min/kg) (Jawad et al, 1987; Mikati et al, 1989; Ramsay et al, Carbamazepine was found to decrease incrementally the half-life of lamotrigine by 1.7 hours for every 1 carbamazepine within the dosing range of 800 to 1600 mg daily (Jawad et al, 1987).
b) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially i teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large related to the levels of the reactive epoxide metabolites (Buehler et al, 1990g; Van Dyke et al, 1991g; Fir The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hyc valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987g; Ramsay et al, 1990g; Spina et al, 1996 combinations increase the risk of major birth defects 3- to 4-fold over monotherapy and about 10-fold ov rates.
c) No pharmacokinetic interaction between carbamazepine and lamotrigine was found in children. Three eleven children with intractable generalized epilepsy who had been treated with carbamazepine for longe started lamotrigine 1 mg/kg/day divided into two daily dosages. The lamotrigine dose was increased by 1 other week until clinical response or side effects occurred. The mean carbamazepine levels did not chan from baseline when lamotrigine was coadministered (29.9 mmol/L vs. 28.8 mmol/L). In addition, the plas of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide, significantly decreased from 6 mmol/L with lamotrigine therapy (Eriksson & Boreus, 1997).
d) Carbamazepine reduces the plasma levels of lamotrigine. A 65-year-old male suffering from complex for 40 years was receiving carbamazepine (400 mg three times daily) and lamotrigine (200 mg three time occurred at least twice a week. Steroids, ipratropium bromide and a beta-agonist were used for an obstru disease. A current pneumonia was being treated with an oral amoxicillin preparation. A trough lamotrigin mcmol/mL and a trough carbamazepine was 11 mcmol/mL. The patient continued to suffer from seizures was gradually replaced by levitiracetam (1500 mg twice daily) within 4 weeks. After 4 weeks of levitiracet patient's carbamazepine plasma levels were 1.3 mcmol/mL and lamotrigine plasma levels were 12.1 mc Lamotrigine levels increased rapidly after reductions in the carbamazepine dose. Levetiracetam and lam

combination was well tolerated and seizures stopped completely after 4 weeks. A drug interaction should when carbamazepine and lamotrigine result in ineffective antiepileptic therapy (Koch et al, 2003).

3.5.1.CH Lapatinib

1) Interaction Effect: decreased lapatinib exposure or plasma concentrations

2) Summary: In healthy participants, concurrent administration of lapatinib with carbamazepine, a CYP3A4-in 100 mg twice daily for 3 days and 200 mg twice daily for 17 days led to a 72% decrease in lapatinib AUC. Th recommended that concurrent use of carbamazepine with lapatinib be avoided. However, if these agents mus concurrently, then depending on tolerability, a gradual titration of lapatinib dose from 1250 mg/day up to 4500 considered. This adjustment is recommended based on pharmacokinetic data and would be expected to adju the therapeutic ranges achieved without CYP3A4 inducers. However, no clinical data is currently available wi adjustments. If carbamazepine is discontinued, the increased lapatinib dose should be reduced to the indicat TYKERB(R) oral tablets, 2007).

3) Severity: major

4) Onset: unspecified

5) Substantiation: probable

6) Clinical Management: Coadministration of lapatinib with carbamazepine, a CYP3A4-inducer, resulted in si decreased lapatinib AUC and should be avoided. However, if concurrent use is warranted, then consider titra lapatinib gradually from 1250 mg/day up to 4500 mg/day, depending on tolerability. Once carbamazepine is d reduce the increased lapatinib dose to the indicated dose (Prod Info TYKERB(R) oral tablets, 2007).

7) Probable Mechanism: induction of CYP3A4-mediated lapatinib metabolism

3.5.1.CI Levetiracetam

1) Interaction Effect: symptoms of carbamazepine toxicity (nystagmus, ataxia, dizziness, double vision)

2) Summary: In pharmacokinetic and clinical studies, concurrent administration of carbamazepine and levetir affect serum levels of either drug (Prod Info KEPPRA(R) oral solution, tablets, 2006). However, in post-marke coadministration of these agents resulted in symptoms consistent with carbamazepine toxicity in 4 individuals refractory epilepsy. While the exact mechanism for this interaction is unknown, it is postulated to be pharmac pharmacokinetic, in origin. Caution is advised when these agents are prescribed together. Patients may neec closely for symptoms of carbamazepine toxicity (nystagmus, ataxia, dizziness, double vision). Reduction of c dosage may be necessary to resolve the symptoms (Sisodiya et al, 2002).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Although in pharmacokinetic and clinical studies, coadministration of carbamazepin levetiracetam did not significantly affect serum levels of either drug (Prod Info KEPPRA(R) oral solution, table marketing experience, coadministration of these agents resulted in symptoms consistent with carbamazepine individuals with severe refractory epilepsy. Therefore, use caution when these agents are prescribed togethe need to be monitored closely for symptoms of carbamazepine toxicity (nystagmus, ataxia, dizziness, double v of carbamazepine dosage may be necessary to resolve the symptoms (Sisodiya et al, 2002).

7) Probable Mechanism: unknown

8) Literature Reports

a) Symptoms of carbamazepine toxicity occurred with coadministration of carbamazepine and levetiracet severe refractory epilepsy. The patients, aged 31 to 57 years old, received levetiracetam as add-on thera anti-epileptic drug (AED) therapy, which included monotherapy with carbamazepine 600 mg twice daily i polytherapy in the other 3 cases, with medications including carbamazepine 600 to 1600 mg/day (regula release), sodium valproate, lamotrigine, primidone, or phenobarbital. Levetiracetam was initiated at 500 daily and slowly titrated up to either 500 mg twice daily (in 2 cases), 1000 mg twice daily (in 1 case), or 1 case). Following introduction of levetiracetam, serum blood levels in 3 of the cases were within the norm ranges for all the AEDs. However, in all 4 cases, upward titration of levetiracetam led to symptoms consi carbamazepine toxicity, which included unsteadiness of gait, nystagmus, double vision, dizziness, nause 1 patient, symptoms worsened upon further increase in levetiracetam dose from 500 mg twice daily to 25 Symptoms resolved with a reduction in carbamazepine dosage from 600 mg once daily or twice daily to twice daily, respectively (in 2 cases), and from 800 mg twice daily to 600 mg twice daily (in 1 case). One discontinued levetiracetam on her own accord following symptom onset and data are not available with r symptom resolution. While the exact mechanism for this interaction is unknown, based on serum levels, interactions or altered compliance were ruled out. It was postulated that this interaction may be pharmac (Sisodiya et al, 2002).

3.5.1.CJ Levonorgestrel

1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness

2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 198

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf use of alternate methods of birth control may be necessary.

7) Probable Mechanism: increased metabolism of contraceptive steroids
8) Literature Reports
a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate receiving oral contraceptives. Increasing the dose of ethinyl estradiol or mestranol in oral contraceptives breakthrough bleeding and decrease the risk of conception. However, higher doses of estrogens may als of vascular side effects, primarily in patients where enzyme induction does not occur. It is recommended estrogen and progestin be given initially in patients receiving an enzyme inducing anticonvulsant; howev pregnancy is a special concern, a moderate dose formulation (50 mcg ethinyl estradiol) should be consic breakthrough bleeding occurs with low-dose contraception, progressive increases in the dose of mestrar (up to 80 mcg) should be considered. If spotting occurs, it is suggested that the contraceptive not be disc rather that a traditional method of barrier contraception be initiated during the remainder of that cycle. Sv dose oral contraceptive is recommended if enzyme inducing anticonvulsants are discontinued in women moderate or high-dose contraceptives.
b) Carbamazepine reduced the area under the plasma concentration time curve (AUC) of ethinyl estrad 4 women taking carbamazepine 300 to 600 mg daily within 8 to 12 weeks of initiation of therapy. Norges also significantly reduced to 29% to 57% of baseline. The authors suggest that breakthrough bleeding ca most women with use of oral contraceptives containing 80 to 100 mcg ethinyl estradiol (Crawford et al, 1
c) Accidental pregnancy occurred in a 20-year-old epileptic who was using phenytoin 400 mg daily plus 400 mg daily (Haukkamaa, 1986). The plasma concentration of levonorgestrel in this patient was very lo pg/mL) when compared to controls (325 +/- 135 pg/mL). Carbamazepine appears to decrease plasma le concentrations by enhancing the hepatic metabolism of the steroid via enzyme induction. Levonorgestrel relied upon as the sole means of contraception in patients on anticonvulsant therapy.

3.5.1.CK Levothyroxine

1) Interaction Effect: decreased levothyroxine effectiveness
2) Summary: Concomitant use of carbamazepine and levothyroxine may decrease levothyroxine efficacy by metabolism potentially resulting in hypothyroidism. Carbamazepine may also reduce serum protein binding o total- and free- T4 by 20% to 40%. If concurrent use of carbamazepine and levothyroxine is required, an incre levothyroxine dose may be necessary (Prod Info SYNTHROID(R) oral tablets, 2008; Prod Info LEVOTHYRO oral tablet, 2007).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Concomitant use of carbamazepine and levothyroxine may result in reduced levoth As a result, an increase in the levothyroxine dose may be required (Prod Info SYNTHROID(R) oral tablets, 2(LEVOTHYROXINE SODIUM(R) oral tablet, 2007). Consider monitoring TSH levels and/or other measures of when carbamazepine is initiated or discontinued during levothyroxine treatment.
7) Probable Mechanism: increased hepatic metabolism of levothyroxine

3.5.1.CL Lithium

1) Interaction Effect: additive neurotoxicity (weakness, tremor, nystagmus, asterixis)
2) Summary: Case reports have described the development of neurotoxicity during concurrent administratior carbamazepine despite normal therapeutic levels of either drug (Rittmannsberger, 1996a; Chaudhry & Water & Richens, 1980).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor for signs of neurotoxicity with concomitant therapy; serum levels have not b predicting this adverse effect. If neurotoxicity occurs, one or both of the agents may need to be discontinued.
7) Probable Mechanism: unknown
8) Literature Reports
a) A potential interaction between lithium and carbamazepine has been reported (Chaudhry & Waters, 1 a 22-year-old woman with bipolar affective disorder, developed neurotoxicity despite therapeutic plasma drugs. Previous reports of neurotoxicity due to either of these agents have occurred when recommendec were exceeded. Toxicity due to carbamazepine was not observed in this case when the plasma level wa (therapeutic: 8 to 12 mcg/mL). Similarly, no neurotoxicity occurred with plasma lithium levels of 0.9 mEq/ to 1.4 Eq/L). However, when the drugs were administered concurrently, neurotoxicity, characterized by u truncal tremors, ataxia, horizontal nystagmus, hyperflexia of all four limbs, and occasional muscle fascicu within three days. Plasma levels of lithium and carbamazepine were 0.9 mEq/L and 7.6 mcg/mL, respect discontinuation of carbamazepine, neurologic symptoms subsided within three days. Therapeutic plasma two drugs administered concomitantly may lead to acute neurotoxicity.
b) Neurotoxic syndromes developed in five manic patients treated with a combination of lithium and carb although all five had therapeutic plasma levels of both drugs (Shukla et al, 1984). The clinical picture of t consisted of symptoms of confusion, drowsiness, generalized weakness, lethargy, coarse tremor, hyperr cerebellar signs. Patients with previous lithium-induced neurotoxicity and those with underlying CNS dise disease appeared to be at greater risk for developing the neurotoxicity when the combination of the two

c) The laboratory effects of adding lithium to carbamazepine were examined in 23 patients with affective (Kramlinger & Post, 1990). The combination produced additive antithyroid effects, particularly on T4 and addition of lithium resulted in prompt reversal of carbamazepine-induced leukopenia.
d) An analysis of the data from other researchers (Chaudhry & Waters, 1983; Shukla et al, 1984) was p (McGinness et al, 1990). The analysis demonstrated no synergistic toxicity between the two drugs, but n hypothetical plot of blood levels of both drugs that lithium appears to contribute more significantly to the t The authors further concluded that usually used therapeutic ranges cannot be used in monitoring for toxi drugs are used together and a two-dimensional plot of serum levels may be of assistance in ascertaining serum levels with combinations of drugs.
e) Over a three-year period, some drug combinations were observed to cause a greater risk of asterixis in patients on a regimen of multiple psychopharmacologic agents (Rittmannsberger, 1996). With regard t clozapine, and lithium, the incidence of asterixis was greatest in those patients that were on at least two agents. Serum levels of all three drugs were within normal therapeutic ranges, suggesting an additive eff therapy rather than the effect of a single agent.
f) Lithium intoxication occurred in a patient following carbamazepine-induced renal failure. A 33-year-old with bipolar manic-depressive disorder was treated with lithium for the last 18 months. Carbamazepine 6 to his drug regimen. Serum lithium levels were 1.08 mEq/L and serum carbamazepine concentration was weeks later. Upon admission he was stuporous but arousable. His serum creatinine was 6.5 mg/dL, and carbamazepine concentration was 11mcg/mL and serum lithium concentration was 3.5 mEq/L. After 2 L was administered, this patient developed pulmonary edema. After one session of hemodialysis, serum lit concentrations decreased to 1.3 mEq/d, and serum creatinine decreased to 3.5 mg/dL. Three weeks late was 1.0 mg/dL and lithium concentrations were within the therapeutic range. Renal failure was most likel carbamazepine induced interstitial nephritis. Patients who are treated with lithium and carbamazepine sh carefully to prevent carbamazepine-induced interstitial nephritis. The presence of fever, eosinophiluria, u casts, and the patients improvement after withdrawal of carbamazepine support the diagnosis of interstit Patients who are treated with lithium and carbamazepine should be followed carefully to prevent carbam interstitial nephritis (Mayan et al, 2001).

3.5.1.CM L-Methylfolate

1) Interaction Effect: decreased carbamazepine serum levels
2) Summary: Concomitant administration of first-generation anticonvulsants, including carbamazepine, with l folate may lead to decreased serum levels of the anticonvulsant, thereby decreasing carbamazepine efficacy risk of seizures. Although there have been no such reports with the use of carbamazepine and l-methylfolate, if these agents are used concomitantly (Prod Info DEPLIN(R) oral tablets, 2006; Prod Info Zervalx(R) oral tab Monitor patients for loss of carbamazepine efficacy.
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if l-methylfolate is prescribed to patients receiving carbamazepir folate may theoretically result in decreased serum carbamazepine levels, thereby reducing carbamazepine e increasing the frequency of seizures (Prod Info DEPLIN(R) oral tablets, 2006; Prod Info Zervalx(R) oral tablet agents are used concomitantly, monitor patients for loss of carbamazepine efficacy.
7) Probable Mechanism: unknown

3.5.1.CN Lopinavir

1) Interaction Effect: decreased lopinavir exposure; increased serum carbamazepine levels and toxicity
2) Summary: Coadministration of carbamazepine and lopinavir/ritonavir may result in reduced lopinavir seru resulting from carbamazepine induction of CYP3A metabolism. The effectiveness of lopinavir/ritonavir is likely in patients receiving concurrent carbamazepine therapy due to reduced lopinavir bioavailability. The once dai for lopinavir/ritonavir should not be used when a patient is also taking carbamazepine (Prod Info KALETRA(F solution, 2005). Carbamazepine toxicity has been reported in an HIV-positive patient upon concomitant treatr lopinavir/ritonavir, as part of a highly active antiretroviral regimen. This may be a result of inhibition of CYP3A carbamazepine metabolism by the protease inhibitors. If used concurrently with lopinavir/ritonavir, consider re carbamazepine dose by 25 to 50%. Additionally, monitor patients for serum carbamazepine levels, 3 to 5 day lopinavir/ritonavir (Bates & Herman, 2006).
3) Severity: major
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Use caution with the coadministration of carbamazepine and lopinavir/ritonavir due lopinavir metabolism. Do not use a once daily dosing regimen of lopinavir/ritonavir concurrently with carbama Additionally, coadministration of carbamazepine with a lopinavir/ritonavir-containing highly active antiretrovira resulted in increased serum carbamazepine levels and toxicity. If used concurrently with lopinavir/ritonavir, co the carbamazepine dose by 25 to 50%. Additionally, monitor patients for serum carbamazepine levels, 3 to 5 initiating the protease inhibitor.
7) Probable Mechanism: carbamazepine induction of CYP3A-mediated lopinavir metabolism; inhibition of CY carbamazepine metabolism by lopinavir/ritonavir
8) Literature Reports
a) Symptoms of carbamazepine toxicity developed in a 50-year-old HIV-positive male upon addition of l

his highly active antiretroviral therapy (HAART). The patient had been stabilized on carbamazepine 400 for 7 months, with a serum concentration within reference range (10.3 mg/L) 1 week prior to starting the tenofovir 300 mg daily; lamivudine 150 mg twice daily; and lopinavir 133 mg/ritonavir 33 mg, 3 capsules 9 of the new HAART regimen, the patient experienced excessive drowsiness, and the carbamazepine se increased by 46% to 15 mg/L. Decreasing the carbamazepine dose to 400 mg twice daily improved drow repeat serum level on day 11 was 7.4 mg/L. On day 12, the patient developed fatigue, difficulty swallowi hemorrhagic lesions over the extremities. The HAART regimen was stopped and carbamazepine dose w 400 mg 3 times daily. The patient was hospitalized 10 days later for evaluation of the rash. Blood tests a marrow toxicity. Subsequently, a neurology consult resulted in tapering of carbamazepine (over 2 to 4 we topiramate 25 mg twice daily and titrating to a target dose of 200 mg twice daily. On day 17 of hospitaliza regimen was re-initiated, replacing lopinavir/ritonavir with nelfinavir 1250 mg twice daily. On day 20, the p feeling tired and unsteady on his feet and the carbamazepine serum level had increased to 15 mg/L. Dec carbamazepine dose as before prompted resolution of symptoms within 24 hours. This interaction betwe as probable by the Naranjo probability scale and inhibition of CYP3A4-mediated carbamazepine metabo lopinavir/ritonavir or nelfinavir was postulated as the probable mechanism (Bates & Herman, 2006).

3.5.1.CO Loxapine

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo seizures, coma)

2) Summary: The concurrent use of carbamazepine and loxapine has resulted in neurotoxicity in one case re 1993a). Also, the use of carbamazepine in pregnant women has been reported to increase the risk of birth de al, 1990j; Van Dyke et al, 1991j; Finnell et al, 1992j).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: For patients receiving concurrent carbamazepine and loxapine therapy, monitor for carbamazepine toxicity and adjust doses accordingly.

7) Probable Mechanism: unknown

8) Literature Reports

a) A patient experienced neurotoxicity (visual disturbances, lethargy, ataxia, and falling) 10 days after ca mg three times a day was added to a regimen including loxapine 350 mg daily (Collins et al, 1993). His s with a reduction of carbamazepine to 100 mg twice daily. Subsequently loxapine was discontinued, and carbamazepine epoxide (an active metabolite) to carbamazepine decreased from 0.76 to 0.18. A retrosp four other cases in which carbamazepine and loxapine had been coadministered showed a greater than carbamazepine epoxide to carbamazepine ratio. Loxapine appeared to interact with carbamazepine to in carbamazepine epoxide plasma concentrations. The mode of action may be induction of carbamazepine epoxide metabolite and/or inhibition of carbamazepine epoxide metabolism to an inactive metabolite.

b) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially i teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large related to the levels of the reactive epoxide metabolites (Buehler et al, 1990i; Van Dyke et al, 1991i; Finn The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hyc valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987i; Ramsay et al, 1990i; Spina et al, 1996h combinations increase the risk of major birth defects 3- to 4-fold over monotherapy and about 10-fold ove rates.

3.5.1.CP Maraviroc

1) Interaction Effect: decreased maraviroc concentrations

2) Summary: Maraviroc is a substrate of CYP3A4. Concomitant administration of a CYP3A4 isoenzyme indu carbamazepine, may increase maraviroc metabolism, leading to loss of virologic response, and possible resis maraviroc. Use caution if maraviroc and carbamazepine are used concomitantly (without a strong CYP3A inh increase the dose of maraviroc to 600 mg twice daily (Prod Info SELZENTRY(R) oral tablets, 2007).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Use caution when carbamazepine is co-administered with maraviroc as the combin loss of virologic response and possible resistance to maraviroc. If maraviroc and carbamazepine are used co (without a strong CYP3A inhibitor), monitor carefully for maraviroc effectiveness and increase the dose of ma twice daily (Prod Info SELZENTRY(R) oral tablets, 2007).

7) Probable Mechanism: induction of CYP3A4-mediated maraviroc metabolism

3.5.1.CQ Mebendazole

1) Interaction Effect: decreased mebendazole effectiveness

2) Summary: In patients with prior or current use of carbamazepine or phenytoin, the use of mebendazole fo resulted in therapeutic failure. This is thought to be due to the lower concentration of mebendazole in the pati anticonvulsants. For treatment of whipworms or hookworms, this interaction is not significant (Luder et al, 198 1986).

3) Severity: moderate

4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of mebendazole. Depending on the reason for use of m higher doses may be required for some therapeutic uses.
7) Probable Mechanism: increased mebendazole metabolism

3.5.1.CR Mefloquine
1) Interaction Effect: loss of seizure control
2) Summary: In patients taking an anticonvulsant, such as carbamazepine, the concomitant use of mefloquir seizure control by lowering the anticonvulsant plasma levels (Prod Info Lariam(R), 2003).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: If mefloquine and carbamazepine must be administered concurrently, monitor the le carbamazepine. Adjustments of the carbamazepine dose may be required. Also monitor the patient for seizu
7) Probable Mechanism: unknown

3.5.1.CS Mestranol
1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness
2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 19
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf use of alternate methods of birth control may be necessary.
7) Probable Mechanism: increased metabolism of contraceptive steroids
8) Literature Reports
a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate receiving oral contraceptives. Increasing the dose of ethinyl estradiol or mestranol in oral contraceptives breakthrough bleeding and decrease the risk of conception. However, higher doses of estrogens may als of vascular side effects, primarily in patients where enzyme induction does not occur. It is recommended estrogen and progestin be given initially in patients receiving an enzyme inducing anticonvulsant; howev pregnancy is a special concern, a moderate dose formulation (50 mcg ethinyl estradiol) should be consic breakthrough bleeding occurs with low-dose contraception, progressive increases in the dose of mestrar (up to 80 mcg) should be considered. If spotting occurs, it is suggested that the contraceptive not be disc rather that a traditional method of barrier contraception be initiated during the remainder of that cycle. Sv dose oral contraceptive is recommended if enzyme inducing anticonvulsants are discontinued in women moderate or high-dose contraceptives.
b) Carbamazepine reduced the area under the plasma concentration time curve (AUC) of ethinyl estrad 4 women taking carbamazepine 300 to 600 mg daily within 8 to 12 weeks of initiation of therapy. Norges also significantly reduced to 29% to 57% of baseline. The authors suggest that breakthrough bleeding ca most women with use of oral contraceptives containing 80 to 100 mcg ethinyl estradiol (Crawford et al, 1
c) Accidental pregnancy occurred in a 20-year-old epileptic who was using phenytoin 400 mg daily plus 400 mg daily (Haukkamaa, 1986). The plasma concentration of levonorgestrel in this patient was very lo pg/mL) when compared to controls (325 +/- 135 pg/mL). Carbamazepine appears to decrease plasma le concentrations by enhancing the hepatic metabolism of the steroid via enzyme induction. Levonorgestrel relied upon as the sole means of contraception in patients on anticonvulsant therapy.

3.5.1.CT Methadone
1) Interaction Effect: decreased methadone effectiveness
2) Summary: The concurrent use of anticonvulsants and methadone resulted in lower methadone levels (eg, ng/mL) (Bell et al, 1988; Ketter et al, 1991).
3) Severity: minor
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Higher methadone doses may be required in patients taking enzyme-inducing medi carbamazepine.
7) Probable Mechanism: increased hepatic metabolism

3.5.1.CU Methylphenidate
1) Interaction Effect: loss of methylphenidate efficacy
2) Summary: Two case reports describe the loss of methylphenidate efficacy after carbamazepine therapy w Carbamazepine is an inducer of cytochrome P450 enzymes, a pathway involved in methylphenidate metabol methylphenidate plasma concentrations are not routinely measured, they may be helpful in patients receiving who are showing no benefits or side effects from methylphenidate (Behar et al, 1998a; Schaller & Behar, 199

3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Clinicians should monitor patient response to methylphenidate therapy when carba initiated. Monitoring of plasma methylphenidate levels may also be helpful. Doses of methylphenidate may ne increased to maintain efficacy.
7) Probable Mechanism: induction by carbamazepine of cytochrome P450 3A4-mediated methylphenidate m
8) Literature Reports
a) A 7-year-old male with severe mental retardation and attention deficit disorder was failing to respond methylphenidate 20 mg every four hours and thiothixene 10 mg daily. Other drug therapy included carba mg daily to control grand mal epilepsy. After five days of confirmed medication compliance, plasma level methylphenidate were measured two hours after the morning dose. No trace of either psychotropic agen metabolites could be found. Doses were increased to methylphenidate 30 mg every four hours and thioth with no evidence of efficacy or side effects. Both agents were then discontinued (Behar et al, 1998).
b) Attention deficit/hyperactivity disorder (ADHD) was being treated with methylphenidate 20 mg three ti year-old female. Because of mood lability and significant impulsivity, carbamazepine was introduced at 2 strict two-hour peak methylphenidate and ritalinic acid serum level was 5.3 ng/mL (normal range 5 to 20 time. ADHD symptoms began to worsen as the carbamazepine dose was increased to 800 mg daily. Six start of combination therapy, the patient's methylphenidate and ritalinic acid strict two-hour peak blood le to 4.2 ng/mL. A month later, the carbamazepine dose was increased to 1000 mg daily with a steady-stat 11.2 mcg/mL. Despite an increase in her methylphenidate dose to 35 mg three times daily, her methylph ritalinic acid peak level had further decreased to 2.4 ng/mL. After another two months, her carbamazepir mg daily with a steady-state blood level of 11.5 mcg/mL, and methylphenidate was increased to 60 mg th regain the benefit from the drug that she had experienced before the initiation of carbamazepine (Schalle

3.5.1.CV Methylprednisolone

1) Interaction Effect: decreased methylprednisolone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, al, 1982e), possibly by inducing the cytochrome P450 3A4 enzymes which are responsible for methylpredniso (Feldweg & Leddy, 1999a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor therapeutic efficacy of the corticosteroid. An increase in the steroid dosage after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased cytochrome P450 3A4-mediated methylprednisolone metabolism
8) Literature Reports
a) A 54-year-old male who developed progressive distal sensory and motor impairment during a four we diagnosed with Churg-Strauss vasculitis. He was treated with methylprednisolone 40 mg intravenously tw rapidly resolved his eosinophilia. Because of nocturnal neuropathic pain, carbamazepine was initiated at Within 24 hours of starting carbamazepine, new motor weakness developed in the patient's fingers, and eosinophils increased from a baseline of 160/mcgL to 1330/mcgL. Carbamazepine therapy was stopped methylprednisolone was replaced with dexamethasone. Intravenous immunoglobulin therapy was also in eosinophils disappeared within 48 hours. The patient was subsequently maintained on oral cyclophosph prednisone, with substantial recovery of motor and sensory function (Feldweg & Leddy, 1999).

3.5.1.CW Metronidazole

1) Interaction Effect: increased carbamazepine serum concentrations and potential carbamazepine toxicity
2) Summary: Significantly increased carbamazepine serum concentrations and CNS toxicity have been repo receiving concurrent metronidazole (Patterson, 1994a). The mechanism was thought to be inhibition by metro cytochrome P450 aromatic oxidative metabolism of carbamazepine. Further study is needed to validate this i
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: When metronidazole and carbamazepine are coadministered, monitor carbamazep concentrations and observe patients for signs and symptoms of carbamazepine toxicity (nausea, dizziness, d effects). Doses of carbamazepine may need to be adjusted when metronidazole is added to or withdrawn fro
7) Probable Mechanism: unknown but may involve inhibition of carbamazepine metabolism by metronidazole
8) Literature Reports
a) A 49-year-old woman was seen in the ER with left quadrant pain thought to be caused by diverticulitis carbamazepine 1000 mg daily for bipolar disorder. Her other medications included conjugated estrogens Her carbamazepine serum concentration at 12 hours was 9 mcg/mL. She was then started on metronida times a day and trimethoprim/sulfamethoxazole double strength twice a day. Two days later she was adr worsening symptoms. Her metronidazole was increased to 500 mg intravenously every eight hours. Cefa and trimethoprim/sulfamethoxazole withdrawn. Two days later she reported nausea, dizziness, and diplo her 10-hour carbamazepine serum concentration was 14.3 mcg/mL, a 60% increase over the previous 9 mechanism of this interaction was thought to be inhibition of the hepatic cytochrome P-450 enzyme syste metronidazole (Patterson, 1994).

3.5.1.CX Mianserin

1) Interaction Effect: decreased mianserin serum concentrations

2) Summary: Serum mianserin levels were reported to be decreased in patients treated with carbamazepine (Leinonen et al, 1991a).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Serum levels and clinical response to mianserin should be carefully monitored if ca added to therapy or discontinued.

7) Probable Mechanism: increased metabolism of mianserin

8) Literature Reports

a) The effect of carbamazepine on mianserin levels was examined in 4 psychiatric inpatients stabilized f days prior to measurement of baseline antidepressant concentrations. The average daily mianserin dos Carbamazepine was added in a mean dose of 593 mg and continued over a 4-week period. Serum mian concentrations were decreased an average of 46% in patients receiving combination therapy compared with mianserin alone (Leinonen et al, 1991).

3.5.1.CY Midazolam

1) Interaction Effect: decreased efficacy of midazolam

2) Summary: Carbamazepine and phenytoin have been shown to greatly reduce the bioavailability of a singl midazolam. Carbamazepine is known to induce the cytochrome P450 3A enzymes, the same pathway that m midazolam during its first-pass and elimination phases. Patients receiving both carbamazepine and midazola have a hypnotic response to midazolam due to the induction of its metabolism caused by carbamazepine (Ba 1996a).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: In a patient receiving carbamazepine therapy, larger doses of midazolam may be re a hypnotic response. Because of patient intervariability, a hypnotic other than midazolam may be preferable.

7) Probable Mechanism: induction of cytochrome P450 3A enzymes by carbamazepine

8) Literature Reports

a) Six patients with epilepsy and seven healthy control subjects were studied to determine the effects of and phenytoin on an oral dose of midazolam. Epileptic patients had been receiving either carbamazepin mg to 900 mg daily), phenytoin (dose range 150 mg to 300 mg daily), or both drugs twice daily for at leas control subjects were not receiving any enzyme-inducing agents. All study participants were administere dose of midazolam 15 mg. In the patient group, the mean area under the concentration-time curve of mi 5.7% (0.60 mcg/min/mL vs. 10.5 mcg/min/mL) and the maximum concentration was 7.4% (5.2 ng/mL vs. the control values. In one patient, only traces of midazolam (less than 0.1 ng/mL) were detectable in the elimination half-life of midazolam was reduced to 1.3 hours in the patient group compared to 3.1 hours in There was no difference in the time to maximum concentration (1 hour) between the two groups. As exp reduced serum concentrations of midazolam, the majority of the patient group did not report any sedatio subjects from the control group experienced sedative effects which lasted from two to four hours. The lo plasma concentrations, decreased elimination half-life, and lack of sedative effects are most likely the re P450 3A enzyme induction by carbamazepine and phenytoin, since midazolam is extensively metabolize enzymes during first-pass and elimination phases (Backman et al, 1996).

3.5.1.CZ Mifepristone

1) Interaction Effect: decreased serum levels of mifepristone and potentially decreased efficacy

2) Summary: Although formal interaction studies have not been conducted, carbamazepine may induce the metabolism of mifepristone, thereby decreasing serum levels of mifepristone (Prod Info MIFEPREX(R) oral ta

3) Severity: moderate

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Clinicians should be aware that carbamazepine may induce mifepristone metabolis resulting in decreased mifepristone efficacy.

7) Probable Mechanism: induction of CYP3A4-mediated metabolism of mifepristone by carbamazepine

3.5.1.DA Milnacipran

1) Interaction Effect: slight reductions in milnacipran plasma levels

2) Summary: In a multiple-dose study involving healthy subjects (provided by the manufacturer), a moderate milnacipran plasma levels (20%) was observed when the drug was given in combination with carbamazepine accompanied by an increase in plasma levels of the N-dealkylated metabolite of milnacipran (inactive). Carba active metabolite were unaffected (Puozzo & Leonard, 1996). The reduced concentration of milnacipran is of significance, and dose adjustment is not indicated during initiation of combined therapy. However, baseline a therapy plasma levels of milnacipran are suggested if prolonged treatment is expected (where assays are av

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable
6) Clinical Management: Dose adjustment is not indicated during initiation of combined therapy with carbama milnacipran. However, baseline and combination-therapy plasma levels of milnacipran are suggested if prolo expected.
7) Probable Mechanism: hepatic enzyme induction by carbamazepine

3.5.1.DB Miokamycin
1) Interaction Effect: an increase in carbamazepine plasma levels
2) Summary: Miokamycin has been reported to increase half-life and area under the concentration-time curv decrease the clearance of carbamazepine in 14 healthy volunteers (Couet et al, 1990a; Prod Info Miokacin(R
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Caution is advised when using miokamycin in combination with carbamazepine. Mo carbamazepine plasma concentrations and adjust the carbamazepine dose as necessary.
7) Probable Mechanism: inhibition of carbamazepine metabolism
8) Literature Reports
a) The effect of miokamycin 800 mg twice daily for 12 days on the pharmacokinetics of carbamazepine single oral dose of 200 mg was assessed in a crossover study involving 14 healthy volunteers. The study statistically significant increase (13%) in half-life and area under the concentration-time curve (AUC) of c decrease in its clearance. The authors also demonstrated that the maximum concentration (Cmax) and A epoxycarbamazepine, a major active metabolite of carbamazepine, were significantly decreased during t miokamycin (Couet et al, 1990; Prod Info Miokacin(R), 1996).

3.5.1.DC Moclobemide
1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures
2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(Info Tegretol(R), 1998d; Thweatt, 1986d). However, there is preliminary evidence that the combination of car an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995i; Barker & Eccleston controlled studies are needed.
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of if the clinical situation permits, before carbamazepine therapy is initiated.
7) Probable Mechanism: unknown
8) Literature Reports
a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics) (Ketter et al, 1995h). In addition to their regular carbamazepine an four patients received phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylc maximum dose 55 mg daily) for a mean duration combination therapy of 52.2 days. During MAOI coadm concentrations of carbamazepine and lithium did not change significantly from baseline values. Self-rate not substantially different. Four patients (three on phenelzine and one on tranylcypromine) responded to were subsequently discharged.
b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984h).
c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru case (Joffe et al, 1985d). Conversely, five patients on tranylcypromine needed a mean daily dose of carb mg to achieve a carbamazepine blood level of 8.0-11.1 mcg/mL (Barklage et al, 1992d). Four other patie phenelzine only required a mean daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9

3.5.1.DD Modafinil
1) Interaction Effect: decreased modafinil efficacy
2) Summary: Coadministration of modafinil with other drugs that are potent inducers of CYP3A4, such as ca could result in decreased efficacy of modafinil which is partially metabolized by the CYP3A4 isoenzyme (Proc modafinil, 2004).
3) Severity: minor
4) Onset: unspecified
5) Substantiation: theoretical

6) Clinical Management: Clinicians should monitor patient response to modafinil therapy when carbamazepir
7) Probable Mechanism: induction by carbamazepine of cytochrome P450 3A4-mediated modafinil metaboli

3.5.1.DE Nafimidone

1) Interaction Effect: carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizur
2) Summary: Concurrent use of nafimidone in 6 patients with intractable seizures taking carbamazepine and in a reduction in carbamazepine elimination by 76 to 87% and a reduction in phenytoin elimination by 38 to 7 showed symptoms characteristic of carbamazepine toxicity by the second day of nafimidone treatment. Effec were apparent within 24 hours of initiation of nafimidone and began to decline within 12 hours of discontinuat Ben-Menachem, 1987a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor carbamazepine concentrations closely when adding or discontinuing nafimi adjust carbamazepine dose accordingly.
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) Addition of nafimidone to the anticonvulsant regimens of 6 patients with intractable seizures taking ca phenytoin resulted in a reduction in carbamazepine elimination by 76% to 87% and a reduction in phenyt 38% to 77%. This effect was apparent within 24 hours of initiation of nafimidone and began to decline wi nafimidone discontinuation. The effect on carbamazepine elimination persisted over the course of 1 year elected to continue therapy beyond the trial period. Two patients showed symptoms characteristic of carl toxicity by the second day of nafimidone treatment. The degree of toxicity was greatly reduced for 4 addi reducing both the phenytoin and carbamazepine doses during the titration of nafimidone. Although the p of this interaction is unknown, the authors postulate that nafimidone may inhibit the cytochrome P-450-m function oxidase system (Treiman & Ben-Menachem, 1987).

3.5.1.DF Nefazodone

1) Interaction Effect: reduced plasma concentrations and efficacy of nefazodone and its active metabolite, ar risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizures, coma)
2) Summary: Coadministration of nefazodone and carbamazepine is contraindicated. Concomitant use may reduce plasma concentrations of nefazodone and its active metabolite, resulting in reduced therapeutic effica (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, suspension, 2007; Prod Info SERZONE(R) oral a study conducted on 12 healthy volunteers, the coadministration of nefazodone with carbamazepine at steac a reduction in the mean AUC of nefazodone and hydroxynefazodone by 93% and 94%, respectively. Additior increase in carbamazepine plasma levels and a 21% decrease in carbamazepine-10,11 epoxide levels were findings suggest that nefazodone inhibits carbamazepine metabolism through the CYP3A4 system, and carb induces nefazodone metabolism through the same pathway (Laroudie et al, 2000a). Two other cases of nefa carbamazepine toxicity have been reported in the literature (Ashton & Wolin, 1996).
3) Severity: contraindicated
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: Concomitant use of carbamazepine and nefazodone is contraindicated due to redu nefazodone and its active metabolite (Prod Info TEGRETOL(R) chewable oral tablets, oral tablets, suspensio SERZONE(R) oral tablets, 2005). In addition, concomitant use may also result in increased toxicity of carbam Wolin, 1996).
7) Probable Mechanism: induction of CYP3A4-mediated nefazodone metabolism; inhibition of CYP3A4-med carbamazepine metabolism
8) Literature Reports
a) Twelve healthy male volunteers participated in an open-label multiple-dose study to explore the poter interaction between carbamazepine and nefazodone. Each subject received nefazodone 200 mg twice d through 5. A four-day washout period followed. On days 10 to 12, carbamazepine 200 mg daily was give was increased to 200 mg twice daily from days 14 to 39. From days 40 to 44, nefazodone 200 mg twice carbamazepine 200 mg twice daily were coadministered. Carbamazepine mean steady-state area under time curve (AUC) increased from 60.77 mcg/hr/mL to 74.98 mcg/hr/mL in the presence of nefazodone, w the metabolite carbamazepine-10,11-epoxide decreased from 7.1 mcg/hr/mL to 5.71 mcg/hr/mL. The ma concentration (Cmax) of carbamazepine increased from 5794 mg/L to 7133.2 mg/L and the Cmax for ca 10,11-epoxide decreased from 680.5 mg/L to 535.2 mg/L. Nefazodone mean steady-state AUC was dec ng/hr/mL to 542 ng/hr/mL in the presence of carbamazepine, although the clinical significance of carbam on nefazodone metabolism has not yet been studied (Laroudie et al, 2000).
b) A 35-year-old female with bipolar disorder developed carbamazepine toxicity following the addition of to 150 mg twice daily) to an existing drug regimen of carbamazepine (1000 mg daily) and risperidone (3 Prior to nefazodone therapy, her carbamazepine serum concentrations ranged from 7.0 mcg/mL to 8.3 m days after her nefazodone dose was increased to 300 mg daily, she presented with lightheadedness and carbamazepine serum concentration was 10.8 mcg/mL (Ashton & Wolin, 1996a).
c) In a second case, a 39-year-old female with bipolar disorder developed carbamazepine toxicity after r 150 mg twice daily) was added to an existing regimen of carbamazepine (1000 mg daily). During concon serum carbamazepine levels increased to 15.1 mcg/mL from a previous range of 5.2 mcg/mL to 6.2 mcg

carbamazepine alone (Ashton & Wolin, 1996a).

3.5.1.DG Nelfinavir

1) Interaction Effect: decreased nelfinavir plasma concentrations; increased serum carbamazepine levels an
2) Summary: The concurrent use of carbamazepine and nelfinavir may result in decreased nelfinavir plasma potentially reducing the efficacy of nelfinavir (Prod Info Viracept(R), 1999). Carbamazepine toxicity has been HIV-positive patient upon concomitant treatment with nelfinavir, as part of a highly active antiretroviral regime result of inhibition of CYP3A4-mediated carbamazepine metabolism by nelfinavir. If used concurrently with ne reducing the carbamazepine dose by 25 to 50%. Additionally, monitor patients for serum carbamazepine leve after initiating nelfinavir (Bates & Herman, 2006).
3) Severity: major
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor patients for signs of reduced efficacy of nelfinavir. Dosing adjustments of ne necessary. Additionally, coadministration of carbamazepine with a nelfinavir, as part of a highly active antiretr has resulted in increased serum carbamazepine levels and toxicity. If used concurrently with nelfinavir, consi carbamazepine dose by 25 to 50% and monitor patients for serum carbamazepine levels, 3 to 5 days after in
7) Probable Mechanism: induction of cytochrome P450 3A-mediated metabolism of nelfinavir; inhibition of C carbamazepine metabolism by nelfinavir
8) Literature Reports
a) Symptoms of carbamazepine toxicity developed in a 50-year-old HIV-positive male upon addition of lo his highly active antiretroviral therapy (HAART). The patient had been stabilized on carbamazepine 400 for 7 months, with a serum concentration within reference range (10.3 mg/L) 1 week prior to starting the tenofovir 300 mg daily; lamivudine 150 mg twice daily; and lopinavir 133 mg/ritonavir 33 mg, 3 capsules 9 of the new HAART regimen, the patient experienced excessive drowsiness, and the carbamazepine se increased by 46% to 15 mg/L. Decreasing the carbamazepine dose to 400 mg twice daily improved drow repeat serum level on day 11 was 7.4 mg/L. On day 12, the patient developed fatigue, difficulty swallowi hemorrhagic lesions over the extremities. The HAART regimen was stopped and carbamazepine dose w 400 mg 3 times daily. The patient was hospitalized 10 days later for evaluation of the rash. Blood tests a marrow toxicity. Subsequently, a neurology consult resulted in tapering of carbamazepine (over 2 to 4 we topiramate 25 mg twice daily and titrating to a target dose of 200 mg twice daily. On day 17 of hospitaliza regimen was re-initiated, replacing lopinavir/ritonavir with nelfinavir 1250 mg twice daily. On day 20, the p feeling tired and unsteady on his feet and the carbamazepine serum level had increased to 15 mg/L. Dec carbamazepine dose as before prompted resolution of symptoms within 24 hours. This interaction betwe as probable by the Naranjo probability scale and inhibition of CYP3A4-mediated carbamazepine metabo lopinavir/ritonavir or nelfinavir was postulated as the probable mechanism (Bates & Herman, 2006).

3.5.1.DH Nevirapine

1) Interaction Effect: decreased plasma concentrations of carbamazepine
2) Summary: Nevirapine is an inducer of cytochrome P450 3A4 enzymes, which are also involved in the met carbamazepine. Although studies involving nevirapine and carbamazepine have not been conducted, nevirap shown to induce the metabolism of carbamazepine, significantly decreasing carbamazepine bioavailability (P (R), 2004).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: probable
6) Clinical Management: Dose adjustment of carbamazepine may be needed due to possible decrease in cli
7) Probable Mechanism: induction of cytochrome P450 3A4-mediated metabolism of carbamazepine by nevi

3.5.1.DI Niacinamide

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo seizures, coma)
2) Summary: Two case reports describe a decrease in carbamazepine clearance when niacinamide was ad decrease seen in the carbamazepine clearance correlated highly with increasing niacinamide doses (Bourge
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor carbamazepine plasma levels in patients receiving niacinamide concomitar carbamazepine doses accordingly.
7) Probable Mechanism: inhibition of cytochrome P450 enzymes by niacinamide
8) Literature Reports
a) Carbamazepine concentration increased in two epileptic patients after the addition of niacinamide. Bo also receiving primidone therapy, and niacinamide was added to decrease the conversion of primidone t Patient 1, a 23-month old male receiving carbamazepine 72.7 mg/kg/day, had a carbamazepine clearanc prior to niacinamide treatment, and the carbamazepine clearance decreased to 2.16 L/kg/day by the time dose had been titrated up to 178 mg/kg/day. In patient 2, a 10-year old male, the carbamazepine clearar from 8.0 L/kg/day before niacinamide therapy to 3.37 L/kg/day when the niacinamide dose was 60 mg/kg suspected that niacinamide inhibited the cytochrome P450 metabolism of carbamazepine (Bourgeois et

3.5.1.DJ Nialamide

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures

2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(Info Tegretol(R), 1998f; Thweatt, 1986f). However, there is preliminary evidence that the combination of carb MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995m; Barker & Eccleston, controlled studies are needed.

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of if the clinical situation permits, before carbamazepine therapy is initiated.

7) Probable Mechanism: unknown

8) Literature Reports

a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and discharged (Ketter et al, 1995l).

b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984l).

c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru (Joffe et al, 1985f). Conversely, five patients on tranylcypromine need a mean daily dose of carbamazep achieve a carbamazepine blood level of 8.0-11.1 mcg/mL. Four other patients receiving phenelzine only daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9 mcg/mL (Barklage et al, 1992f).

3.5.1.DK Nifedipine

1) Interaction Effect: decreased nifedipine exposure and may decrease nifedipine efficacy

2) Summary: Concurrent administration of nifedipine and carbamazepine may induce CYP3A4-mediated nife and decrease exposure to nifedipine, which may increase the risk of hypertension or angina (Prod Info Adala Release Tablets, 2004).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: Concomitant administration of nifedipine and carbamazepine may decrease exposu Monitor patient for loss of calcium channel blocker effects, including clinical signs or symptoms of hypertensio Consider a dose adjustment of nifedipine.

7) Probable Mechanism: induction of CYP3A4-mediated nifedipine metabolism

3.5.1.DL Nilotinib

1) Interaction Effect: decreased nilotinib plasma concentrations

2) Summary: Nilotinib is a CYP3A4 substrate. Coadministration of rifampin, a strong CYP3A4 inducer, at a d for 12 days decreased nilotinib AUC by approximately 80% in healthy subjects. Although not studied with car a strong CYP3A4 inducer, a similar interaction would be expected. Concomitant use of carbamazepine and n therefore be avoided. However, if concomitant use is required, nilotinib dose may need to be increased depe tolerability. Upon discontinuation of carbamazepine, reduce the nilotinib dose to the indicated dose (Prod Info capsules, 2007).

3) Severity: major

4) Onset: unspecified

5) Substantiation: theoretical

6) Clinical Management: Avoid concomitant administration of carbamazepine, a strong CYP3A4 inducer, and CYP3A4 substrate, as this may result in decreased nilotinib plasma concentrations and consequently, subthe concomitant administration is warranted, consider increasing nilotinib dose depending on patient tolerability. discontinuation of the strong CYP3A4 inducer, reduce the nilotinib dose to the indicated dose (Prod Info TAS capsules, 2007).

7) Probable Mechanism: induction of CYP3A4-mediated nilotinib metabolism

3.5.1.DM Nimodipine

1) Interaction Effect: decreased nimodipine effectiveness

2) Summary: A single study has shown that concurrent use of enzyme inducing antiepileptic agents (phenyto and carbamazepine) with nimodipine has resulted in decreased nimodipine levels (Tartara et al, 1991b).

3) Severity: minor

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor clinical response to nimodipine, with dose adjustments as needed to achiev cardiovascular response.

7) Probable Mechanism: increased nimodipine metabolism

8) Literature Reports

a) Three groups of eight subjects were studied (Tartara et al, 1991). Group 1 was comprised of healthy had epileptic patients treated at least four months with carbamazepine, phenobarbital, phenytoin (all enz a combination, and group 3 included epileptic patients treated for at least four months with sodium valpro the control group, nimodipine AUCs averaged a 7-fold decrease in the enzyme inducer group, probably d first-pass metabolism. The nimodipine AUCs were increased by 50% in the valproate-treated group.

3.5.1.DN Norelgestromin

1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness

2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 198

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf use of alternate methods of birth control may be necessary.

7) Probable Mechanism: increased metabolism of contraceptive steroids

8) Literature Reports

a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate receiving oral contraceptives. Increasing the dose of ethinyl estradiol or mestranol in oral contraceptives breakthrough bleeding and decrease the risk of conception. However, higher doses of estrogens may als of vascular side effects, primarily in patients where enzyme induction does not occur. It is recommended estrogen and progestin be given initially in patients receiving an enzyme inducing anticonvulsant; howev pregnancy is a special concern, a moderate dose formulation (50 mcg ethinyl estradiol) should be consid breakthrough bleeding occurs with low-dose contraception, progressive increases in the dose of mestrar (up to 80 mcg) should be considered. If spotting occurs, it is suggested that the contraceptive not be disc rather that a traditional method of barrier contraception be initiated during the remainder of that cycle. Sv dose oral contraceptive is recommended if enzyme inducing anticonvulsants are discontinued in women moderate or high-dose contraceptives.

b) Carbamazepine reduced the area under the plasma concentration time curve (AUC) of ethinyl estrad 4 women taking carbamazepine 300 to 600 mg daily within 8 to 12 weeks of initiation of therapy. Norges also significantly reduced to 29% to 57% of baseline. The authors suggest that breakthrough bleeding ca most women with use of oral contraceptives containing 80 to 100 mcg ethinyl estradiol (Crawford et al, 1

c) Accidental pregnancy occurred in a 20-year-old epileptic who was using phenytoin 400 mg daily plus 400 mg daily (Haukkamaa, 1986). The plasma concentration of levonorgestrel in this patient was very lo pg/mL) when compared to controls (325 +/- 135 pg/mL). Carbamazepine appears to decrease plasma le concentrations by enhancing the hepatic metabolism of the steroid via enzyme induction. Levonorgestrel relied upon as the sole means of contraception in patients on anticonvulsant therapy.

3.5.1.DO Norethindrone

1) Interaction Effect: a decrease in plasma concentrations of estrogens and in estrogen effectiveness

2) Summary: Breakthrough bleeding, spotting, and pregnancy have been reported in women on anticonvulsa contraceptives (Prod Info Ortho Evra(TM), 2001; Mattson et al, 1986a; Crawford et al, 1986; Haukkamaa, 198

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: In some women the use of higher estrogen content in the contraceptive may be suf use of alternate methods of birth control may be necessary.

7) Probable Mechanism: increased metabolism of contraceptive steroids

8) Literature Reports

a) Concomitant administration of oral contraceptives with enzyme-inducing anticonvulsant agents, prima phenytoin, carbamazepine, or primidone, has been reported to result in an increased failure rate of contr et al, 1986). The benzodiazepines and valproic acid have not been associated with increased failure rate receiving oral contraceptives. 3.5.1.DQ Nortriptyline

1) Interaction Effect: decreased nortriptyline effectiveness

2) Summary: One case has been reported in which nortriptyline levels dropped by more than half after carba
added (Brosen & Kragh-Sorensen, 1993b). Similar effects have been observed with other tricyclic antidepres
al, 1991k; Brown et al, 1988c; Moody et al, 1977c).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor for clinical efficacy of the nortriptyline therapy and for any signs of toxicity o
Serum levels of both agents should be considered when either agent is added or discontinued, with appropria
adjustments made accordingly.

7) Probable Mechanism: increased nortriptyline metabolism

3.5.1.DR Olanzapine

1) Interaction Effect: reduced olanzapine efficacy

2) Summary: Carbamazepine induces CYP1A2 mediated oxidation. Concomitant administration of olanzapir
carbamazepine 200 mg twice daily increased the clearance of olanzapine by 50% (Prod Info Zyprexa(R), 199

doses of carbamazepine may cause an even greater effect on olanzapine clearance. In a study of 11 healthy concurrent administration of olanzapine and carbamazepine resulted in a 46% increase in olanzapine clearar 1998). Because patients respond to a relatively wide range of olanzapine serum concentrations, close clinica symptom patterns and changes is necessary whenever carbamazepine is added to or withdrawn from olanza need for olanzapine dose adjustments will most likely be highly patient specific (Licht et al, 2000a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor patients for olanzapine efficacy. Doses of olanzapine may need to be adjus concomitantly with carbamazepine.
7) Probable Mechanism: induction of cytochrome P450 1A2-mediated olanzapine metabolism
8) Literature Reports
a) A 23-year-old paranoid schizophrenic female was admitted to the hospital for treatment of hallucinatic Her only medication on admission was perphenazine 12 mg daily, but carbamazepine 600 mg daily was aggressive outbursts. Perphenazine was replaced by risperidone 6 mg daily due to akathisia, rigidity, an risperidone was also discontinued due to extrapyramidal side effects. Olanzapine 15 mg daily was starte psychiatric symptoms improved over the next three weeks. Because her aggressive outbursts were still carbamazepine was discontinued due to lack of efficacy. She had received cotherapy with olanzapine 15 carbamazepine 600 mg daily for three consecutive weeks. The day prior to carbamazepine discontinuati olanzapine serum concentration was measured at 21 ng/mL. Over the next few weeks, her olanzapine c increased by 114% to 45 ng/mL. The dose of olanzapine was decreased to 10 mg daily and a correspon olanzapine level occurred. This case report suggests that carbamazepine induces the metabolism of ola likely through the cytochrome P450 1A2 enzyme system (Licht et al, 2000).

3.5.1.DS Omeprazole
1) Interaction Effect: an increased risk of carbamazepine toxicity
2) Summary: Omeprazole has been reported to increase the elimination half-life, increase the area under the time curve (AUC), and decrease the clearance of a single-dose of carbamazepine (Dammann, 1996a). Conv Getz, 1995a) described a patient who had no alteration in the carbamazepine plasma level during concurrent omeprazole for helicobacter pylori gastritis. One of the reasons for the conflicting results may be that carbam own metabolism, thereby possibly causing different interactions between single-dose and multiple-dose thera carbamazepine.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor patients receiving concurrent carbamazepine and omeprazole therapy for s carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vomiting, apnea, seizures, coma). Also moni serum levels. Doses of carbamazepine may need to be reduced.
7) Probable Mechanism: inhibition of carbamazepine metabolism
8) Literature Reports
a) The administration of a single dose of carbamazepine to nine patients receiving omeprazole therapy prolongation of the carbamazepine half-life (17.2 hours vs. 37.3 hours) and an increase in the AUC from 668 mcg/hr/mL. The clearance of carbamazepine decreased from 20.7 mL/hr/kg to 12.5 mL/hr/kg. These any adjuvant therapy of omeprazole has the potential to interact with carbamazepine concentrations, and administered with close monitoring of the carbamazepine serum levels (Dammann, 1996).
b) An epileptic patient stabilized on carbamazepine (900 mg daily) therapy, had a serum level of 7.5 mg the addition of clarithromycin (500 mg three times daily) and omeprazole (20 mg twice daily), the carbam risen to 14 mg/L. Despite carbamazepine dose reductions of 200 mg daily, the plasma level reached 20. clarithromycin was then discontinued, and metronidazole and bismuth subsalicylate were substituted. Th carbamazepine returned to normal, even though therapy with omeprazole was continued. Omeprazole is hepatic microsomal cytochrome P450 2C enzymes, whereas carbamazepine is metabolized by and indu different metabolic pathways between omeprazole and carbamazepine suggest that in this patient, claritl solely responsible for the increased carbamazepine serum levels and no drug interaction exists between carbamazepine (Metz & Getz, 1995).

3.5.1.DT Oxcarbazepine
1) Interaction Effect: decreased plasma concentration of the active 10-monohydroxy metabolite of oxcarbaze
2) Summary: Concurrent administration of oxcarbazepine and carbamazepine (CBZ) has resulted in a 40% d plasma concentration of the active 10-monohydroxy derivative (MHD) of oxcarbazepine (Prod Info TRILEPTA oral suspension, 2005). Although the exact mechanism for this decrease is unknown, it is believed to be parti potential induction of oxcarbazepine's metabolism by CBZ, which is strong inducer of cytochrome P450 enzy 1994). Although, the clinical significance of this interaction is unknown, decreased plasma MHD concentratio potential loss of oxcarbazepine efficacy. If oxcarbazepine and carbamazepine are administered concurrently, to oxcarbazepine may need to be monitored.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: established
6) Clinical Management: Coadministration of oxcarbazepine and carbamazepine may result in a decreased d

the active 10-monohydroxy metabolite of oxcarbazepine. Monitor patients for clinical response to oxcarbazep
7) Probable Mechanism: potential induction of cytochrome P450-mediated oxcarbazepine metabolism
8) Literature Reports
a) In a randomized, double-blind, placebo-controlled trial in adults, coadministration of carbamazepine (
oxcarbazepine resulted in decreased levels of the pharmacologically active 10-monohydroxy derivative (
oxcarbazepine. Patients (n=12) being treated with a mean CBZ dose of 1025 milligrams (mg) (range 40
administered a single 600 mg oral dose of oxcarbazepine and were randomized, a week later, to receive
oxcarbazepine three times daily or matched placebo for 3 weeks. Active controls (n=7) were untreated p
received the single 600 mg oxcarbazepine dose and 3 weeks active treatment. Study results showed tha
the concentration-time curve (AUC) for MHD at steady state was reduced by 40% (90% confidence inter
57% decrease) in the CBZ-treated group compared to the active controls (p less than 0.05) while AUC fo
significantly. Although the exact mechanism for this decrease is unknown, it was partially attributed to a p
of oxcarbazepine metabolism by carbamazepine, a strong inducer of cytochrome P450 enzymes (McKee
Info TRILEPTAL(R) oral tablets, oral suspension, 2005).

3.5.1.DU Paliperidone
1) Interaction Effect: decreased paliperidone concentration
2) Summary: Concomitant use of paliperidone and carbamazepine decreased the maximum concentration (C
area under the concentration-time curve (AUC) values of paliperidone by 37%. Coadministration with carbam
CYP3A4 inducer, could increase paliperidone renal clearance by 35%. The dose of paliperidone should be ev
administered concurrently with carbamazepine. If therapy with carbamazepine is discontinued, the dose of pa
be decreased if necessary (Prod Info INVEGA(TM) extended-release oral tablets, 2007).
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Coadministration of paliperidone and carbamazepine resulted in decreased paliperi
concentrations. Dosing of paliperidone should be evaluated when it is administered concurrently with carbam
with carbamazepine is discontinued, the dose of paliperidone should be decreased if necessary(Prod Info IN
extended-release oral tablets, 2007).
7) Probable Mechanism: induction of paliperidone metabolism
8) Literature Reports
a) Coadministration of paliperidone 6 mg daily and carbamazepine 200 mg twice daily decreased the pa
steady-state maximum concentration (Cmax) and area under the concentration-time curve (AUC) by app
This decrease is caused by a 35% increase in renal clearance of paliperidone. There is little effect on the
bioavailability of paliperidone when coadministered with carbamazepine. Carefully evaluate paliperidone
initiation or discontinuation of carbamazepine (Prod Info INVEGA(TM) extended-release oral tablets, 200

3.5.1.DV Pancuronium
1) Interaction Effect: decreased pancuronium duration of action
2) Summary: It has been demonstrated that, in patients taking carbamazepine for at least one month prior to
pancuronium, the recovery time after being given pancuronium was about 65% faster when compared to con
& Ebrahim, 1987a).
3) Severity: moderate
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: Monitor patients for an appropriate clinical response to the neuromuscular blocker.
intervals or higher doses of pancuronium may be needed in patients receiving carbamazepine.
7) Probable Mechanism: unknown
8) Literature Reports
a) Nine patients on chronic carbamazepine therapy undergoing craniotomy for tumors or cerebrovascula
pancuronium 0.1 mg/kg intravenously to facilitate endotracheal intubation. As compared with controls, th
from neuromuscular blockade was significantly (65%) reduced. Times to percent recovery of baseline tw
controls and the carbamazepine group are as follows: 25%, 85 vs 30 minutes; 50%, 106 vs 39 minutes;
minutes; 90%, 149 vs 57 minutes. Carbamazepine and pancuronium may compete for binding sites at th
junction or carbamazepine may increase the rate of pancuronium metabolism (Roth & Ebrahim, 1987).

3.5.1.DW Pargyline
1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures
2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(
Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(
Info Tegretol(R), 1998j; Thweatt, 1986j). However, there is preliminary evidence that the combination of carba
MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995u; Barker & Eccleston, 1
controlled studies are needed.
3) Severity: contraindicated
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors
contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of

if the clinical situation permits, before carbamazepine therapy is initiated.
7) Probable Mechanism: unknown
8) Literature Reports
a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and discharged (Ketter et al, 1995t).
b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984t).
c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru (Joffe et al, 1985j). Conversely, five patients on tranylcypromine need a mean daily dose of carbamazep achieve a carbamazepine blood level of 8.0-11.1 mcg/mL. Four other patients receiving phenelzine only daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9 mcg/mL (Barklage et al, 1992j).

3.5.1.DX Pentobarbital
1) Interaction Effect: decreased carbamazepine effectiveness with loss of seizure control
2) Summary: Concomitant use of carbamazepine and primidone (a prodrug of phenobarbital) has been sugg primidone concentration/dose ratio, while increasing the phenobarbital concentration to primidone concentrat al, 1983e). Concurrent therapy has also been reported to lower carbamazepine concentrations (Benetello & F with the barbiturate decreasing the level of carbamazepine while increasing the level of 10, 11-epoxide metab carbamazepine (McKauge et al, 1981c; Eichelbaum et al, 1985b). Evidence from these studies indicates that effects may be more pronounced in children.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: With combined carbamazepine-pentobarbital therapy, monitor patients for seizure a pediatric patients, and adjust doses accordingly.
7) Probable Mechanism: microsomal enzyme induction with altered metabolism of either drug
8) Literature Reports
a) Concomitant administration of primidone and carbamazepine has been reported to result in lack of se low levels of carbamazepine in a 15 year-old male with partial complex seizures. Withdrawal of the primi significant increases in carbamazepine serum levels with decreases in carbamazepine-10, 11-epoxide le reduction (60%) in carbamazepine clearance (Benetello & Furlanut, 1987d).
b) A study of primidone levels and metabolism related to age and coadministration of other anticonvulsa children metabolize primidone more extensively than older persons and that coadministration of carbama primidone causes lower primidone to dose ratios and higher derived phenobarbital to primidone levels co primidone monotherapy (Battino et al, 1983d).
c) Decreased levels of primidone, which is converted to phenobarbital and PEMA in vivo, have been rep taking carbamazepine. A retrospective study statistically analyzed routine determinations of serum conce anticonvulsant medications in patients on combination regimens. A phenobarbital-carbamazepine interac specifically examined. A lowering of primidone levels during combination therapy with carbamazepine wa difference was not statistically significant. It was unknown how long patients were on primidone therapy i before the levels were taken, so auto-induction of primidone could not be ruled out (Windofer & Saver, 1
d) One study prospectively examined carbamazepine in patients already on other anticonvulsants. Eigh studied. Four patients were on phenytoin and phenobarbital, and four were on phenytoin, phenobarbital Although the authors concluded that serum phenobarbital and primidone levels appeared to actually incr patients after nine days of carbamazepine therapy, numerical data were not given. The increased levels and primidone could reflect only the incremental changes typical of rises to steady state levels (Cereghir
e) One study examined 14 patients on concomitant carbamazepine and phenobarbital therapy. A mean carbamazepine levels was noted with an increase in levels of carbamazepine epoxide and free carbama The carbamazepine epoxide to carbamazepine ratio was also increased in these patients. No effect on p phenobarbital metabolite levels was observed (Ramsay et al, 1990h). Similarly, a prospective, controlled carbamazepine reduction and discontinuation produced no change in phenobarbital levels in patients on therapy (Duncan et al, 1991c).
f) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially ir teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large related to the levels of the reactive epoxide metabolites (Buehler et al, 1990h; Van Dyke et al, 1991h; Fir The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with

other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19) (barbiturates, felbamate), or drugs epoxide hydrolase, such as valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987h; Ramsay et et al, 1996g). Such combinations increase the risk of major birth defects 3- to 4-fold over monotherapy a over background rates.

3.5.1.DY Phenelzine

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures

2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(Info Tegretol(R), 1998a; Thweatt, 1986a). However, there is preliminary evidence that the combination of car an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995c; Barker & Ecclestor controlled studies are needed.

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: Avoid concurrent administration of carbamazepine and monoamine oxidase inhibitc monoamine oxidase inhibitors 14 days or longer before starting carbamazepine therapy. Successful concomi reported; monitor carbamazepine levels and adjust doses accordingly.

7) Probable Mechanism: unknown

8) Literature Reports

a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and discharged (Ketter et al, 1995b).

b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine two months of follow up at the time of publication (Barker & Eccleston, 1984b).

c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru (Joffe et al, 1985a). Conversely, five patients on tranylcypromine need a mean daily dose of carbamazep achieve a carbamazepine blood level of 8.0 to 11.1 mcg/mL. Four other patients receiving phenelzine on daily dose of carbamazepine 450 mg to attain a blood level of 8.7 to 10.9 mcg/mL (Barklage et al, 1992a

3.5.1.DZ Phenobarbital

1) Interaction Effect: decreased carbamazepine effectiveness with loss of seizure control

2) Summary: Concomitant use of carbamazepine and primidone (a prodrug of phenobarbital) has been sugg primidone concentration/dose ratio, while increasing the phenobarbital concentration to primidone concentrat al, 1983a). Concurrent therapy has also been reported to lower carbamazepine concentrations (Benetello & F with the barbiturate decreasing the level of carbamazepine while increasing the level of carbamazepine meta al, 1981a; Eichelbaum et al, 1985). Evidence from these studies indicates that the metabolic effects may be r in children.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: theoretical

6) Clinical Management: With combined carbamazepine-phenobarbital therapy, monitor patients for seizure pediatric patients, and adjust doses accordingly.

7) Probable Mechanism: microsomal enzyme induction with altered metabolism of either drug

8) Literature Reports

a) Concomitant administration of primidone and carbamazepine has been reported to result in lack of se low levels of carbamazepine in a 15 year-old male with partial complex seizures. Withdrawal of the primi significant increases in carbamazepine serum levels with decreases in carbamazepine-10, 11-epoxide le reduction (60%) in carbamazepine clearance (Benetello & Furlanut, 1987).

b) A study of primidone plasma levels and metabolism related to age and coadministration of other antic that children metabolize primidone more extensively than older persons and that coadministration of carb primidone causes lower primidone to dose ratios and higher derived phenobarbital to primidone levels cc primidone monotherapy (Battino et al, 1983).

c) Decreased levels of primidone, which is converted to phenobarbital and PEMA in vivo, have been rep taking carbamazepine. A retrospective study statistically analyzed routine determinations of serum conce anticonvulsant medications in patients on combination regimens. A phenobarbital-carbamazepine interac specifically examined. A lowering of primidone levels during combination therapy with carbamazepine wa

difference was not statistically significant. It was unknown how long patients were on primidone therapy i
before the levels were taken, so auto-induction of primidone could not be ruled out (Windofer & Saver, 1
d) A study prospectively examined carbamazepine in patients already on other anticonvulsants. Eight pa
studied. Four patients were on phenytoin and phenobarbital, and four were on phenytoin, phenobarbital
Although the authors concluded that serum phenobarbital and primidone levels appeared to actually incr
patients after nine days of carbamazepine therapy, numerical data were not given. The increased levels
and primidone could reflect only the incremental changes typical of rises to steady-state levels (Cereghir
e) A study was done on 14 patients on concomitant carbamazepine and phenobarbital therapy. A mean
carbamazepine levels was noted with an increase in levels of carbamazepine epoxide and free carbama
The carbamazepine epoxide to carbamazepine ratio was also increased in these patients. No effect on p
phenobarbital metabolite levels was observed (Ramsay et al, 1990b). Similarly, a prospective, controlled
carbamazepine reduction and discontinuation produced no change in phenobarbital levels in patients on
therapy (Duncan et al, 1991a).
f) If phenytoin or carbamazepine (or any prodrugs) is used in pregnant women, there is a substantially ir
teratogenicity with many combinations of other anticonvulsants. The teratogenicity of these drugs is large
related to the levels of the reactive epoxide metabolites (Buehler et al, 1990b; Van Dyke et al, 1991b; Fir
The epoxide/parent drug ratio is generally increased when phenytoin or carbamazepine is combined with
other drugs that induce cytochrome P450 enzymes (3A4, 2C9, 2C19) (barbiturates, felbamate), or drugs
epoxide hydrolase, such as valproic acid, progabide, and lamotrigine (Bianchetti et al, 1987b; Ramsay et
et al, 1996b). Such combinations increase the risk of major birth defects 3- to 4-fold over monotherapy a
over background rates.

3.5.1.EA Phenprocoumon

1) Interaction Effect: decreased anticoagulant effectiveness
2) Summary: Concomitant carbamazepine and warfarin therapy has been reported to result in a decreased a
effect, secondary to the induction of hepatic metabolism of the anticoagulant (Massey, 1983b; Cohen & Arms
Koch-Weser & Koch-Weser, 1975b; Kendall & Boivin, 1981b; Hansen et al, 1971c).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: In patients receiving oral anticoagulant therapy, the prothrombin time ratio or INR (i
normalized ratio) should be closely monitored with the addition and withdrawal of treatment with carbamazep
reassessed periodically during concurrent therapy. Adjustments of the phenprocoumon dose may be necessa
maintain the desired level of anticoagulation.
7) Probable Mechanism: increased phenprocoumon metabolism

3.5.1.EB Phenytoin

1) Interaction Effect: increased phenytoin concentrations and decreased carbamazepine concentrations
2) Summary: Concurrent use of phenytoin and carbamazepine may decrease carbamazepine levels (Zielinsk
1987a; Randall & Tett, 1993). The addition of carbamazepine to phenytoin therapy may decrease (Hansen et
increase (Browne et al, 1988) phenytoin levels.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Serum levels of both phenytoin and carbamazepine should be measured after initia
discontinuation of either agent, with appropriate dosage adjustment made accordingly. Serum levels should a
following dosage adjustments and periodically thereafter.
7) Probable Mechanism: inhibition of cytochrome P450 2C19-mediated metabolism of phenytoin by carbama
8) Literature Reports
a) Twenty-four epileptic patients who were stabilized on phenytoin (PHT) and had carbamazepine (CBZ
drug regimen were studied. The mean phenytoin level increased from 13.89 +/- 4.68 to 19 +/- 4.75 (35.9
effect of carbamazepine on phenytoin in an individual is unpredictable; 12 of the subjects showed no cha
levels while the other 12 patients showed an average increase of 81.3% in phenytoin concentration. Five
with increased levels had symptoms of acute phenytoin toxicity (Zielinski et al, 1985).
b) Concomitant administration of carbamazepine and phenytoin has been reported to result in a dual int
simultaneous effects of inhibition of phenytoin metabolism by carbamazepine and induction of carbamaz
by phenytoin. The result is potential phenytoin intoxication and significant reductions of carbamazepine p
concentrations to subtherapeutic levels. These dual effects appear to be especially significant when phe
levels approach a change from linear to saturation kinetics. It is suggested that the interaction may be av
minimized by adjusting phenytoin plasma levels to approximately 13 mcg/mL prior to the addition of carb
regimen or increasing carbamazepine doses (Zielinski & Haidukewych, 1987).
c) Factors influencing simultaneous plasma concentrations of carbamazepine and its epoxide metabolite
(McKauge et al, 1981) and it was found that plasma carbamazepine concentrations were significantly lov
taking carbamazepine and phenytoin than those taking carbamazepine alone. In contrast to another stud
epoxide levels were unaltered (Pynnonen et al, 1980). Other researchers studied carbamazepine plasma
four groups of epileptic patients on a variety of anticonvulsants (Christiansen & Dam, 1973). Their results
administration of phenytoin or phenobarbital to patients receiving carbamazepine results in a significant
carbamazepine plasma concentration when compared to patients receiving carbamazepine alone. It sho

however, that some subjects in the trial were treated with carbamazepine for only one week prior to the i phenytoin. Carbamazepine has been shown to induce its own metabolism for up to 30 days after the initi thus lowering carbamazepine plasma concentration (Pynnonen et al, 1980). This may account for some carbamazepine plasma concentration in subjects also receiving phenytoin.

d) A prospective controlled study of the effects of reduction and discontinuation of phenytoin and carbar levels of concomitant antiepileptic drugs was conducted (Duncan et al, 1991). Phenytoin discontinuation 48% increase in total carbamazepine concentration and a 30% increase in free carbamazepine concentr change in carbamazepine epoxide concentrations. The authors suggest that phenytoin is a strong induce enzymes metabolizing carbamazepine to carbamazepine epoxide, but has less of an effect on the epoxi enzyme. This results in elevations in carbamazepine-epoxide/carbamazepine ratios in patients on conco Conversely, when carbamazepine was discontinued, phenytoin concentrations decreased by a mean of change in free fraction. The authors propose that this may result from inhibition of phenytoin metabolism carbamazepine. There appeared to be no impact on protein binding of either drug. Similar results were n researchers in 49 patients on concomitant phenytoin and carbamazepine therapy (Ramsay et al, 1990a)

e) If phenytoin or carbamazepine is used in pregnant women, there is a substantially increased risk of te many combinations of other anticonvulsants. The teratogenicity of these drugs is largely or wholly relatec the reactive epoxide metabolites (Buehler et al, 1990a; Van Dyke et al, 1991a; Finnell et al, 1992a). The drug ratio is generally increased when phenytoin or carbamazepine is combined with each other, any oth induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hydrolase, such as progabide and lamotrigine (Bianchetti et al, 1987a; Ramsay et al, 1990a). Such combinations increase th birth defects three- to four-fold over monotherapy and about 10-fold over background rates.

3.5.1.EC Pipecuronium

1) Interaction Effect: resistance to neuromuscular blockade

2) Summary: Phenytoin and carbamazepine have been reported to cause some resistance to neuromuscula patients treated with pipecuronium. A prolonged onset time of action was observed in patients with therapeut levels, but the accelerated recovery from paralysis was seen in all patients treated with anticonvulsants, rega plasma level (Hans et al, 1995a; Jellish et al, 1993a).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: In patients on chronic carbamazepine therapy, higher doses of pipecuronium may b the depth of neuromuscular blockade and adjust the dose of pipecuronium accordingly.

7) Probable Mechanism: unknown

8) Literature Reports

a) Twenty adults scheduled for neurosurgery were enrolled in a study. The patients were then divided in group 1 (n=10) was not on anticonvulsant therapy, and group 2 (n=10) was being treated with either phe carbamazepine (n=5). All patients achieved muscle relaxation by a single intravenous dose of pipecuron The onset time was prolonged in patients receiving anticonvulsants when compared to controls (230.5 s seconds). Of the patients who had therapeutic anticonvulsant levels (n=6), the onset time was more prol seconds) than the patients (n=4) who had subtherapeutic levels (181.8 seconds). The recovery index wa shortened in patients who were receiving anticonvulsant therapy when compared to controls (35 min vs. plasma anticonvulsant level was not a discriminant factor for recovery from the neuromuscular blockade

b) An accelerated recovery rate from pipecuronium-induced neuromuscular blockade in patients receivi alone and in combination with other anticonvulsants was observed. Nineteen adult patients were divided six healthy patients who had never received any anticonvulsant medications, and 13 epileptic patients wi seizures who had been treated for years with anticonvulsants. Of these 13 epileptic patients, they were f a group who received carbamazepine as monotherapy (n=6) and a group who was treated with carbama phenytoin or valproic acid (n=7). Anesthesia was induced with thiopental sodium and fentanyl prior to a s bolus dose of pipecuronium 0.08 mg/kg. No statistical significance was reached when comparing the tim (T-1 25%), T-1 50%, and T-1 75%, although there was a trend suggesting that patients on carbamazepir the effects of pipecuronium more quickly than controls. However, the train-of-four recovery times were si shortened in the carbamazepine monotherapy group and the multiple anticonvulsant group when compa Results were as follows when comparing controls with the carbamazepine monotherapy and carbamaze anticonvulsant groups: train-of-four recovery to 10% (TR 10%), 142 vs. 101 vs. 78 minutes; TR 20%, 16 minutes; and TR 25%, 172 vs. 130 vs. 101 minutes (Jellish et al, 1993).

3.5.1.ED Praziquantel

1) Interaction Effect: decreased praziquantel effectiveness

2) Summary: A controlled study demonstrated that carbamazepine reduced the AUC of praziquantel by 90% plasma level by 92% (Bittencourt et al, 1992). Phenytoin also significantly reduced praziquantel AUC and pea concentration in the same study. Because seizure disorders commonly accompany neurocysticercosis, comb these agents may frequently be necessary. Cimetidine (an enzyme inhibitor) has been successfully employed counteract the enzyme induction caused by phenytoin and phenobarbital, however these results have not be controlled prospective study (Dachman et al, 1994).

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable
6) Clinical Management: If concomitant use is necessary, an increased dose of praziquantel may be required effective.
7) Probable Mechanism: increased praziquantel metabolism

3.5.1.EE Prednisolone
1) Interaction Effect: decreased prednisolone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of prednisolone (Privitera Olivesi, 1986f).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of prednisolone. An increase in prednisolone dosage m after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased prednisolone metabolism

3.5.1.EF Prednisone
1) Interaction Effect: decreased prednisone effectiveness
2) Summary: Carbamazepine has been demonstrated to increase the metabolism of corticosteroids (Olivesi, al, 1982d). Although not specifically reported for prednisone, a similar interaction could be expected.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: theoretical
6) Clinical Management: Monitor therapeutic efficacy of the corticosteroid. An increase in the steroid dosage after three to five days of concurrent carbamazepine therapy.
7) Probable Mechanism: increased prednisone metabolism

3.5.1.EG Primidone
1) Interaction Effect: decreased carbamazepine effectiveness with loss of seizure control
2) Summary: Concomitant use of carbamazepine and primidone (a prodrug of phenobarbital) may lower the concentration/dose ratio, while increasing the phenobarbital concentration to primidone concentration ratio (E 1983c). Concurrent therapy has also been reported to lower carbamazepine concentrations (Benetello & Furl the barbiturate decreasing the level of carbamazepine while increasing the level of carbamazepine metabolite 1981b; Eichelbaum et al, 1985a). Evidence from these studies indicates that the metabolic effects may be mo children.
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: With combined carbamazepine-primidone therapy, monitor patients for seizure activ pediatric patients, and adjust doses accordingly.
7) Probable Mechanism: microsomal enzyme induction with altered metabolism of either drug
8) Literature Reports
a) Concomitant administration of primidone and carbamazepine has been reported to result in lack of se low levels of carbamazepine in a 15-year-old male with partial complex seizures. Withdrawal of the primi significant increases in carbamazepine serum levels with decreases in carbamazepine-10,11-epoxide le reduction (60%) in carbamazepine clearance (Benetello & Furlanut, 1987b).
b) A study of primidone plasma levels and metabolism related to age and coadministration of other antic done. This study found that children metabolize primidone more extensively than older persons and that of carbamazepine with primidone causes lower primidone to dose ratios and higher derived phenobarbita levels compared with primidone monotherapy (Battino et al, 1983b).
c) Decreased levels of primidone, which is converted to phenobarbital and PEMA in vivo, have been rep taking carbamazepine. A retrospective study statistically analyzed routine determinations of serum conce anticonvulsant medications in patients on combination regimens. A phenobarbital-carbamazepine interac specifically examined. A lowering of primidone levels during combination therapy with carbamazepine wa difference was not statistically significant. It was unknown how long patients were on primidone therapy i before the levels were taken, so auto-induction of primidone could not be ruled out (Windofer & Saver, 1
d) One study analyzed 14 patients on concomitant carbamazepine and phenobarbital therapy. A mean c carbamazepine levels were noted with an increase in levels of carbamazepine epoxide and free carbama No effect on phenobarbital or phenobarbital metabolite levels was observed (Ramsay et al, 1990c). Simi prospective, controlled study of carbamazepine reduction and discontinuation produced no change in ph in patients on concomitant therapy (Duncan et al, 1991b).
e) If phenytoin or carbamazepine is used in pregnant women, there is a substantially increased risk of te many combinations of other anticonvulsants. The teratogenicity of these drugs is largely or wholly related the reactive epoxide metabolites (Buehler et al, 1990c; Van Dyke et al, 1991c; Finnell et al, 1992c). The drug ratio is generally increased when phenytoin or carbamazepine is combined with each other, any oth induce cytochrome P450 enzymes (3A4, 2C9, 2C19), or drugs which inhibit epoxide hydrolase, such as progabide and lamotrigine (Bianchetti et al, 1987c; Ramsay et al, 1990c). Such combinations increase th birth defects three- to four-fold over monotherapy and about 10-fold over background rates.

3.5.1.EH Procarbazine

1) Interaction Effect: hypertensive urgency, hyperpyrexia, and seizures

2) Summary: Concomitant MAO inhibitor and carbamazepine therapy is contraindicated (Prod Info Tegretol(
Simultaneous use may theoretically result in hyperpyrexia, excitation, and seizure activity (Prod Info Parnate(
Info Tegretol(R), 1998g; Thweatt, 1986g). However, there is preliminary evidence that the combination of car
an MAOI may be safe and efficacious, even in some refractory cases (Ketter et al, 1995o; Barker & Eccleston
controlled studies are needed.

3) Severity: contraindicated

4) Onset: rapid

5) Substantiation: theoretical

6) Clinical Management: The concurrent administration of carbamazepine and monoamine oxidase inhibitors
contraindicated by the manufacturer. Monoamine oxidase inhibitors should be discontinued for a minimum of
if the clinical situation permits, before carbamazepine therapy is initiated.

7) Probable Mechanism: unknown

8) Literature Reports

a) A double-blind study was conducted in ten inpatients with depression that had proved refractory to m
therapies (electroconvulsive therapy, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, ca
benzodiazepines, and antipsychotics). In addition to their regular carbamazepine and lithium doses, four
phenelzine (mean maximum dose 67.5 mg daily) and six patients received tranylcypromine (mean maxir
daily) for a mean duration combination therapy of 52.2 days. During MAOI coadministration, serum conc
carbamazepine and lithium did not change significantly from baseline values. Self-rated side effects were
different. Four patients (three on phenelzine and one on tranylcypromine) responded to this therapy and
discharged (Ketter et al, 1995n).

b) A 60-year-old woman who had an atypical endogenous, depressive illness of psychotic intensity was
intermittently with cyclic antidepressants and intermittent electroconvulsive therapy. Following an acute v
illness, she was treated successfully with a combination of phenelzine and L-tryptophan. Following a few
improvement, her situation worsened and she was subsequently treated with zimelidine and lithium. Faili
placed on a regimen of tranylcypromine with doses increasing progressively up to 30 mg daily in conjunc
and tryptophan. Subsequently, carbamazepine was added in small doses with increments to achieve a p
approximately 5 mg/L. This regimen proved successful, and she was discharged home and had remaine
two months of follow up at the time of publication (Barker & Eccleston, 1984n).

c) Addition of tranylcypromine to carbamazepine therapy did not significantly affect carbamazepine seru
(Joffe et al, 1985g). Conversely, five patients on tranylcypromine need a mean daily dose of carbamazep
achieve a carbamazepine blood level of 8.0-11.1 mcg/mL. Four other patients receiving phenelzine only
daily dose of carbamazepine 450 mg to attain a blood level of 8.7-10.9 mcg/mL (Barklage et al, 1992g).

3.5.1.EI Propoxyphene

1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo
seizures, coma)

2) Summary: Concurrent propoxyphene therapy significantly increases carbamazepine concentrations and n
moderate to severe neurotoxicity (Allen, 1994a; Oles et al, 1989; Yu et al, 1986a; Kubacka & Ferrante, 1983;
1997a).

3) Severity: major

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Concurrent use of propoxyphene and carbamazepine should be avoided. Use of ar
analgesic, such as a codeine or hydrocodone, should be considered. If concomitant therapy with propoxyphe
carbamazepine is required, closely monitor carbamazepine serum concentrations. Dosage reductions are like
necessary.

7) Probable Mechanism: decreased hepatic metabolism

8) Literature Reports

a) In an observational study of elderly patients, carbamazepine serum concentrations were significantly
carbamazepine side effects were significantly more common when propoxyphene was taken concomitar
used both carbamazepine and propoxyphene were compared to patients who took either carbamazepine
and to patients who took neither of these drugs. The patients were matched for gender, age, and concor
In patients who took propoxyphene and carbamazepine the average dose of carbamazepine was lower (
compared to 378.6 mg) and the average serum level of carbamazepine was higher (28.2 mcmol/L compa
mcmol/L), than in those that took carbamazepine, but not propoxyphene; serum concentrations of carba
metabolites were also higher. In addition, side effects related to carbamazepine occurred significantly mo
patients taking both carbamazepine and propoxyphene, including depression, sedation, sleep disturbanc
restlessness (Bergendal et al, 1997).

b) Seven outpatients (6 with epilepsy and 1 with trigeminal neuralgia) were receiving carbamazepine alo
combination with phenobarbital, clonazepam, or ethosuximide (Dam & Christiansen, 1977). Study subjec
coadministered propoxyphene 65 mg 3 times a day. In 5 patients, carbamazepine clearance decreased
carbamazepine plasma levels increased 44% to 77%. The other 2 patients discontinued the propoxyphe
due to severe side effects.

c) Six epileptic patients who had taken carbamazepine (600 to 800 mg/day) for more than 6 months we

dextropropoxyphene 65 mg 3 times/day (Hansen et al, 1980). A 66% mean increase in carbamazepine s concentrations was observed 6 days after initiation of propoxyphene dosing.

d) Three elderly patients were administered carbamazepine 200 mg 3 times a day (one patient only rec a day) and dextropropoxyphene 32 mg every 4 hours or 64 mg every 6 hours (Yu et al, 1986). All 3 deve carbamazepine toxicity and 2 became comatose.

e) A 24-year-old epileptic man on maintenance carbamazepine therapy was given dextropropoxyphene ear infection (Allen, 1994). He experienced acute onset ataxia, marked intention tremor, slurred speech, multidirectional nystagmus. On presentation, he was hardly able to stand. During the preceding 24 hours coproxaml tablets (propoxyphene 32.5 mg, acetaminophen 325 mg). A fourfold increase in his carbamaz concentration was found. Carbamazepine was withheld for 48 hours, by which time his serum concentra normal. His symptoms rapidly resolved.

3.5.1.EJ Protriptyline

1) Interaction Effect: decreased protriptyline plasma concentrations and increased carbamazepine plasma c possible toxicity (ataxia, nystagmus, apnea, seizures, coma)

2) Summary: The concomitant use of carbamazepine and tricyclic antidepressants has been reported to dec antidepressant plasma concentrations and raise carbamazepine levels (Leinonen et al, 1991j; Brown et al, 19 Kragh-Sorensen, 1993a). Although not reported specifically for protriptyline, a similar interaction would be ex Carbamazepine is known to induce enzyme action. Tricyclic antidepressants can lower the seizure threshold stabilized on anticonvulsants.

3) Severity: moderate

4) Onset: delayed

5) Substantiation: probable

6) Clinical Management: Monitor patients for antidepressant efficacy and carbamazepine toxicity (nausea, vo tremor, blurred vision) with concurrent use. Doses of protriptyline may need to be increased and carbamazep reduced. Serum carbamazepine levels might be considered when a tricyclic antidepressant is added to or dis therapy.

7) Probable Mechanism: alterations in hepatic metabolism

8) Literature Reports

a) The effect of carbamazepine on doxepin levels was studied in 17 psychiatric inpatients stabilized for a days prior to measurement of baseline antidepressant concentrations. The average daily doxepin dosag Carbamazepine was added in a mean dose of 593 mg and continued over a 4-week period. In patients r combination therapy, serum doxepin concentrations were decreased an average of 46% (Leinonen et al,

b) Concomitant administration of imipramine and carbamazepine to children with attention deficit disord reported to result in a 50% decrease in the total plasma concentration of imipramine plus desipramine (E

c) One case was reported in which nortriptyline levels dropped by more than half after carbamazepine w & Kragh-Sorensen, 1993).

3.5.1.EK Psyllium

1) Interaction Effect: decreased absorption and effectiveness of carbamazepine

2) Summary: In healthy volunteers, carbamazepine bioavailability was reduced when psyllium was administe (Etman, 1995a). If patients are treated with carbamazepine and psyllium, their administration times of should far as possible, and plasma levels of carbamazepine should be monitored (Etman, 1995a).

3) Severity: moderate

4) Onset: rapid

5) Substantiation: probable

6) Clinical Management: If patients are treated with carbamazepine and psyllium, their administration times s separated as far as possible, and plasma levels of carbamazepine should be monitored.

7) Probable Mechanism: reduced dissolution rate and slowed diffusion of carbamazepine

8) Literature Reports

a) Decreased absorption, a decreased maximum concentration, and reduced area under the curve (AU carbamazepine were noted after administration with a psyllium product to 4 healthy volunteers. Voluntee other medications one week prior to and during the study. Carbamazepine 200 mg orally was administer husk (psyllium) suspended in 200 milliliters (mL) of water. Cmax with carbamazepine alone was 2.33 mi (mcg/hour), which was reduced to 1.11 mcg/hour when psyllium was added. AUC with carbamazepine a micrograms/milliliter/hour (mcg/mL/hour), when psyllium was added AUC was reduced to 25.03 mcg/mL increased from 5.52 hours to 24.14 hours with psyllium cotreatment. Bioavailability was reduced to 55% carbamazepine alone. Statistical significance values were not provided. The mechanism of interaction w due to a decrease in the amount of biological fluid available in the gastrointestinal tract as a result of wat psyllium, which would reduce the dissolution rate of the drug from the tablet. Diffusion of the drug may b result of gel formation by psyllium. Administration times of carbamazepine and psyllium should be separ possible, and plasma levels of carbamazepine should be monitored (Etman, 1995).

3.5.1.EL Quetiapine

1) Interaction Effect: decreased serum quetiapine concentrations

2) Summary: Increased doses of quetiapine may be required to maintain control of symptoms of schizophrer receiving carbamazepine, a hepatic enzyme inducer (Prod Info Seroquel(R), 2001).

3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is indicated when quetiapine is administered with carbamazepine or other i cytochrome P450 3A. Increased doses of quetiapine may be required to maintain control of psychotic sympto receiving quetiapine and carbamazepine.
7) Probable Mechanism: unknown

3.5.1.EM Quinupristin
1) Interaction Effect: an increased risk of carbamazepine toxicity (ataxia, nystagmus, diplopia, headache, vo seizures, coma)
2) Summary: Quinupristin/dalfopristin is a potent inhibitor of cytochrome P450 3A4 enzymes and may cause carbamazepine concentrations when administered concurrently. Because carbamazepine possesses a narro window, carbamazepine concentrations should be closely monitored during therapy with quinupristin/dalfopris carbamazepine should be adjusted accordingly (Prod Info Synercid(R) I.V., 1999).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor the trough carbamazepine concentrations when therapy with quinupristin/d administered concurrently. Dose reductions of carbamazepine may be required. Also monitor the patient for e carbamazepine toxicity.
7) Probable Mechanism: inhibition of cytochrome P450 3A4-mediated carbamazepine metabolism

3.5.1.EN Ranolazine
1) Interaction Effect: decreased ranolazine plasma concentrations
2) Summary: The concomitant use of carbamazepine and ranolazine is contraindicated. Ranolazine is a sub glycoprotein and is primarily metabolized by CYP3A. In pharmacokinetic studies, coadministration of 600 mg CYP3A and P-glycoprotein inducer) with ranolazine 1000 mg twice daily resulted in a 95% decrease in ranol concentration. Although not evaluated, concomitant use of ranolazine and other CYP3A and P-glycoprotein i carbamazepine, could result in a similar interaction (Prod Info RANEXA(R) extended-release oral tablets, 200
3) Severity: contraindicated
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: The concomitant use of ranolazine and CYP3A inducers, such as carbamazepine, i (Prod Info RANEXA(R) extended-release oral tablets, 2008).
7) Probable Mechanism: induction of P-glycoprotein- and CYP3A-mediated ranolazine metabolism

3.5.1.EO Rapacuronium
1) Interaction Effect: resistance to neuromuscular blocking action
2) Summary: Some medications, including carbamazepine, may enhance resistance to the neuromuscular b nondepolarizing agents such as rapacuronium (Prod Info Raplon(TM), 1999). Dose adjustments of rapacuror needed when these agents are being used concurrently.
3) Severity: minor
4) Onset: rapid
5) Substantiation: theoretical
6) Clinical Management: The dose of rapacuronium may need to be adjusted upward in patients receiving cc carbamazepine.
7) Probable Mechanism: receptor up-regulation

3.5.1.EP Remacemide
1) Interaction Effect: reduced remacemide exposure and increased carbamazepine exposure
2) Summary: Coadministration of carbamazepine with remacemide may significantly decrease serum levels and its active metabolite. A remacemide-induced increase in serum levels of carbamazepine may also occur 1991; Walker & Patsalos, 1995a; Bialer, 1993a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor the patient for reduced remacemide effectiveness. Higher doses of remace necessary during concomitant therapy with carbamazepine. However, until target therapeutic serum levels/op remacemide are known (as well as its potential for interaction with other anticonvulsants), it will be difficult to with this agent in refractory epilepsy. In addition, because carbamazepine serum concentrations may be mod during concomitant therapy, monitor the patient for signs and symptoms of carbamazepine toxicity.
7) Probable Mechanism: induction by carbamazepine of remacemide metabolism
8) Literature Reports
a) Preliminary studies in epileptic patients receiving either carbamazepine or phenytoin (monotherapy) h significantly lower steady-state serum concentrations of both remacemide and its desglycinated (active) compared to values achieved in healthy volunteers receiving remacemide alone (Muir & Palmer, 1991; V 1995; Bialer, 1993). Serum level reductions of both parent compound and active metabolite have been 5

many patients (Bialer, 1993).
b) In addition, serum concentrations of both carbamazepine and phenytoin have been increased by up t combined remacemide therapy (Walker & Patsalos, 1995). Interaction data for remacemide and other ar unavailable.

3.5.1.EQ Repaglinide
1) Interaction Effect: decreased repaglinide plasma concentrations
2) Summary: Repaglinide is metabolized by the CYP2C8 and CYP3A4 enzyme systems. Coadministration w carbamazepine, an inducer of CYP2C8 and CYP3A4 enzyme systems, may result in decreased repaglinide p concentrations. Use caution if carbamazepine and repaglinide are coadministered (Prod Info PRANDIN(R) or Dosage adjustments to repaglinide may be necessary and blood glucose concentrations should be carefully m
3) Severity: moderate
4) Onset: unspecified
5) Substantiation: theoretical
6) Clinical Management: Caution is advised if carbamazepine and repaglinide are coadministered as this ma induction of repaglinide metabolism, thereby decreasing repaglinide plasma concentrations (Prod Info PRANI 2006). Dosage adjustments to repaglinide may be necessary and blood glucose concentrations should be ca
7) Probable Mechanism: induction of CYP2C8- and CYP3A4-mediated repaglinide metabolism

3.5.1.ER Rifampin
1) Interaction Effect: elevated carbamazepine levels and toxicity (ataxia, nystagmus, diplopia, headache, vor seizures, coma)
2) Summary: Carbamazepine toxicity following the addition of antituberculosis medication to chronic anticonv has been reported (Fleenor et al, 1991a). Carbamazepine levels had previously been 8.5 to 9.5 mcg/mL with toxicity. Isoniazid 300 mg daily was well tolerated for three days prior to the introduction of rifampin 600 mg d hours of initiation of rifampin, the patient developed nausea, ataxia, confusion and drowsiness. The carbama noted to be 16.9 mcg/mL. The authors suggest that rifampin may have augmented the enzyme inhibiting effe
3) Severity: moderate
4) Onset: rapid
5) Substantiation: probable
6) Clinical Management: Monitor the patient for signs of carbamazepine toxicity, including ataxia, nystagmus headache, vomiting, apnea, seizures, and coma. A carbamazepine plasma concentration may be helpful in d carbamazepine toxicity.
7) Probable Mechanism: inhibition of carbamazepine metabolism

3.5.1.ES Rifapentine
1) Interaction Effect: decreased anticonvulsant effectiveness
2) Summary: The efficacy of anticonvulsants may be impaired with concomitant use of rifapentine. Rifapentin the metabolism of other coadministered drugs that are metabolized by cytochrome P450 3A4 or 2C8/9. Dosa anticonvulsants may be necessary if given concurrently with rifapentine (Prod Info Priftin(R), 2000).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor serum anticonvulsant levels and with concomitant use and adjust doses ac
7) Probable Mechanism: increased hepatic metabolism

3.5.1.ET Risperidone
1) Interaction Effect: increased risperidone clearance
2) Summary: The manufacturer reports that carbamazepine may increase risperidone clearance with chronic Patients should be closely monitored. Patients may be placed on a lower dose of risperidone between 2 to 4 planned discontinuation of carbamazepine therapy to adjust for the expected increase in plasma concentratio plus 9-hydroxyrisperidone. Eleven subjects received risperidone titrated to 6 mg/day orally for 3 weeks, follow coadministration of carbamazepine for an additional 3 weeks. Plasma concentrations of risperidone and 9-hy were decreased by 50%. The plasma concentrations of carbamazepine were unaffected (Prod Info Risperdal 2003a). One published case report describes a patient who had risperidone levels which were less than expe carbamazepine therapy, along with decreased risperidone efficacy. The risperidone level dramatically increas carbamazepine was discontinued (de Leon & Bork, 1997a). Carbamazepine is an inducer of cytochrome P45 enzymes, while risperidone is primarily metabolized by CYP2D6. Whether carbamazepine is also inducing C risperidone may be partly metabolized by CYP3A is uncertain (Lane & Chang, 1998; de Leon & Bork, 1998). decrease in risperidone levels caused by carbamazepine may result in decreased therapeutic efficacy. When used in combination with carbamazepine larger doses of risperidone may be required to achieve or maintain antipsychotic effect (Spina et al, 2000a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor therapeutic efficacy of risperidone following the addition of carbamazepine weeks of therapy; higher risperidone doses may be needed. Patients may be placed on a lower dose of rispe to 4 weeks before the discontinuation of carbamazepine therapy to adjust for the expected increase in plasm

risperidone plus 9-hydroxyrisperidone.
7) Probable Mechanism: induction of cytochrome P450-mediated metabolism of risperidone by carbamazepi
8) Literature Reports
a) Carbamazepine was reported to induce the metabolism of risperidone in a 22-year-old male with chro resulting in low risperidone levels and lack of effectiveness. The patient was started on carbamazepine 6 risperidone 4 mg daily. The plasma concentration of 9-hydroxyrisperidone was less than half the expecte when the dose of risperidone was doubled to 8 mg daily. After achieving a therapeutic plasma concentra hydroxyrisperidone (19 mcg/L), the dose of carbamazepine was tapered and stopped. Plasma levels of 9 hydroxyrisperidone increased to 49 mcg/L, necessitating a decrease in the dose of risperidone (de Leon
b) Plasma concentrations of risperidone and 9-OH risperidone decreased when carbamazepine was ad when it was discontinued. One study evaluated the pharmacokinetic interactions between risperidone an Thirty-four patients with a DSM-IV diagnosis of schizophrenia, schizoaffective disorder, or bipolar disorde the study. All patients were stabilized on risperidone alone or in combination with carbamazepine for at le Steady-state plasma concentrations of risperidone and 9-hydroxyrisperidone (9-OH risperidone) were co treated with risperidone alone and patients comedicated with carbamazepine. The plasma concentration risperidone and the sum of risperidone and 9-OH risperidone (active moiety) differed significantly among patients evaluated with and without comedication, the plasma concentrations of risperidone and 9-OH ris decreased when carbamazepine was added or increased when it was discontinued. The results demons patients receiving risperidone alone, the concentration of the active moiety (risperidone plus its active me risperidone) was reduced by approximately 70% when carbamazepine was given concomitantly (Spina e
c) The concomitant use of carbamazepine and risperidone leads to a marked decrease in the steady-sta concentrations of risperidone and 9-hydroxyrisperidone through stimulation of an inducible cytochrome a influence of the cytochrome P450 2D6 genotype. A 50-year-old male with chronic schizophrenia and def activity was given carbamazepine with his existing risperidone therapy. Carbamazepine 800 mg/day for 5 to his medication regimens as a mood stabilizer. After 4 weeks of carbamazepine treatment, the patient symptoms including hallucinations, paranoid delusions, ideas of reference, and mild excitement. Plasma risperidone and its active metabolite 9-hydroxyrisperidone, had decreased from 22 and 30 ng/mL, respec Carbamazepine concentration was 8.2 mcg/mL. The risperidone dose was increased to 9 mg/day, carba discontinued, and lorazepam 5 mg/day was added. Psychotic symptoms improved over the following 3 w concentrations of risperidone and 9-hydroxyrisperidone increased to 40 and 57 ng/mL, respectively. A re in the plasma concentrations of risperidone and 9-hydroxyrisperidone suggest that the CYP2D6 genotyp susceptibility to a clinically important interaction with risperidone and carbamazepine (Spina et al, 2001).
d) Eleven schizophrenic patients in a drug interaction study received oral risperidone titrated to 6 mg/da followed by concurrent administration of carbamazepine for an additional 3 weeks. The plasma concentr risperidone and its pharmacologically active metabolite, 9-hydroxyrisperidone, were decreased by about initiation of therapy with carbamazepine, patients should be closely monitored during the first 4-8 weeks, risperidone may need to be adjusted. A dose increase or additional risperidone may need to be consider carbamazepine is discontinued, the dosage of risperidone should be re-evaluated and, if necessary, dec dose of risperidone may be required between 2 to 4 weeks before the planned discontinuation of carbam adjust for the expected increase in plasma concentrations of risperidone plus 9-hydroxyrisperidone (Proc Consta(TM), 2003).

3.5.1.EU Ritonavir
1) Interaction Effect: increased carbamazepine serum concentrations and potential toxicity
2) Summary: Coadministered ritonavir may significantly increase serum concentrations of carbamazepine du inhibition of cytochrome P450 3A enzymes, resulting in carbamazepine toxicity (Prod Info NORVIR(R), 2005; 2000a).
3) Severity: moderate
4) Onset: delayed
5) Substantiation: probable
6) Clinical Management: Monitor carbamazepine serum levels and follow patients for signs and symptoms of toxicity (nausea, drowsiness, dizziness, weakness, headache). Reduce doses of carbamazepine as required
7) Probable Mechanism: decreased carbamazepine metabolism
8) Literature Reports
a) A 36-year-old HIV-positive patient maintained on carbamazepine and phenytoin to control seizures ex dizziness and progressive gait disorder after the addition of ritonavir to his antiretroviral treatment. The p managed for over a year when his antiretroviral therapy, consisting of lamivudine, didanosine and saquir augmented with ritonavir 600mg twice a day. At that time, serum phenytoin and carbamazepine levels w 16.5mcg/mL and 6.5mcg/mL, respectively. Approximately two months later, the patient presented with di impaired gait. Carbamazepine serum levels were measured at 18mcg/mL while phenytoin levels remaine (14.7mcg/mL). Carbamazepine was discontinued and replaced with primidone, resulting in resolution of and continued seizure control. Viral load remained undetectable (Garcia et al, 2000).
b) A case report demonstrates a severe interaction between ritonavir and carbamazepine resulting in ca toxicity. A 36-year-old AIDS patient with a history of alcoholism, intravenous drug use, hepatitis B and C tuberculosis, and seizures developed elevated plasma carbamazepine levels leading to CNS disorders v concomitant treatment with ritonavir. His anticonvulsant medication regimen consisted of carbamazepine times daily, phenytoin 200 mg in the morning and 100 mg at night. Two days after initiation of the new ar schedule (after 4 ritonavir doses), he presented with diplopia, disorientation, drowsiness, vertigo, and se
